REALIZATION CALCULUS

Komorebi Math

Technical Manual and Reference

The Python library

Komorebi P.

Finite constructions. Explicit contracts. Inspectable evidence.

Preface

Komorebi Math brings exact algebra, numerical calculation, symbolic expressions and finite computational models into one Python library. This manual develops the mathematical objects behind its interfaces and records their domains, invariants, return values, failure modes and evidence boundaries. It is both a connected exposition and a detailed working reference.

The first parts introduce the shared language and its main constructions. Later chapters connect arithmetic, signals, nonlinear dynamics, integration, quantum models and portable results. The reference appendices retain the stable, beta and research API records, the module inventory, executable examples, command options, schemas, diagnostic recipes and notation. Documentation standards and design specifications follow the operational reference. Specifications marked `[PLANNED]` remain specifications, rather than assertions of an implemented or executed contract.

The distinction between exact algebra and finite evidence matters throughout. A numerical residual, a sampled check, a source-derived inventory and a proved identity answer different questions. Each retains its own hypotheses and limitations. Read each claim with the assumptions and evidence supplied beside it.

The manual is designed for both first use and sustained reference. Begin with the practical guide for environment setup, two small calculations, and a route into your subject. Part-level guides and chapter introductions explain where to start and what to consult next. Detailed contracts and examples remain available when a calculation requires a closer look.

Reference scope

The detailed source-derived records and recorded execution observations describe the reference implementation from which the comprehensive manual was assembled. Older package filenames, version strings, verifier names and failure observations are retained where they identify a literal historical command or an audited record. They must not be read as a fresh qualification of the current release. Current test and verification inventories, with their source binding and methodology, are collected in Appendix O. The practical guide at the beginning of this volume supplies current-source introductory workflows. Literal reference transcripts retain the versions they name.

Reading paths

Start with the practical guide and a small example. Consult Parts I and II for the library's conventions and evidence vocabulary. Continue through the mathematical part relevant to the calculation at hand. Use Appendices A–D to locate a public object or implementation module, E and F for executable examples and command options, and G–N for persistence, diagnostics, dependencies and detailed cross-references. The glossary and notation index are in Appendix M. PDF bookmarks expose the deeper reference hierarchy while the printed contents show the principal divisions.

Source and publication note

The comprehensive reference baseline is the preserved `komorebi_math` source documentation associated with the `1.0.0b4` implementation inventory. The current software release is bound to source commit `5f2b7ddc879c12d2bb00cbe5c487aa0bc7709222`. Historical execution counts and source-derived records remain explicitly scoped to their recorded baseline. Appendix O supplies a separate current-source crosswalk. Neither a static crosswalk nor this editorial work constitutes new hardware qualification or a new proof audit.

The 131 stable, 83 beta and 1,312 research symbol records were compared with the frozen current-release manifests. All 1,526 records agree exactly. This establishes continuity of the recorded interfaces; it does not assert that every historical failure observation or command workflow still describes current implementation behavior.

Original software and documentation are distributed under the MIT License. Third-party notices and separately supplied data terms continue to apply. The source package includes the editable manuscript, typesetting files, original source, preservation checks and proofreading records.

A practical guide to this manual

You can use Komorebi Math without reading this book from beginning to end. Start with one small calculation, learn how to interpret its result, and then follow the chapter for your subject. The detailed reference is there when you need an exact import name, argument, assumption, or failure condition.

The manual has three complementary layers. The chapters explain mathematical objects and show how to use them. The connected recipes combine those objects into workflows. The appendices give detailed lookup records. A useful reading pattern is **example, explanation, reference**: run a small example, read the relevant explanation, and consult the reference before changing its inputs or scale.

Choose a starting point

What you want to do	Start here	Keep nearby
Install the library and complete a first calculation	The setup and examples below, then Chapters 3–4	Chapter 5 for interpreting results
Understand the library's organizing ideas	Chapter 2, then Chapters 9–12	Appendix M for terminology
Work with exact coordinates, bases, or rational matrices	Chapters 15–20, then Chapter 64	Appendix A for stable names
Work with sequences, generating functions, or arithmetic	Chapters 21–27, then Chapter 65	The scalar-domain guidance in Chapter 8
Process signals or build numerical operators	Chapters 28–36A, then Chapter 66	Appendix J for dependencies
Work with derivatives, jets, nonlinear maps, or dynamics	Chapters 37–46, then Chapter 67	Appendix K before scaling up
Integrate finite exact objects or evaluate typed expressions	Chapters 47–52, then Chapter 68	Chapter 5 and the relevant API card
Explore finite quantum, deformation, or Langlands models	Chapters 53–58, then Chapter 69	The local hypotheses and evidence class of each model
Save, export, reload, or extend a calculation	Chapters 59–63, then Chapter 70	Appendix G for portable records
Diagnose an error or unexpected result	Chapter 6 and Appendix I	The failing object's contract and your environment details
Maintain or verify the project	Chapters 71–74A and Appendix O	Part XIV for documentation standards and design specifications

Chapter ranges describe a route, not required reading. For example, a signal-processing reader can start with the signal conventions in Chapter 31 and return to packet algebra when a later operation needs it. The glossary is a reference aid, not an examination to pass before using the library.

What to know before you start

For the introductory Python examples, you should be comfortable importing modules, calling functions, reading lists and tuples, and running a script from a terminal. A terminal command belongs in PowerShell or a POSIX shell. A Python listing belongs in a Python file or interpreter. Output listings show what a program prints and should not be entered as commands.

For the mathematical chapters, the prerequisite depends on the task. Basic vectors and matrices are enough for the first packet and coordinate examples. Later arithmetic, differential, signal, and quantum topics introduce their own

specialized objects. Read the local definitions before relying on a familiar word: a signal frame and a redundant algebraic frame have different meanings, as Appendix M explains.

In a displayed map, the domain describes valid inputs and the codomain describes outputs. In a matrix acting on a column vector, columns correspond to input coordinates and rows to output coordinates. A hypothesis is a condition the construction needs. An invariant is a property that should remain true. A residual measures a discrepancy in a numerical check. A certificate records the checks and assumptions reported by its producer. These terms recur because they help you decide whether a result fits your intended use.

Set up one environment

Use the source checkout or distribution supplied with the release you intend to run. The current-source instructions here refer to the 1.0.0 source identified in the publication note. The detailed historical commands in Chapter 3 remain useful when reproducing their explicitly named reference environment.

The package requires Python 3.11 or newer; the declared support matrix is Python 3.11, 3.12, and 3.13. Use an interpreter from that matrix and check its version before creating an environment. Run the following commands from the **software source directory containing `pyproject.toml`**, rather than from the manual's editable-source directory.

On a POSIX shell:

```
python3 --version
python3 -m venv .venv
. .venv/bin/activate
python -m pip install .
python -m pip check
```

On Windows PowerShell:

```
py --version
py -m venv .venv
$py = (Resolve-Path .\.venv\Scripts\python.exe).Path
& $py -m pip install .
& $py -m pip check
```

If the default interpreter is outside that matrix, select an installed supported version before running the environment-creation command. The Windows form invokes the environment's interpreter directly, so activation is unnecessary. On either platform, installing from source can require downloading build tools and dependencies. An offline installation requires those dependencies to be available locally too.

If you are using a supplied wheel instead, replace the installation target `.` with that wheel's actual path. Use one installation route in a fresh environment. Do not combine an editable checkout and a wheel installation while trying to establish which copy is being imported.

After installation, run this Python check with that same interpreter:

```
import sys
import komorebi_math as km

print("Python:", sys.executable)
print("Version:", km.__version__)
print("Imported from:", km.__file__)
```

For the identified current source, the version should be `1.0.0`. The executable and import paths depend on your machine. If the version is unexpected, check those paths before changing the example. A local file named `komorebi_math.py` or another environment can cause Python to import a different object than intended.

The examples below use the core installation. Optional dependencies are introduced when a particular operation needs them; use Chapter 3 and Appendix J to choose them. Installing every optional backend is unnecessary for a first calculation.

Your first exact calculation

This example changes two coordinates using a rational matrix and then reverses the change. Save the listing as `first_exact.py` and run `python first_exact.py` in the activated POSIX environment, or `& $py .\first_exact.py` in PowerShell.

```
from fractions import Fraction
from komorebi_math.stable import ExactCoordinateTransform, Exactness

transform = ExactCoordinateTransform(
    "A", "B",
    ((1, Fraction(1, 2)), (0, 1)),
    "USER-GUIDE-SHEAR",
    "A rational coordinate example",
)
original = (Fraction(2), Fraction(3))
mapped = transform.apply(original)
restored = transform.inverse().apply(mapped)
certificate = transform.certificate().require()

assert mapped == (Fraction(7, 2), Fraction(3))
assert restored == original
assert certificate.exactness is Exactness.EXACT

print("Mapped:", ", ".join(str(value) for value in mapped))
print("Restored:", ", ".join(str(value) for value in restored))
print("Evidence:", certificate.exactness.value)
```

Expected output:

```
Mapped: 7/2, 3
Restored: 2, 3
Evidence: exact
```

The first output coordinate is two plus half of three. The second is unchanged. `Fraction(1, 2)` supplies a rational value directly. The strings `A` and `B` identify the source and target coordinate systems for this record; they do not ask the library to discover a basis. The identifier `USER-GUIDE-SHEAR` labels this example's contract and does not supply an independent proof.

The assertions check the expected value and inverse roundtrip. The certificate's `.require()` method enforces acceptance of the finite record reported by the producer. In this example, the matrix is invertible; a valid transform record in general need not be invertible. Chapter 16 explains the distinction and the conditions for inversion.

Your first numerical packet calculation

A packet decomposition lets you inspect components and then reconstruct an object. In this two-dimensional example, the first component keeps the first coordinate and the second component keeps the second. Save it as `first_packets.py` and run it with the same interpreter.

```
import numpy as np
from komorebi_math.stable import Exactness, PacketSystem

packets = PacketSystem(
    [np.diag([1.0, 0.0]), np.diag([0.0, 1.0])],
    names=("left", "right"),
)
certificate = packets.certificate().require()
original = np.array([2.0, 3.0])
coordinates = packets.analyze(original)
restored = coordinates.reconstruct()

np.testing.assert_array_equal(restored, original)
assert certificate.exactness is Exactness.NUMERICAL

print("Components:", [value.real.tolist() for value in coordinates.values])
print("Restored:", restored.real.tolist())
print("Evidence:", certificate.exactness.value)
```

Expected output:

```
Components: [[2.0, 0.0], [0.0, 3.0]]
Restored: [2.0, 3.0]
Evidence: numerical
```

Here each component is represented in the original two-dimensional space. Reconstruction adds the components. Other coordinate systems may use different coefficient representations, so read their contracts before transferring this interpretation.

The numerical label remains appropriate even though this simple run returns the expected values exactly. It identifies the floating computation, rather than a rational-arithmetic proof. The equality assertion is suitable for these particular inputs. In a general floating workflow, choose the norm and tolerance required by the operation instead of copying an exact equality check without considering rounding.

Read a result before using it

Start with the returned value, then inspect the information that qualifies it. A useful order is:

1. **Meaning and shape.** What mathematical object is returned, and which axes, coordinates, or units does it use?
2. **Acceptance.** Does its producer report validity? If further work requires acceptance, enforce the documented check.
3. **Evidence class.** Is the result exact, numerical, conditional, heuristic, or planned? API stability is a separate property.
4. **Conditions.** Which assumptions were checked, and which remain the caller's responsibility?
5. **Numerical interpretation.** If there is a residual or tolerance, which quantity does it measure and in which norm?
6. **Next operation.** Does the result meet the input requirements of the operation you intend to call next?

Do not assume that every result object has the same fields or methods. Chapter 5 explains the common certificate model; each API card identifies what its particular operation returns. The literal code above uses methods supported by those two objects.

Find an object without reading every card

If you know the public Python name, search for it in Appendices A, B, and C. These are the stable, beta, and research references. If you know only a task, start with the route table above or the connected recipes in Part XI, then follow their named objects into the reference. If you know an implementation module, use Appendix D.

Read a card in this order: import route, purpose, signature, input contract, return value, failure conditions, and example. Then inspect its evidence and backend notes. The signature tells you how to call an object; the surrounding contract tells you when that call makes sense. An alias can name the same implementation, but a similarly named object need not have the same meaning.

Use the PDF's bookmarks to move directly to a chapter or reference group. The printed contents keep the principal divisions compact. Exact name searches work best when you copy a public name from the source or from a code listing; typeset line wrapping can divide a long identifier visually. Chapter and section numbers remain the preferred references when discussing the book with another reader.

When something goes wrong

Begin with the smallest example that reproduces the problem. Keep the original error message. Changing several settings at once can hide the cause.

Symptom	First useful check	Continue with
Import fails or the version is unexpected	Confirm the interpreter, imported path, installation target, and optional dependency	Chapter 3 and Appendix J
A name or argument is rejected	Compare the exact spelling, namespace, signature, and reference version	Chapter 7 and Appendices A–F
A dimension, domain, or validation error occurs	Check shape, source/target labels, scalar type, and the failing contract	Chapter 6 and Appendix I
A numerical answer differs from an expectation	Check axis, normalization, precision, norm, tolerance, and conditioning	The domain chapter and Chapter 8
A certificate is rejected	Inspect failed checks and assumptions before changing tolerances	Chapter 5 and Appendix H
A calculation uses too much memory or time	Reduce the smallest relevant dimension or order, then inspect the growth estimate	Appendix K
A saved record cannot be loaded	Check schema version, supported codec, integrity information, and migration route	Chapters 61–62 and Appendices G and L

When asking for help, include the package version, interpreter and platform, relevant optional backend versions, a small complete example, its inputs, the full error or unexpected output, and what you expected. For a numerical issue, include the tolerance and precision. For a persistence issue, describe the record type and version. These details usually locate the problem more quickly than a screenshot of a long session.

Continue with confidence

After the first examples, choose one domain chapter and reproduce its smallest working case. Change one input, predict the effect, and inspect both the value and its evidence. Then try the documented failure case so you know what the boundary looks like. Only after those steps should you increase dimension, order, precision, or data volume.

Use the declared source baseline and the local contract to decide whether an example applies to your calculation. The reference distinguishes documented interfaces from executed backend and platform checks, and from mathematical assumptions that remain to be established.

Reading the evidence

The reference records describe the library's public mathematical and computational surfaces. Their inventories and execution observations belong to the documented reference baseline. Source inspection, command-line parsing, finite numerical checks and mathematical proofs remain separate forms of evidence.

The documentation-source crosswalk joins the configured documentation and repository records to API, module, command and example entries. Its recorded checks include finite correction probes and lookup scenarios. Acceptance by an argument parser does not establish that a command handler executed successfully. Lexical code and assertion counts support navigation, rather than blanket execution or proof coverage.

Extension discovery deserves particular care. Loading an entry point or a callable factory runs its code in the caller process. Catching ordinary exceptions does not provide child-process isolation. The default does not activate extensions, but discovery can still import and run factory code.

The recorded documentation checks resolve ordinary local file links within their stated source set. They do not establish that every local fragment or external URL resolves. A lexical Markdown scan can also mistake mathematical punctuation for a link; that limitation is not itself a mathematical or site-build failure.

Reference observations about native platforms, accelerators, PowerShell, certificates, persistence and resource controls retain their stated limitations. Current test and verification inventory is supplied separately in Appendix O. No new Lean proof audit is claimed.

Part I. Orientation and first execution

A practical first route. Begin with Chapter 2 for the purpose of the library, Chapter 3 for the environment, and Chapter 4 for a small computation you can inspect from input to result. Use the label table in Section 1.1 as a reference. Chapters 0 and 1 explain how the full manual is organized; they can be read more closely after your first successful example.

The first examples assume basic Python: imports, function calls, lists, and reading an exception. The numerical packet example also uses small matrices and vectors. The exact coordinate example uses rational numbers. You do not need the advanced operator, signal-processing, or arithmetic chapters before running those examples.

Your immediate goal	Start here	What to look for
Understand the library's purpose	Chapter 2	finite objects, supported workflows, and the limits of each claim
Set up an environment	Chapter 3	the intended interpreter, package identity, and required dependencies
Run a small calculation	Sections 4.3 and 4.4	reconstructed values and the accompanying certificate
Understand a result label	Section 1.1, then Chapter 5	API stability, exactness, validity, and assumptions
Diagnose an unsuccessful run	Section 3.5, then Chapter 6	environment, input, assumption, or resource failure
Find an importable name	Appendices A through C	the exported name, signature, tier, and related examples

Reading the examples. A Python listing contains program text. A shell listing contains commands to enter in the named shell. An output listing shows what a run produced and should not be pasted into the interpreter. Run a complete example, including its imports and setup, before adapting individual lines. When a later listing continues an example, keep the preceding variables in the same Python session.

The recorded examples retain the package identity stated beside them. For a new installation, follow the current package instructions supplied with your release. To reproduce an older transcript exactly, use its named package and dependency profile. A historical version assertion is a reproduction check, not an instruction to change the identity of a newer installation.

0. Coverage contract

The coverage contract states what the guide covers and defines what "covered" means. The contract is tied to the shipped `komorebi-math==1.0.0b4` reference source and its recorded handoff. The handoff revision is distinct from the installed package version.

Coverage is a documentation property. It means that a public object has one canonical place in the guide, its aliases are visible, and its executable or verification routes are mapped. It does **not** mean that every mathematical statement is exact, that every optional backend is installed, or that a finite certificate proves a continuum theorem. Those are separate claims and receive separate evidence labels in Chapter 1.

0.1 Source sets

Komorebi Math exposes three Python API tiers and several non-Python surfaces. The stable tier is the frozen compatibility promise for the 1.x line. The beta tier is curated but still allowed to evolve before promotion. The research tier is the broad additive workspace where implemented finite constructions can appear without immediately becoming compatibility commitments. The command-line interface, examples, and verification suites are part of the user experience, so the guide treats them as first-class source sets rather than appendices.

Let

$$\mathcal{S}_{\text{stable}}, \quad \mathcal{S}_{\beta}, \quad \mathcal{S}_{\text{research}}, \quad \mathcal{C}_{\text{CLI}}, \quad \mathcal{E}_{\text{examples}}, \quad \mathcal{D}_{\text{docs}}, \quad \mathcal{V}_{\text{verification}}$$

denote the frozen stable API, curated beta API, broad research API, command-line interface, executable examples, documentation corpus, and verification/release interfaces.

The guide coverage target is

$$\mathcal{G} = \mathcal{S}_{\text{stable}} \cup \mathcal{S}_{\beta} \cup \mathcal{S}_{\text{research}} \cup \mathcal{C}_{\text{CLI}} \cup \mathcal{E}_{\text{examples}} \cup \mathcal{V}_{\text{verification}}.$$

Measured inventory for the audited reference-source tree:

Surface	Inventory
Stable manifest	131 entries: 58 classes, 61 functions, 12 data symbols
Beta manifest	83 entries: 45 classes, 28 functions, 10 data symbols
Research manifest	1,312 entries: 518 classes, 733 functions, 61 data symbols
Research manifest implementation owners	201: 196 package-owned and 5 standard-library owners
Python implementation modules	300
Executable Python examples	57
Executable PowerShell examples	8
Root PowerShell/shell workflow wrappers	42: 21 PowerShell and 21 shell wrappers
Documentation chapters	71
Verification modules	50
Installed verification-suite names	51
Frozen portable codecs	51 codecs and 1 adjacent migration
Export formats	11
Test modules	130

These numbers describe the recorded source baseline rather than every release of the project. Adding or removing a public symbol in a later release requires both a new manifest and a corresponding guide update. The documentation corpus $\mathcal{D}_{\text{docs}}$ informs the explanations, but it is not included in $\mathcal{G}$ as an independent public execution surface: prose cannot make an unimplemented interface real.

Outline-level placement validation:

$$\text{placed}(\text{manifest implementation owners}) = 201/201, \qquad \text{placed}(\text{shipped examples}) = 65/65.$$

0.2 Canonical implementation map

The same implementation can be re-exported through several supported namespaces. Explaining each re-export as though it were a different class would create duplicate prose that drifts over time. The canonicalization map therefore collapses aliases to the defining implementation while retaining every public import path.

Class and function aliases are mapped to one implementation explanation. Data exports remain keyed by exported name unless source declares an alias:

$$\pi(N, n, k, m, q, \sigma) = \begin{cases} (m, q), & k \in \{\text{class}, \text{function}\}, \\ (N, n), & k = \text{data}. \end{cases}$$

Here $\mathcal{A}$ is the set of exported records, N the namespace, n the exported name, k the manifest kind, $m.q$ the reflected implementation identity, and σ the reflected signature. Every stable exported name still receives its own Appendix A anchor. Deliberate callable aliases cross-link their shared explanation.

The data branch is essential. Several distinct constants reflect as `builtins.int`, `builtins.str`, or `pathlib.Path`, and Python may intern equal immutable values. Neither a shared type owner nor object identity makes those constants semantic aliases.

This prevents duplicate explanations for objects re-exported through `komorebi_math`, domain namespaces, `komorebi_math.beta`, `komorebi_math.stable`, `komorebi_math.v1`, and `komorebi_math.api.v1`.

For example, the stable compatibility namespaces export one shared `CoordinateTransform` object:

```
import komorebi_math.stable as stable
import komorebi_math.v1 as v1
import komorebi_math.api.v1 as api_v1

assert stable.CoordinateTransform is v1.CoordinateTransform
assert v1.CoordinateTransform is api_v1.CoordinateTransform
```

The guide therefore gives `CoordinateTransform` and `ExactCoordinateTransform` distinct export-name anchors, identifies their one shared implementation, and lists the three versioned routes on both cards. Alias identity is an API fact. It does not imply that unrelated names or domain concepts are mathematically interchangeable.

0.3 Coverage invariant

The anchor rule makes documentation drift mechanically detectable. A public manifest entry with no anchor is an omission. Two canonical anchors for one exported name are duplicate entries. Declared aliases that resolve to different implementations indicate a contract conflict that must be repaired before the guide can be declared complete.

For every manifest entry s, exactly one guide anchor must exist:

$$\forall s \in \mathcal{S}_{\text{stable}} \cup \mathcal{S}_{\beta} \cup \mathcal{S}_{\text{research}}, \qquad \#\,\text{Anchor}(s) = 1.$$

For every CLI command c and executable example e:

$$\#\,\mathrm{Recipe}(c) \geq 1, \qquad \#\,\mathrm{GuideMap}(e) \geq 1.$$

The source inventory places all 201 manifest owner strings (196 package-owned and five standard-library owners) and all 65 shipped executable examples. A separate machine-readable coverage ledger and digest remain `[PLANNED]` in this reference baseline. The inventory is an editorial record checked against that source rather than a generated release gate.

What this establishes. Every audited public surface has a destination, aliases have one canonical explanation, and omissions can be named.
What this does not establish. Placement alone does not prove an implementation correct, a numerical result exact, an optional backend usable, or a release qualified on hardware that was not tested.

0.4 Explicit exclusions

The exclusions keep the guide honest and usable. Private helpers are discussed only when a public failure or serialization contract cannot be understood without them. Historical APIs are retained for migration, but they do not compete with the current reference. Most importantly, truth status follows the executed finite path: no amount of documentation polish promotes a result to a stronger class.

- Private names beginning with _ are not reference entries unless needed to explain a public contract.
- Historical APIs remain in migration appendices rather than the main current reference.
- Planned, heuristic, conditional, numerical, and exact claims remain visibly distinct.
- The guide does not elevate finite certificates into unproved global or continuum theorems.

Chapter 0 summary. The object is the versioned public surface. The operation is canonical placement. The evidence is the manifest/module/example audit. The next chapter defines how every placed statement is labeled and read.

1. Editorial and symbolic grammar

Komorebi Math combines exact finite algebra, floating computation, conditional constructions, exploratory methods, and reserved interfaces. A single label such as "verified" is too vague. The evidence grammar below distinguishes what was computed, which hypotheses were checked, and what conclusion the evidence supports.

The labels are local. Read them beside the statement, example, or symbol they qualify. A class can be `[STABLE]` while one method is `[NUMERICAL]`. A `[RESEARCH]` function can still implement an `[EXACT]` finite identity. API stability and mathematical evidence answer different questions.

1.1 Entry labels

Label	Meaning
`[STABLE]`	frozen 1.x compatibility surface
`[BETA]`	curated beta surface
`[RESEARCH]`	additive research surface
`[EXACT]`	exact finite algebra/arithmetic under checked hypotheses
`[NUMERICAL]`	floating computation with residual/tolerance
`[CONDITIONAL]`	conclusion depends on listed unchecked assumptions
`[HEURISTIC]`	exploratory discovery or estimate
`[PLANNED]`	reserved but not production implemented
`[PORTABLE]`	supported by strict portable serialization
`[BACKEND]`	behavior depends on NumPy, SymPy, SciPy, JAX, PyTorch, or CuPy
`[CERT]`	returns or exposes a certificate/report

Several labels may appear together. For example, `[STABLE][EXACT][CERT][PORTABLE]` means that the import path is frozen, the executed finite construction is exact under its checked hypotheses, a machine-readable certificate is available, and a strict serialization route is supported. It says nothing about unchecked continuum assumptions unless a separate theorem supplies them.

1.2 Canonical symbol card

A symbol card is the smallest complete reference unit. It begins with the Python object the reader can import, but it does not stop at a signature. The mathematical type explains what the callable means. Hypotheses bound its domain. Invariants say what the implementation checks. Failures show where the contract rejects an input, and examples connect the abstract map to an executable path.

Every public class, function, method family, and data symbol receives this record:

1. **Identity**

- canonical qualified name
- public aliases
- stability tier
- source module

2. **Signature**

- exact Python signature
- type variables and accepted protocols

3. **Mathematical type**

- domain X
- codomain Y
- map $f : X \to Y$

4. **Definition**

- symbolic formula or finite algorithm

5. **Hypotheses**

- dimensions, fields/rings, positivity, invertibility, regularity, tolerance, resource budget

6. **Invariants**

- identities checked on construction or certification

7. **Exactness class**

- exact, numerical, conditional, heuristic, or planned

8. **Return contract**

- raw value, record, `ComputationResult`, `ConditionalResult`, `Certificate`, or domain report

9. **Failures**

- exception types and invalid inputs

10. **Persistence and export**

- portable tag/version, JSON shape, renderer support

11. **Backend behavior**

- required and optional dependencies

12. **Complexity and budgets**

- finite sizes, asymptotic cost, memory, guards

13. **Examples**

- minimal
- connected workflow
- adversarial/failure
- optional performance/backend example

14. **Related symbols**

- constructors, transforms, inverses, certificates, CLI commands, examples, tests

Not every field needs equal length, but none may be silently inapplicable. If an operation has no portable representation, the card says so. If its complexity has not been established, the card labels the estimate rather than replacing it with a benchmark. This is how the later reference can be exhaustive without pretending that every public object carries the same guarantee.

1.3 Canonical example card

An example is a finite experiment with an explicit claim boundary. The tuple below records not only the API calls and happy-path output, but also the hypotheses, certificate assertions, intentional failure, and reproducibility metadata needed to run it again.

Every example is specified as

$$\mathfrak{E} = (I, H, A, O, C, F, R),$$

where I is input data, H checked and unchecked hypotheses, A API calls, O expected output, C certificate assertions, F intentional failure/adversary, and R reproducibility metadata.

Required example levels:

- E_0: one-screen minimal example
- E_1: realistic connected example
- E_2: certificate inspection
- E_3: invalid/adversarial input
- E_4: backend or scaling variant when relevant

A reproducible rendered example names the package revision, interpreter, backend, tolerance or exact scalar domain, deterministic seed when one exists, input, expected output, and expected failure. Platform-dependent text such as a resolved executable path is described rather than frozen into an incorrect literal output.

1.4 Global mathematical conventions

- Scalars: $\mathbb{Z}, \mathbb{Q}, \mathbb{R}, \mathbb{C}, \mathbb{F}_p, \mathbb{Z}/p^k\mathbb{Z}$
- Vectors are columns unless stated otherwise.
- Matrices act on the left.
- A^* denotes conjugate transpose.
- I_X denotes the identity on X.
- P_i denotes a packet projector or coordinate selector only when the local chapter defines which.
- Signal convolution is signal-first.
- Rational/exact objects are not silently coerced into numerical certificates.
- Tolerances are explicit and never redefine exact equality.

Composition follows execution order. If $T_{B\leftarrow A}$ maps coordinates from A to B and $T_{C\leftarrow B}$ follows it, then

$$T_{C\leftarrow A} = T_{C\leftarrow B}T_{B\leftarrow A}.$$

The distinction between transpose and adjoint is never suppressed, and the word "projector" is reserved for an idempotent map in the local scalar domain. A redundant analysis-synthesis reconstruction component need not itself be an idempotent projector.

1.5 Canonical chapter specification

The chapter record is an authoring contract, not a second runtime API. It keeps prose, formulas, failures, examples, and complexity statements synchronized with one source-backed object set.

Every chapter is expanded as the record

$$\mathfrak{C} = (\Sigma, \mathcal{T}, \mathcal{M}, \mathcal{H}, \mathcal{I}, \mathcal{R}, \mathcal{F}, \mathcal{E}, \mathcal{Q}),$$

with

Field	Symbolic role
Σ	notation and public symbol set
$\mathcal{T}$	mathematical types, shapes, and scalar domains
$\mathcal{M}$	typed maps and defining algorithms
$\mathcal{H}$	preconditions and unverified hypotheses
$\mathcal{I}$	exact identities, invariants, and residual tests
$\mathcal{R}$	result and certificate schemas
$\mathcal{F}$	exceptions, rejected inputs, and conditional branches
$\mathcal{E}$	minimal, connected, certified, adversarial, and backend examples
$\mathcal{Q}$	complexity, memory, precision, and resource guards

The prose stage is therefore a rendering map

$$\text{RenderGuide} : \mathfrak{C} \longmapsto (\text{explanation}, \text{API cards}, \text{code}, \text{outputs}, \text{cross-links}),$$

not a second source of mathematical claims.

The rendering step may improve order and explanation, but it may not strengthen the evidence class, invent a parameter, or hide a rejected branch. When a code path and an older prose statement disagree, the current implementation and its committed contract are audited first. The guide does not choose the more impressive claim.

1.6 Exactness and evidence lattice

The five evidence classes enforce *non-promotion*. The order below is a documentation ranking from stronger finite evidence to weaker or future claims. It is not a theorem that one class automatically converts into another.

Claims occupy the source-backed proof-strength set

$$\mathcal{L} = \{\mathsf{P}, \mathsf{H}, \mathsf{C}, \mathsf{N}, \mathsf{E}\},$$

where

$$\mathsf{P} = \text{planned}, \quad \mathsf{H} = \text{heuristic}, \quad \mathsf{C} = \text{conditional}, \quad \mathsf{N} = \text{numerically certified}, \quad \mathsf{E} = \text{exactly certified}.$$

The guide's strongest-to-weakest editorial order is

$$\mathsf{E} \succ \mathsf{N} \succ \mathsf{C} \succ \mathsf{H} \succ \mathsf{P}.$$

The runtime `Exactness` `StrEnum` records categories but the enum itself implements no comparison or rank operation. The research expression layer separately provides `exactness_strength` and `weakest_exactness` for controlled certificate composition. Chapter 5 states that narrower rule explicitly. The editorial order is also distinct from the unordered `ClaimStatus` taxonomy used for provenance.

Class	Reader test
`exact`	Are all relevant identities decided in the stated finite exact domain?
`numerical`	Is a normed residual bounded by an explicit tolerance?
`conditional`	Which assumptions remain unchecked by the executed construction?
`heuristic`	What is being explored or estimated without a complete guarantee?
`planned`	Is this interface reserved rather than production implemented?

No implicit promotion is allowed. A promotion $a \rightsquigarrow b$ must cite a verification predicate V such that

$$V(x) = \mathsf{true} \Longrightarrow \mathrm{class}(x) = b.$$

In particular, numerical residual bounds do not imply exact equality, finite verification does not imply an infinite theorem, and a portable roundtrip does not prove mathematical validity.

> **Evidence boundary.** Decreasing a floating tolerance does not turn a numerical certificate into exact algebra. Running more finite cases does not prove an infinite statement. Serialization proves that a record survives its codec, not that the record's mathematical claim is true.

1.7 Traceability relations

Traceability answers "where did this statement come from?" The reference links a public symbol to its defining module, one guide anchor, runnable examples, tests, and relevant verification suites. Tests can share symbols and symbols can have many tests, but implementation identity and canonical guide placement are unique.

Let S be public symbols, M implementation modules, X executable examples, T tests, V verification suites, and D guide anchors, with $D_{\mathrm{API}} \subseteq D$ the API-card anchors. The guide records the relations

$$R_{SM} \subseteq S \times M, \quad R_{SD} \subseteq S \times D, \quad R_{SX} \subseteq S \times X, \quad R_{ST} \subseteq S \times T, \quad R_{SV} \subseteq S \times V.$$

Completion requires

$$\begin{aligned} \forall s \in S: &\quad \deg_{R_{SM}}(s) = 1, \quad \deg_{R_{SD}}(s) = 1, \\ \forall x \in X: &\quad \deg_{R_{SX}^{-1}}(x) \geq 1, \\ \forall d \in D_{\mathrm{API}}: &\quad \deg_{R_{SD}^{-1}}(d) \geq 1. \end{aligned}$$

1.8 Shape and domain grammar

Shapes are part of the contract. A matrix described only as "compatible" is not fully documented: the card states the dimension equations, scalar domain, orientation, axis, boundary convention, and batching rule before presenting the formula.

The guide uses the type grammar

$$\tau ::= R \mid R^n \mid R^{m \times n} \mid R[x]_{<n} \mid \mathrm{Seq}_N(R) \mid \mathrm{Signal}_{N \times C}(R) \mid \mathrm{Op}(X, Y) \mid \mathrm{Cert}(P),$$

with R an explicitly declared scalar domain. A callable is documented as

$$f : (x_1 : \tau_1, \ldots, x_k : \tau_k; \theta \in \Theta) \longrightarrow (y : \tau_y, c : \mathrm{Cert}(P)),$$

and every dimension equation is stated before the defining formula. Broadcast, axis, boundary, and batch conventions are part of Θ, never implicit.

1.9 Symbolic example ladder

The ladder keeps a friendly first success and an honest failure branch on the same page. Not every symbol needs a performance example, but every operation with meaningful rejection behavior receives an adversarial or invalid input.

For a public map $f : X \to Y$, the default five-example family is

$$
\begin{array}{lll}
E_0: & x_0 \in X, & y_0 = f(x_0), \\
E_1: & x_1 \in X_{\text{realistic}}, & y_1 = f(x_1), \\
E_2: & (y_2, c_2) = f_{\text{cert}}(x_2), & c_2.\texttt{valid} = \mathsf{true}, \quad c_2.\texttt{require}() = c_2, \\
E_3: & x_3 \notin \mathrm{Dom}(f), & f(x_3) \rightsquigarrow \mathrm{Reject}, \\
E_4: & x_4^{(b)} \in X_b, & f_b(x_4^{(b)}) \approx f_{b'}(x_4^{(b')}).
\end{array}
$$

The last comparison is exact only for exact backends. Otherwise the guide states the norm, tolerance, precision, seed, and device used.

1.10 Function, class, method, and data forms

These forms prevent stateful objects from being documented as if every method were a pure mathematical function. A mutation records both the returned value and the post-state invariant. Public data symbols record identity and mutability, because a shared registry constant and a newly constructed value have different compatibility consequences.

Each manifest kind has a fixed symbolic expansion.

For a function,

$$f_\theta : D_\theta \subseteq X_1 \times \cdots \times X_k \to Y, \qquad (x_1, \ldots, x_k) \mapsto y.$$

For a state-bearing class,

$$\mathcal{O} = (s, V_s, C_s),$$

where s is immutable or mutable state, V_s the construction invariant, and C_s the certificate factory. A pure method has type

$$m : \mathcal{O} \times X \to Y,$$

while a mutating method is shown as a transition

$$m : (\mathcal{O}_t, x) \longmapsto (\mathcal{O}_{t+1}, y), \qquad V_{s_t} \Longrightarrow V_{s_{t+1}}.$$

For a public data symbol a, the card records

$$a \in A, \qquad \mathrm{identity}(a), \qquad \mathrm{mutability}(a), \qquad \mathrm{serialization}(a).$$

1.11 Certificate normal form

The tuple below is the guide's comparison form. It lets certificate-producing families be discussed consistently, but it is not a universal recomputation performed by the `Certificate` data class. The producing API sets `valid` from its own domain rule, and the actual `.require()` implementation remains authoritative.

A certificate is documented through

$$\mathfrak{K} = (v, e, r, \tau, h_c, h_u, d, t, m),$$

where $v \in \{\mathsf{true}, \mathsf{false}\}$, e is the exactness class, $r = (r_i)$ residuals, τ an optional tolerance, h_c checked hypotheses, h_u unchecked assumptions, d diagnostics, t an optional theorem or contract identifier, and m the human-readable status.

Runtime enforcement is intentionally simple:

$$\mathrm{Require}(\mathfrak{K}) = \begin{cases} \mathfrak{K}, & v = \mathsf{true}, \\ \mathrm{ValidationError}, & v = \mathsf{false}. \end{cases}$$

The `Certificate` record does not independently derive `valid` from residuals. Residual and assumption consistency are separate guide-level audits of the producing API's documented exact, numerical, conditional, heuristic, or planned rule. The actual package semantics of `.require()` remain authoritative when a domain-specific certificate specializes this normal form.

A certificate should therefore be read in this order: `valid`, `exactness`, residuals and tolerance, checked assumptions, unchecked assumptions, theorem or contract identifier, diagnostics, and message. Calling `.require()` is the explicit transition from inspection to enforced acceptance.

1.12 Complexity and resource form

Complexity claims identify their evidence. An exact operation count, an asymptotic bound, a measured wall-clock time, and a heuristic estimate are not interchangeable. Resource guards are documented as behavior because rejecting a too-large construction can be part of the public safety contract.

Every nontrivial operation records a resource tuple

$$\mathfrak{Q} = (n_1, \ldots, n_k; T(\mathbf{n}), M(\mathbf{n}), P, B),$$

with input dimensions $\mathbf{n}$, time T, memory M, precision P, and enforced budget B. Claims are tagged as

$$\mathsf{proved\ bound}, \quad \mathsf{implementation\ count}, \quad \mathsf{measured\ benchmark}, \quad \mathsf{heuristic\ estimate}.$$

Hardware timing records never substitute for asymptotic or exact operation counts.

1.13 Persistence and migration form

Portable records are versioned mathematical data, not arbitrary object dumps. The guide records both the canonical encoder and the strict decoder, including unknown-field rejection, depth and size limits, digest scope, and the supported adjacent migration. A roundtrip is checked on the encoded finite record.

For every portable type X, document

$$\mathrm{encode}_v : X \to J_v, \qquad \mathrm{decode}_v : J_v \to X, \qquad \mathrm{decode}_v \circ \mathrm{encode}_v = I_X,$$

plus the adjacent migration

$$\mu_{v \to v+1} : J_v \to J_{v+1}.$$

The symbolic schema includes tag, version, payload grammar, canonical ordering, depth and size limits, digest scope, rejected unknown fields, and tamper cases.

1.14 Fully expanded symbol-card exemplar

The card below defines the format used throughout the function inventory. Notice that the certificate validates the transform record while invertibility remains a separate diagnostic. A singular square transform can be a valid record and still be impossible to invert.

`[STABLE][EXACT][CERT]`

$$\begin{aligned}\text{Name} &= \texttt{komorebi_math.stable.CoordinateTransform},\\ \text{Alias} &= \texttt{ExactCoordinateTransform},\\ \text{Impl} &= \texttt{komorebi_math.coordinates.transform.CoordinateTransform}.\end{aligned}$$

Constructor:

$$\text{CoordinateTransform}(s : \text{Str}, t : \text{Str}, T : \mathbb{Q}^{m\times n}, \vartheta : \text{Str}, \delta : \text{Str} = \texttt{""}) \to \mathcal{T}_{t\leftarrow s}.$$

State and action:

$$c_t = T_{t\leftarrow s} c_s, \qquad \text{apply} : \mathbb{Q}^n \to \mathbb{Q}^m.$$

For $m = n$ and $\det T \neq 0$,

$$\mathcal{T}_{s\leftarrow t} = \mathcal{T}_{t\leftarrow s}^{-1}, \qquad T^{-1}T = TT^{-1} = I_n.$$

Composition is ordered by execution:

$$\mathcal{T}_{t\leftarrow s}.\,\text{then}(\mathcal{T}_{u\leftarrow t}) = \mathcal{T}_{u\leftarrow s}, \qquad T_{u\leftarrow s} = T_{u\leftarrow t} T_{t\leftarrow s}.$$

Construction hypotheses and failures:

$$m, n \geq 1, \quad s \neq \texttt{""}, \quad t \neq \texttt{""};$$

ragged or empty matrices and dimension mismatches raise dimension errors, blank names or incompatible composition labels raise validation errors, and inversion of a rectangular or singular matrix is rejected.

Certificate normal form:

$$\mathfrak{K}_T = (\mathsf{true}, \mathsf{EXACT}, \emptyset, \emptyset, h_T, \emptyset, d, \vartheta, m_T),$$

where h_T records the finite rational matrix and declared dimensions, m_T reads "exact coordinate transform validated,'' and d records $(m, n, m = n, \det T, \text{invertible}(T))$. The certificate validates the transform record. Invertibility remains a separate diagnostic and is not implied for rectangular or singular transforms.

Symbolic example family:

$$T = \begin{bmatrix} 1 & \frac{1}{2} \\ 0 & 1 \end{bmatrix}, \quad c_s = \begin{bmatrix} 2 \\ 3 \end{bmatrix}, \quad c_t = Tc_s = \begin{bmatrix} \frac{7}{2} \\ 3 \end{bmatrix},$$

followed by exact inverse roundtrip, a three-system composition, a source-label composition failure, and a singular-matrix inversion failure. This is the model of detail required for every manifest symbol card.

> **Chapter 1 summary.** The object is a source-backed claim or public symbol. The operation is typed documentation. The evidence is its local label and certificate record. The next chapter shows how those rules organize the library without collapsing its domains into one meaning.

2. What Komorebi Math is

Komorebi Math is a typed Python library for executing finite packet mathematics across operator systems, coordinate transforms, refinement, arithmetic, signals, nonlinear constructions, exact integration, and expression calculus. Its unifying idea is not that these subjects have one meaning. It is that many of their finite computations can expose the same kinds of objects: generators, addresses, operators, packet decompositions, transfer blocks, refinements, constraints, certificates, and reconstructions.

The reference baseline combines a research API with a frozen stable compatibility surface. Use the stable namespace when import and signature continuity matter most. Use beta and research surfaces when the additional construction is worth a looser compatibility promise. In every tier, mathematical truth status is reported separately from API stability.

2.1 Finite execution language

The nine verbs below are an organizing vocabulary. A workflow may use only two or three of them. It does not need to instantiate a universal pipeline.

$$\text{seed} \to \text{address} \to \text{operate} \to \text{project} \to \text{transfer} \to \text{refine} \to \text{constrain} \to \text{complete} \to \text{reconstruct}.$$

Stage	Finite role	Implemented status in `STAGES`
seed	choose finite generating data	yes
address	name legal paths or coordinates	yes
operate	apply a realized operator	yes
project	resolve an object into packets	yes
transfer	expose source-to-target blocks	yes
refine	pass between compatible finite levels	yes
constrain	form defects and obstruction problems	yes
complete	construct compatible inverse limits in general	**no**
reconstruct	return to an ambient finite object	yes

The explicit `no` beside `complete` is a boundary, not a missing footnote. Some modules implement finite completion checks or domain-specific completion data, but `UnifiedSystem` does not claim to construct a general inverse limit.

2.2 What the shared language does and does not identify

The shared language makes composition boundaries inspectable. A packet coordinate object knows its originating system. A transfer block records source and target packets. A refinement requires compatible levels. A certificate says which finite identities were checked. These interfaces let workflows connect without erasing their native mathematics.

- shared finite interfaces
- domain-specific meanings
- exact versus numerical realizations
- finite versus continuum boundaries
- research APIs versus compatibility promises

The language does **not** identify a signal channel with an arithmetic residue, a quantum sector with a polynomial coordinate family, or a small residual with an exact zero. Nor does the presence of a finite algorithm assert convergence, regularity, or a continuum theorem that the implementation does not check.

What this establishes. Komorebi Math has a common finite execution vocabulary and typed cross-domain junctions.
What this does not establish. The domains are not collapsed into one semantics, and the common vocabulary is not a proof of a universal theory.

2.3 Reader pathways

The guide can be entered by task rather than read straight through. Begin with Chapters 0 through 4 and use Appendix A for exact stable-name lookup. Every domain path should include Chapter 5's certificate and result-type reference, Chapter 6's failure contract, the stability and backend boundaries in Chapters 7 and 8 that apply to its examples, and the Part III foundation that matches its finite objects: typed realizations in Chapter 9, generated actions in Chapter 10, packet blocks in Chapter 11, or resolution changes in Chapter 12.

- P_0: install and run a verified example
- P_1: exact algebra and arithmetic
- P_2: coordinates, refinement, and signal processing
- P_3: nonlinear, integration, and typed expressions
- P_4: quantum, deformation, and finite Langlands models
- P_5: extension, export, verification, and release maintenance

Path	Continue with	Typical profile
P_0 first execution	Chapters 3 through 5, then one domain chapter	core
P_1 exact algebra and arithmetic	Parts III, IV, V	core plus `exact` where named
P_2 coordinates, refinement, signals	Parts III, IV, VI	core. Add `scientific` selectively
P_3 nonlinear and expression workflows	Parts VII and VIII	core plus the backend named by the example
P_4 quantum, deformation, finite Langlands	Part IX	research tier. Read all claim boundaries
P_5 extension and release maintenance	Parts X and XII	`publication` or `dev`

Dense symbol inventories remain search-first reference material. The prose path teaches a concept once, then points to the canonical cards rather than repeating the same foundation in every domain.

2.4 `UnifiedSystem` and cross-domain composition boundaries

`UnifiedSystem` is a component-optional container for one finite construction. It can hold an operator grammar and realization, a seed system, a packet system, named ambient operators, a refinement tower, and metadata. `validate()` runs the consistency checks supported by the component combinations that are present. Named operators are dimension-checked when a packet system is available, metadata is descriptive, and absent or presently unchecked components contribute no failure. This makes partial systems useful, but it also means that a metadata-only instance returning a valid certificate has not validated absent mathematics.

Define a finite unified system by

$$\mathcal{U} = (\Gamma, \rho, \mathcal{S}, \mathcal{P}, \{A_\alpha\}_{\alpha\in\Lambda}, \mathcal{T}, \mu),$$

where Γ is an optional operator grammar, ρ its realization, $\mathcal{S}$ a seed system, $\mathcal{P}$ a packet system, $A_\alpha : X \to X$ named ambient operators, $\mathcal{T}$ an optional refinement tower, and μ metadata.

The validation predicate is the conjunction

$$V_{\mathcal{U}} = V_{\rho\vDash\Gamma} \wedge V_{\mathrm{hull}(\mathcal{S})} \wedge V_{\mathcal{P}} \wedge V_{\dim} \wedge V_{\{A_\alpha\}} \wedge V_{\mathcal{T}},$$

with absent components contributing the neutral truth value. Dimension compatibility requires

$$\dim \mathcal{S} = \dim \mathcal{P}, \qquad A_\alpha \in R^{d\times d}, \qquad \mathcal{P} \simeq \mathcal{T}_\ell \text{ for some level } \ell$$

whenever the corresponding components are present.

Public operations are typed as

$$\begin{aligned}
\text{validate} &: \mathcal{U} \to \text{Certificate},\\
\text{analyze} &: X \to \text{PacketCoordinates}(\mathcal{P}),\\
\text{block_operator}_\alpha &: A_\alpha \mapsto (P_i A_\alpha P_j)_{i,j},\\
\text{refine}_{r\to s} &: K_r \to K_s,\\
\text{coarsen}_{s\to r} &: K_s \to K_r,\\
\text{obstruction} &: (L, d) \mapsto [Lc = d].
\end{aligned}$$

The public methods expose those component requirements directly:

Method	Required component	Result
`validate()`	none. Checks whatever is present	`Certificate`
`analyze(x)`	packet system	`PacketCoordinates`
`block_operator(name)`	packet system and named operator	`PacketOperator`
`refine_coordinates(...)`	refinement tower	refined coordinates
`coarsen_coordinates(...)`	refinement tower	coarsened coordinates
`obstruction(L, d)`	correction map and defect	`LinearObstructionProblem`
`summary()`	none	finite dictionary summary

The guide must make the implemented completion boundary explicit:

$$\begin{aligned}
\mathsf{SEED} \to \mathsf{ADDRESS} \to \mathsf{OPERATE} \to \mathsf{PROJECT}\\
\to \mathsf{TRANSFER} \to \mathsf{REFINE} \to \mathsf{CONSTRAIN}\\
\to \mathsf{COMPLETE} \to \mathsf{RECONSTRUCT}.
\end{aligned}$$

where `COMPLETE` is a declared cross-domain stage but is not asserted as a general implemented inverse-limit construction. Missing packet or refinement components, unknown operators, inconsistent dimensions, and failed component certificates receive separate examples.

The shipped `examples/quickstart.py` builds a four-dimensional shift, a cyclic seed hull, even/odd packets, and the associated block operator. On the audited source it reports a valid **numerical** system, hull dimension four, and off-diagonal block norm $\sqrt{2}$. The NumPy backend determines the numerical label even though the displayed matrices contain only zeros and ones.

> **Chapter 2 summary.** The object is a finite typed system. The operation is composition through explicit stages. The evidence is component-level validation. The next chapter binds those operations to a specific interpreter and dependency profile.

3. Installation and environment profiles

Before you start. Choose whether you are installing a delivered package or working on a source checkout. Commands that mention `release/`, `constraints/`, `examples/`, or a repository wrapper require those files in the current working directory. An installed package does not by itself supply a working checkout. Run such commands from the matching source or distribution bundle and confirm that the named file exists before invoking it.

The literal wheel names and version assertions below reproduce the stated reference baseline. Keep the package, constraint file, and expected version from one release together. If you are using the current release, use its supplied installation instructions and artifact names. An optional profile is needed only when the selected example calls for it; the core first program is the simplest starting point.

A Komorebi Math result belongs to a specific interpreter and dependency profile. For that reason, this guide invokes pip through the same Python executable that will run the example. The recorded commands below assume that the reference handoff has been extracted and the shell is at the repository root.

The declared floor is Python 3.11. The recorded qualification matrix covers Python 3.11, 3.12, and 3.13. Python 3.13 matches the recorded Windows replay most closely. The bundled wheel is the canonical package artifact in the handoff. Installation is fully offline only when every required dependency is also available from a local cache or wheelhouse. A name-only `pip install komorebi-math` command assumes an external package-index publication and is therefore not assumed by these installation instructions.

3.1 Core installation

On Windows PowerShell, create a clean environment and retain its resolved interpreter path:

```
py -3.13 -m venv .venv
$py = (Resolve-Path .\.venv\Scripts\python.exe).Path

& $py -m pip install --upgrade pip
& $py -m pip install -c .\constraints\base-py313.txt `
    .\release\dist\komorebi_math-1.0.0b4-py3-none-any.whl

& $py -m pip check
& $py -c "import komorebi_math as km; assert km.__version__ == '1.0.0b4'; print(km.__version__)"
& $py -m komorebi_math info
```

The identity check must print `1.0.0b4`. `komorebi info` then prints the same package identity and the finite stage language. Use `& $py -m ...` rather than an unqualified `python`, `pip`, or `komorebi` command when several Conda or virtual environments are visible in the prompt.

The equivalent POSIX setup is:

```
python3.13 -m venv .venv
. .venv/bin/activate

python -m pip install --upgrade pip
python -m pip install \
  -c constraints/base-py313.txt \
  ./release/dist/komorebi_math-1.0.0b4-py3-none-any.whl

python -m pip check
python -c "import komorebi_math as km; assert km.__version__ == '1.0.0b4'; print(km.__version__)"
python -m komorebi_math info
```

Choose exactly one source-oriented alternative when developing the library. Editable installation keeps imports bound to the checked-out source:

```
& $py -m pip install -e ".[exact,scientific,yaml]"
```

Installing the source distribution exercises a clean PEP 517 rebuild before installation:

```
& $py -m pip install --force-reinstall `
    .\release\dist\komorebi_math-1.0.0b4.tar.gz
```

Do not combine those alternatives in one environment when diagnosing import provenance. A successful import from an editable checkout does not prove that the bundled wheel or source distribution was installed correctly.

3.2 Optional dependency lattice

The core wheel requires NumPy. Optional extras add one feature family at a time. They do not change the package version.

$$\forall x \in \{\text{exact}, \text{scientific}, \text{yaml}, \text{jax}, \text{torch}, \text{publication}\}, \qquad \mathcal{P}_{\text{core}} \subseteq \mathcal{P}_x.$$

Extra	Adds	Use it for
`exact`	SymPy	symbolic/exact backend paths that explicitly request SymPy
`scientific`	SciPy, mpmath	scientific routines and high-precision analytic paths
`plot`	Matplotlib	plotting examples
`yaml`	PyYAML	YAML export/import paths
`jax`	JAX	JAX directional-differentiation adapter
`torch`	PyTorch	PyTorch directional-differentiation adapter
`autodiff`	JAX and PyTorch	both autodiff adapters
`test`	pytest	source test execution
`docs`	MkDocs	documentation build
`build`	build, setuptools, wheel	distribution construction
`publication`	test, build, docs, exact, scientific, YAML	reference publication gate
`dev`	publication tools, Ruff, mypy	repository development
`all`	exact, scientific, plotting, YAML	broad mathematical extras only

Despite its name, `all` does not install JAX, PyTorch, CuPy, test tools, MkDocs, or build tools. CuPy is intentionally not a declared extra because its package must match the local CUDA line.

Append extras to the bundled wheel path before public package-index release:

```
& $py -m pip install `
    ".\release\dist\komorebi_math-1.0.0b4-py3-none-any.whl[exact,scientific,yaml]"
```

Many exact rational facilities, including the `Fraction`-based coordinate transform in Chapter 4, do **not** require SymPy. Install an extra because a named workflow needs it, not because the word “exact” appears in a theorem.

3.3 Windows, Linux, CPU, and CUDA profiles

The base CPU profile is the default and is enough for Chapters 0 through 4. A complete Windows publication replay should use the handoff's isolated launcher rather than adding publication dependencies to the reader's working environment:

```
$hostPython = if ($env:CONDA_PREFIX) {
    Join-Path $env:CONDA_PREFIX "python.exe"
} else {
    (Get-Command python.exe -ErrorAction Stop).Source
}

powershell.exe -NoProfile -ExecutionPolicy Bypass `
    -File .\Run_Block21_Windows_Qualification.ps1 `
    -Python $hostPython
```

The launcher creates a temporary virtual environment, installs the bundled wheel with the `publication` profile, runs `pip check`, requires MkDocs, and executes the publication gate. It removes the temporary environment after success. On failure it retains the environment and prints its location so the same interpreter can be inspected. Internet access, a configured package index, or a populated local wheel cache is required for dependencies not already present.

The `-Quick` switch omits the complete pytest run. It is a diagnostic preflight, not final publication qualification.

On POSIX systems the supplied runner uses the active environment and does not create one:

```
python3.13 -m venv .venv-publication
. .venv-publication/bin/activate
python -m pip install --upgrade pip
python -m pip install \
  './release/dist/komorebi_math-1.0.0b4-py3-none-any.whl[publication]'
python -m pip check

PYTHON="$(command -v python)" ./run_block21_publication_gate.sh
```

GPU qualification is separate from CPU publication qualification. Discovering `cupy` or an installed PyTorch build does not establish that the CUDA runtime, device, and directional primitives are usable. The GPU gate requires a compatible CUDA-specific PyTorch installation and exactly one matching CuPy distribution. It reports its own hardware evidence.

> **Environment boundary.** A green core example proves that example in the resolved interpreter. A green publication gate binds the wider finite release contract. Neither result silently qualifies unavailable hardware.

3.4 `Settings`, `configure`, `get_settings`, and `settings_context`

Runtime settings are immutable records stored in a Python context variable. The default record uses the NumPy backend name, tolerance `1e-10`, and construction validation. `get_settings()` returns the active record. `configure(...)` replaces selected fields in the current context and returns the new record. `settings_context(...)` is the safer choice for examples because it restores the exact previous context even when the body raises:

```
from komorebi_math import get_settings, settings_context

before = get_settings()
try:
    with settings_context(tolerance=1e-14) as scoped:
        assert scoped.tolerance == 1e-14
        raise RuntimeError("demonstrate restoration")
except RuntimeError:
    pass

assert get_settings() == before
print(before)
```

Expected default output:

```
Settings(backend='numpy', tolerance=1e-10, validate_on_construction=True)
```

The tolerance and construction-validation fields are consumed by core objects that consult them. The `backend` field is retained in the settings record, but `get_backend(None)` and core constructors default to NumPy and do not consult that field in this release. Pass `backend="sympy"` or another supported backend explicitly to the operation whose backend matters. `configure(backend="unknown")` stores the string. Rejection can occur later when `get_backend()` is actually called.

3.5 Optional-backend probe and failure isolation

Use the CLI for a human-readable environment report and the Python probe for a small programmatic record:

```
& $py -m komorebi_math doctor
```

```
from komorebi_math.backends import available_backends, get_backend

presence = available_backends()
print(presence)
numpy_backend = get_backend("numpy")
assert numpy_backend.name == "numpy"
```

`available_backends()` reports import presence for NumPy, SymPy, SciPy, mpmath, and CuPy. Presence is not the same as selection or qualification: NumPy is registered by default. SymPy is loaded lazily when its extra is installed. SciPy and mpmath are feature dependencies rather than general linear-algebra backend names, and CuPy presence alone neither registers a backend nor proves a working GPU. `komorebi doctor` similarly reports the environment without installing or certifying an optional package.

Symptom	Check	Recovery
wrong package version	print `sys.executable` and `komorebi_math.__version__`	invoke pip and the module through the resolved interpreter
`BackendUnavailableError`	inspect `available_backends()` and the requested operation	install the named extra or choose an available backend
import succeeds but dependencies conflict	run `python -m pip check`	rebuild a clean environment under the supplied constraint file
publication runner cannot build docs	confirm MkDocs is installed	use the `publication` profile. Do not relabel a skipped docs build as strict
Windows qualification fails	read the retained temporary-environment path	rerun diagnostics with that environment's `python.exe`

The smallest successful import is not a release gate, and the full release gate is not the right first diagnostic. Start with identity, `pip check`, and the smallest certificate relevant to the intended workflow. Escalate only after those pass.

> **Chapter 3 summary.** The object is a resolved Python environment. The operation is profile-specific installation. The evidence is identity, dependency consistency, and the relevant finite gate. The next chapter runs the first mathematical program in that environment.

4. First verified program

What success looks like. By the end of this chapter, you should be able to identify the imported package, reconstruct one numerical vector, perform one exact rational roundtrip, and explain the difference between the two certificates. Run Sections 4.3 and 4.4 unchanged first. Then change one input value at a time and inspect the resulting values and evidence. Section 4.5 is an intentional failure demonstration, so its rejected certificate is the expected outcome.

The first executable path moves from environment identity to two small mathematical checks. The mandatory path uses only the bundled core wheel and NumPy: it constructs a two-packet decomposition, inspects its certificate, analyzes a vector, and reconstructs it. A second path uses Python `Fraction` values to demonstrate a genuinely exact coordinate transform without requiring SymPy.

All code in this chapter was executed against the delivered `1.0.0b4` source. The output blocks omit only platform-dependent executable paths. Run examples with the resolved interpreter from Chapter 3.

4.1 Package identity and `komorebi info`

Begin by proving which package the interpreter imports:

```
& $py -c "import sys, komorebi_math as km; print(sys.executable); print(km.__version__)"
& $py -m komorebi_math info
```

After the local executable path, the version and CLI output are shown below, reflowed for print:

```
1.0.0b4
komorebi-math 1.0.0b4
language:
  seed -> address -> operate -> project -> transfer
  -> refine -> constrain -> complete -> reconstruct
implemented blocks:
  finite dimensional core through Block 17;
  production finite DSP;
  research-tier Blocks 18-20 for frame algebra,
  finite integration, and typed exact expressions
```

The final line is a release summary, not an assertion that every feature is in the frozen stable namespace. The package version is the authoritative identity. The handoff revision identifies the surrounding delivery package.

4.2 Capability discovery and `komorebi features`

The feature registry shows the declared status and scope of each domain:

```
& $py -m komorebi_math features
```

Representative rows include `algorithms implemented`, `coordinates implemented`, `core implemented`, `backends partial`, and `langlands.global partial`, each followed by a finite summary. Status values describe the static project registry. They do not report which optional package is installed in the current environment. Use `komorebi doctor` or `available_backends()` for that question.

Before relying on stable compatibility, the short installed checks are:

```
& $py -m komorebi_math api check --stable
& $py -m komorebi_math verify stable
```

The stable manifest contains 131 symbols. Its committed digest for this release is `23cd9e47a1663f2d4b3c0fef50f9f7d8c88d4af2f8bbc57e7ba76461e6e69276`.

4.3 Minimal packet roundtrip

Let

$$P_{\text{left}} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \qquad P_{\text{right}} = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}.$$

The projectors are idempotent, annihilate each other, and sum to the identity. For $x = (2, 3)^T$, analysis produces the embedded packet coordinates $(2, 0)^T$ and $(0, 3)^T$. Synthesis adds them back to x.

```python
import numpy as np

from komorebi_math.stable import Exactness, PacketSystem

packets = PacketSystem(
    [np.diag([1.0, 0.0]), np.diag([0.0, 1.0])],
    names=("left", "right"),
)

certificate = packets.certificate().require()
x = np.array([2.0, 3.0])
coordinates = packets.analyze(x)
reconstructed = coordinates.reconstruct()

np.testing.assert_array_equal(reconstructed, x)
assert certificate.exactness is Exactness.NUMERICAL

print("packets:", [value.real.tolist() for value in coordinates.values])
print("reconstructed:", reconstructed.real.tolist())
print("exactness:", certificate.exactness.value)
print("residuals:", certificate.residuals)
```

Expected output:

```
packets: [[2.0, 0.0], [0.0, 3.0]]
reconstructed: [2.0, 3.0]
exactness: numerical
residuals: {'idempotence': 0.0, 'annihilation': 0.0, 'completeness': 0.0}
```

`[NUMERICAL][CERT]` The residuals happen to be exactly representable zeros in this run, but the NumPy execution path remains numerical. The backend determines the certificate's exactness class. The tolerance determines whether numerical residuals are accepted. Visual simplicity of the matrix entries does not promote the result to exact algebra.

This example establishes the finite packet axioms and roundtrip for one input in the resolved environment. It does not establish a continuum decomposition or a backend-independent theorem beyond the implemented finite contract.

4.4 Minimal exact coordinate transform

The stable exact transform stores a finite rational matrix. Use `Fraction`, not a floating literal, to keep the scalar domain $\mathbb{Q}$:

$$T_{B\leftarrow A} = \begin{bmatrix} 1 & \frac{1}{2} \\ 0 & 1 \end{bmatrix}, \qquad T_{B\leftarrow A} \begin{bmatrix} 2 \\ 3 \end{bmatrix} = \begin{bmatrix} \frac{7}{2} \\ 3 \end{bmatrix}.$$

```python
from fractions import Fraction

from komorebi_math.stable import ExactCoordinateTransform, Exactness

Q = Fraction
transform = ExactCoordinateTransform(
    "A",
    "B",
    ((1, Q(1, 2)), (0, 1)),
    "GUIDE-CH4-EXACT-SHEAR",
    "exact rational shear",
)

vector = (Q(2), Q(3))
mapped = transform.apply(vector)
restored = transform.inverse().apply(mapped)
certificate = transform.certificate().require()

assert mapped == (Q(7, 2), Q(3))
assert restored == vector
assert certificate.exactness is Exactness.EXACT
assert transform.roundtrip_valid()

print("mapped:", mapped)
print("restored:", restored)
print("determinant:", transform.determinant)
print("exactness:", certificate.exactness.value)
```

Expected output:

```
mapped: (Fraction(7, 2), Fraction(3, 1))
restored: (Fraction(2, 1), Fraction(3, 1))
determinant: 1
exactness: exact
```

`[EXACT][CERT]` The inverse roundtrip is decided by rational matrix arithmetic. The transform certificate validates the finite record and reports determinant and invertibility diagnostics. Certificate validity alone is not an invertibility theorem for every record: a singular square transform can be a well-formed valid record with the `invertible` diagnostic set to `False`.

4.5 Minimal certificate inspection

A certificate can be inspected before acceptance is enforced with `.require()`. To demonstrate that distinction, intentionally construct an invalid packet family with automatic construction validation disabled. The second projector has eigenvalue $1/2$, so it is neither idempotent nor part of a complete decomposition:

```
import numpy as np

from komorebi_math.stable import PacketSystem, ValidationError

bad = PacketSystem(
    [np.diag([1.0, 0.0]), np.diag([0.0, 0.5])],
    names=("left", "right"),
    validate=False,
)

failed = bad.certificate()
print("valid:", failed.valid)
print("exactness:", failed.exactness.value)
print("residuals:", failed.residuals)
print("message:", failed.message)

try:
    failed.require()
except ValidationError as error:
    print(type(error).__name__ + ":", error)
```

Expected output:

```
valid: False
exactness: numerical
residuals: {'idempotence': 0.25, 'annihilation': 0.0, 'completeness': 0.5}
message: projectors do not form a complete packet system
ValidationError: projectors do not form a complete packet system
```

The `validate=False` argument is appropriate here only because the example's purpose is to inspect the failed record. Under the default settings, the constructor calls `.require()` and rejects the invalid family immediately. In ordinary application code, disabling validation should be an explicit, auditable decision rather than a way to suppress an inconvenient certificate.

For any domain-specific certificate, inspect the fields in this order: `valid`, `exactness`, residuals and tolerance, checked assumptions, unchecked assumptions, theorem or contract identifier, diagnostics, and message. Then call `.require()` when the next operation is permitted only on acceptance.

4.6 Public capability tour

The two examples above are intentionally small. The shipped deterministic tour is the next connected check:

```
& $py .\examples\block21_public_capability_tour.py --json
```

When reviewing the source tree rather than the installed wheel, bind imports to that tree first:

```
$env:PYTHONPATH = Join-Path (Get-Location) "src"
& $py .\examples\block21_public_capability_tour.py --json
```

The finite tour exercises exact polyphase refinement, redundant analysis-synthesis, Euler-to-Fibonacci coordinates, exact finite integration, a rejected false certificate, typed expressions, portable roundtrips, and the frozen 131-symbol stable contract. For the committed inputs its capability record digest is:

```
0e20e32f4ad9004d5248d258813b6acfec7b9e96cc30c001aa6865aba9039fdf
```

`[EXACT][NUMERICAL][CERT]` applies per sub-result, not to the tour as one undifferentiated theorem. The digest binds a deterministic structured record. It is release reproducibility evidence. It does not prove all behavior in all domains or on all backends.

For full Windows qualification, use the isolated launcher from Chapter 3. It adds dependency consistency, strict documentation, API and release contracts, the complete source test suite, and the tour. The guide treats the output as an environment-stamped execution record, not a timeless test-count claim.

> **Chapter 4 summary.** Inspect each finite packet or coordinate result and its certificate. Use the asserted roundtrip as a check on the example. Chapter 5 explains the result and certificate types.

> **Part I execution evidence.** The Chapter 0–4 Python examples were executed against the recorded reference source. Installation and qualification commands were checked against its paths and scripts. Execution claims retain their recorded environment scope.

Part II. Trust, types, and execution semantics

Use this part when deciding whether a result is usable. Start with Chapter 5 when an operation returns a certificate or result wrapper. Use Chapter 6 when it raises an exception or reports a failed check. Chapter 7 explains which imports carry a compatibility promise. Chapter 8 explains which arithmetic and optional dependencies a computation actually uses.

A short review of any result follows four questions:

1. Did the operation accept the input and complete its declared check?
2. Was the executed arithmetic exact, numerical, conditional, or heuristic?
3. Which assumptions and tolerances limit the conclusion?
4. Does the next operation require an accepted certificate, a particular scalar domain, or a stronger hypothesis?

Keep the result and its certificate together while answering these questions. A number alone usually does not preserve enough context to explain how it was obtained. The examples in this part show both accepted and rejected records so that a failure can be recognized and diagnosed without guessing.

5. Certificates and result types

Komorebi Math does not treat a returned value as the whole result of a mathematical computation. Many public operations also return evidence about what was checked, how it was checked, and what remains assumed. The common record for that evidence is `Certificate`. `ComputationResult[T]` and `ConditionalResult[T]` pair such a record with a value.

These types enforce a small runtime contract that is conservative by design. They make evidence visible and provide a standard failure boundary, but they do not re-prove the mathematics recorded by a producing API. In particular, a `Certificate` stores the producer's Boolean `valid`. It does not recompute that Boolean from the residuals, tolerance, or assumptions supplied beside it.

5.1 `Exactness`: classify the executed evidence

`Exactness` is a string-valued enumeration with five members:

Member	Stored value	Reader interpretation
`Exactness.EXACT`	`"exact"`	Finite identities were decided in the declared exact domain.
`Exactness.NUMERICAL`	`"numerical"`	A finite numerical check used an explicit error rule.
`Exactness.CONDITIONAL`	`"conditional"`	The conclusion retains named unchecked assumptions.
`Exactness.HEURISTIC`	`"heuristic"`	The result is exploratory or estimated.
`Exactness.PLANNED`	`"planned"`	The interface or claim is reserved, not established.

The enum member records the path that actually ran. It is not selected by the user's desired conclusion. A zero residual from a NumPy computation remains `NUMERICAL`. Zero floating-point output does not turn that computation into exact algebra. Conversely, an exact finite computation may be invalid because an exact identity failed.

The enum itself defines no ordering methods. The research namespace exposes an explicit ordering for evidence composition:

```
exactness_strength(value: Exactness) -> int
weakest_exactness(*values: Exactness) -> Exactness
```

The implemented ranks are

$$\operatorname{rank}(\text{exact}) = 0, \quad \operatorname{rank}(\text{numerical}) = 1, \quad \operatorname{rank}(\text{conditional}) = 2, \quad \operatorname{rank}(\text{heuristic}) = 3, \quad \operatorname{rank}(\text{planned}) = 4.$$

A larger rank denotes a weaker guarantee. `weakest_exactness()` returns the largest supplied rank, with `EXACT` as the empty meet. Both helpers require real `Exactness` members. They reject raw strings. These helpers belong to the research root API rather than the frozen stable namespace, so Chapter 7's API tier rules apply to them.

Exactness and validity answer different questions:

`exactness` : What kind of evidence was produced?
`valid` : Did the producer's declared finite check pass?

Neither answer determines the other. An invalid exact certificate and a valid numerical certificate are both ordinary states.

5.2 `Certificate`: one machine-readable evidence record

The frozen stable constructor is

```
Certificate(
    valid: bool,
    exactness: Exactness,
    residuals: dict[str, float] = <factory>,
    tolerance: float | None = None,
    assumptions_checked: tuple[str, ...] = (),
    assumptions_unchecked: tuple[str, ...] = (),
    diagnostics: dict[str, Any] = <factory>,
    theorem_id: str | None = None,
    message: str = "",
) -> None
```

In the guide's comparison notation, write

$$C = (v, e, R, \tau, H_{\checkmark}, H_{?}, D, t, m).$$

Field	Declared type	Meaning
`valid`	`bool`	Producer-supplied outcome of its declared check.
`exactness`	`Exactness`	Evidence class of the executed path.
`residuals`	`dict[str, float]`	Named finite discrepancies or counts.
`tolerance`	`float | None`	Numerical comparison scale, when applicable.
`assumptions_checked`	`tuple[str, ...]`	Conditions established by the finite execution.
`assumptions_unchecked`	`tuple[str, ...]`	Conditions retained rather than established.
`diagnostics`	`dict[str, Any]`	Explanatory backend, size, method, or audit data.
`theorem_id`	`str | None`	Optional theorem, contract, or operation label.
`message`	`str`	Human-readable success or failure description.

The declared schema is informative, but the base constructor does not validate or coerce every field. A producing API is responsible for constructing a coherent record. Direct callers should therefore use `Exactness` members, finite float residuals, a nonnegative numerical tolerance when one is needed, and nonempty assumption labels. Passing the raw string `"exact"` instead of `Exactness.EXACT`, for example, creates a malformed record whose later methods need not behave correctly.

For an exact identity check, a typical producer implements

$$v \iff \bigwedge_i R_i = 0, \qquad e = \text{exact}, \qquad \tau = \emptyset.$$

For a numerical check, the rule is producer-specific and should be documented beside the operation. A common form is

$$v \iff \bigwedge_i R_i \le b_i(\tau, \text{scale}), \qquad e = \text{numerical}.$$

There is no universal norm or scaling convention hidden in `Certificate`. Readers must inspect the producing function's contract before interpreting a residual. A count such as `failed_checks` and a norm such as `roundtrip` are both stored as floats, but they do not have the same mathematical units.

The data class is frozen and slot-based: fields cannot be rebound. That immutability is shallow. The `residuals` and `diagnostics` dictionaries remain mutable objects, so code that needs an archival record should avoid modifying them after construction and should serialize the final certificate promptly.

5.3 `ComputationResult[T]` and `ConditionalResult[T]`

`ComputationResult[T]` pairs an arbitrary value with one certificate:

```
ComputationResult(value: T, certificate: Certificate) -> None
```

Its convenience interface is exactly

```
result.valid          # result.certificate.valid
result.exact          # result.certificate.exactness is Exactness.EXACT
result.require()      # require the certificate, then return result.value
```

Symbolically,

$$\text{RequireResult}(x, C) = \begin{cases} x, & C.\text{valid is true}, \\ \text{ValidationError}, & C.\text{valid is false}. \end{cases}$$

The `exact` property classifies evidence only. It does not include a validity test, so `result.exact` can be true while `result.valid` is false. Acceptance code should call `result.require()` rather than use `result.exact` as a proxy for success. The raw `value` also remains directly accessible on an invalid result. The wrapper cannot prevent a caller from bypassing its evidence.

`ConditionalResult[T]` has the same two stored fields:

```
ConditionalResult(value: T, certificate: Certificate) -> None
```

Its constructor enforces one invariant:

$$C.\text{exactness} \textbf{ is } \texttt{Exactness.CONDITIONAL}.$$

A nonconditional certificate raises `ValueError("ConditionalResult requires a conditional certificate")`. Nothing else is inferred. The constructor does not require `valid=True`, does not require a nonempty `assumptions_unchecked`, and does not discharge any assumption. Unlike `ComputationResult`, `ConditionalResult` has no convenience `.valid`, `.exact`, or `.require()` member. Inspect and, when appropriate, enforce `result.certificate` explicitly.

Conditional producers use `valid` in more than one legitimate way. A symbolic plan may be internally well formed and therefore valid while still listing external hypotheses. A completion gate may instead remain invalid until all named inputs have been supplied. The message, checked assumptions, and unchecked assumptions determine which interpretation applies.

5.4 `.require()`, residuals, diagnostics, and serialization

`Certificate.require()` is intentionally small:

```
Certificate.require(self) -> Certificate
```

It returns the same object when `valid` is truthy. When `valid` is false, it raises `ValidationError` with `message`. An empty message uses the fallback `"certificate validation failed"`. It does not compare residuals with the tolerance, inspect assumptions, interpret diagnostics, or resolve the theorem identifier. Those checks must already have been performed by the producer.

Read a certificate in this order:

1. Inspect `valid` and `exactness` together.
2. Identify the formula and norm represented by every residual.
3. Read the tolerance only under that producer's numerical rule.
4. Separate checked conditions from unchecked assumptions.
5. Treat `theorem_id` as a label, not as proof by itself.
6. Use diagnostics to explain the run, never to override `valid`.
7. Call `.require()` at the boundary where invalid evidence must stop work.

The presentation serializers are

```
Certificate.to_dict(self) -> dict[str, Any]
Certificate.to_json(self, *, indent: int = 2) -> str
```

`to_dict()` recursively converts the data-class fields and replaces the enum object by its string value. `to_json()` sorts keys and uses `default=str` for objects that ordinary JSON cannot encode. It is useful for reports, but that fallback can erase type information. It should not be described as a typed roundtrip format.

The portable persistence layer separately registers `Certificate` under codec tag `core.certificate`, version 1. `dumps_portable()` places the encoded record in a canonical, SHA-256-checked envelope. `loads_portable()` validates that envelope before reconstruction. The digest detects an unchanged-versus-tampered payload, not authorship or a trusted signature. Direct portable serialization of `ComputationResult` or `ConditionalResult` is not implemented. Only the certificate itself has this built-in codec. The generic `to_serializable()` presentation export for a result is a different facility.

Worked example: a numerical packet certificate

This example was executed against the recorded reference source. It uses NumPy, so a zero observed residual remains numerical evidence.

```
import numpy as np

from komorebi_math import (
    Certificate,
    ComputationResult,
    Exactness,
    PacketSystem,
    describe,
)
from komorebi_math.stable import ValidationError

system = PacketSystem(
    [np.diag([1, 0]), np.diag([0, 1])],
    names=("left", "right"),
    tolerance=1e-12,
)
certificate = system.certificate()
coordinates = system.analyze(np.array([2.0, 3.0]))
```

```
result = ComputationResult(coordinates.reconstruct(), certificate)

record = describe(PacketSystem)
assert record is not None

print(result.valid, certificate.exactness.value)
print(result.exact, np.allclose(result.require(), [2.0, 3.0]))
print(certificate.residuals)
print(certificate.tolerance)
print(certificate.assumptions_checked)
print(certificate.assumptions_unchecked)
print(certificate.diagnostics)
print(record.status.value, record.identifier == certificate.theorem_id)
```

The same example adds a controlled failure branch:

```

failed = ComputationResult(
    "untrusted value",
    Certificate(
        False,
        Exactness.NUMERICAL,
        residuals={"roundtrip": 1e-4},
        tolerance=1e-12,
        message="roundtrip residual exceeds tolerance",
    ),
)

try:
    failed.require()
except ValidationError as error:
    print(f"{type(error).__name__}: {error}")
```

Expected output:

```
True numerical
False True
{'idempotence': 0.0, 'annihilation': 0.0, 'completeness': 0.0}
1e-12
('common dimension', 'idempotence', 'annihilation', 'completeness')
()
{'backend': 'numpy', 'ambient_dimension': 2, 'packet_count': 2}
proved True
ValidationError: roundtrip residual exceeds tolerance
```

The first Boolean pair says that the result passed but is not exact. The roundtrip assertion is a separate check of the value. The last line shows the enforcement boundary: the invalid wrapper stores a value, but `.require()` does not release it.

5.5 Certificate composition without evidence promotion

The research expression layer provides a source-backed rule for combining certificates:

```
compose_certificates(
    certificates: Iterable[Certificate],
    *,
    operation: str | None = None,
    theorem_id: str | None = None,
    assumptions_checked: Iterable[str] = (),
    assumptions_unchecked: Iterable[str] = (),
    diagnostics: Mapping[str, Any] | None = None,
) -> Certificate
```

For children $C_0, \dots, C_{n-1}$, it implements

$$v_{\text{out}} = \bigwedge_i v_i, \qquad e_{\text{out}} = max_{\text{rank}}\{e_0, \dots, e_{n-1}\}.$$

If any unchecked assumption remains and the computed class is stronger than `CONDITIONAL`, the output is weakened to `CONDITIONAL`. Assumptions are deduplicated in encounter order, and unchecked status wins when the same label appears in both sets. Residual keys receive deterministic `child0:`, `child1:`, and later prefixes. The aggregate tolerance is the maximum non-`None` child tolerance. This is summary metadata, not permission to compare every residual against one universal bound. Child and local diagnostics occupy separate nested namespaces.

The outer theorem identifier is whatever the caller supplies. Composition records child theorem identifiers in diagnostics but does not silently promote one child identifier to the theorem for the whole pipeline.

`exact_internal_certificate()` is a related research helper:

```
exact_internal_certificate(
    operation: str,
    *,
    theorem_id: str | None = None,
    assumptions_checked: Iterable[str] = (),
    diagnostics: Mapping[str, Any] | None = None,
) -> Certificate
```

It constructs valid exact evidence for an operation declared exact by construction. The helper validates its metadata, not the mathematical operation named by the caller. It should therefore be used only inside an implementation whose exact finite rule has already been established.

Worked example: compose, then retain the condition

```
from komorebi_math import compose_certificates
from komorebi_math.stable import (
    Certificate,
    ConditionalResult,
    Exactness,
)

exact = Certificate(
    True,
    Exactness.EXACT,
    residuals={"identity": 0.0},
    assumptions_checked=("finite input", "shared premise"),
    theorem_id="GUIDE.CH5.A",
)
numerical = Certificate(
    True,
```

```
    Exactness.NUMERICAL,
    residuals={"roundtrip": 3e-13},
    tolerance=1e-12,
    assumptions_checked=("bounded input",),
    theorem_id="GUIDE.CH5.B",
)

combined = compose_certificates(
    (exact, numerical),
    operation="demo pipeline",
    theorem_id="GUIDE.CH5.COMPOSE",
    assumptions_unchecked=("shared premise", "external convergence"),
)
conditional = ConditionalResult("pipeline value", combined)

print(conditional.value)
print(combined.valid, combined.exactness.value, combined.tolerance)
print(combined.residuals)
print(combined.assumptions_checked)
print(combined.assumptions_unchecked)
print(combined.diagnostics["composition"]["child_theorem_ids"])
print(combined.require() is combined)

try:
    ConditionalResult(0, exact)
except ValueError as error:
    print(f"{type(error).__name__}: {error}")
```

Expected output:

```
pipeline value
True conditional 1e-12
{'child0:identity': 0.0, 'child1:roundtrip': 3e-13}
('finite input', 'bounded input')
('shared premise', 'external convergence')
('GUIDE.CH5.A', 'GUIDE.CH5.B')
True
ValueError: ConditionalResult requires a conditional certificate
```

The numerical child prevents an exact output, and the unchecked assumptions weaken the composition further to conditional. Although the combined finite record is valid, `external convergence` remains an explicit premise.

5.6 Theorem identifiers and mathematical provenance

`Certificate.theorem_id` is an optional string. In practice it may name a paper theorem, a finite contract, a compatibility check, or an internal operation. The base record does not require it to be present or nonempty, and `.require()` does not look it up. A matching identifier is useful audit evidence only when the producing API and its documentation establish the link.

The research namespace supplies a separate provenance taxonomy:

```
ClaimStatus(*values)

ProvenanceRecord(
    identifier: str,
    title: str,
    status: ClaimStatus,
    source: str,
    assumptions: tuple[str, ...] = (),
    limitations: tuple[str, ...] = (),
```

```
    verification_suite: str | None = None,
) -> None

describe(obj: Any) -> ProvenanceRecord | None
```

`ClaimStatus` contains `definition`, `proved`, `classical input`, `conditional theorem`, `finite certificate`, `heuristic`, `conjecture`, and `planned`. It classifies the documented mathematical source claim. It is not an alternative spelling of execution `Exactness`.

`describe()` accepts an object or a qualified object name. It returns the attached `ProvenanceRecord`, or `None` when no record can be resolved. The CLI uses the same mechanism:

```
komorebi describe komorebi_math.core.packets.PacketSystem
```

For `PacketSystem`, the record identifies `PSC-I-T20`, status `proved`, source `Paper I`, its finite-family assumption, and verification suite `core.packets`. The worked example nevertheless obtains a numerical certificate because it executed through NumPy. This is not a contradiction: the provenance record classifies the documented theorem, while the certificate classifies one concrete run.

The module `komorebi_math.provenance` also contains `documented()`, `register_record()`, and `records()` for package authors and extensions. They are not frozen stable/root reader APIs. The registry is process-local and populated by imports. `records()` should not be presented as a complete static catalog. Registration can replace an existing key, so extension authors must manage identifier collisions themselves.

5.7 Cautions and defining failure cases

- A valid certificate is evidence under its producer's contract, not a universal proof object.
- `valid=True` does not imply exactness, and exactness does not imply validity.
- A zero numerical residual does not promote a computation to exact.
- `.require()` trusts `valid`. It does not independently audit the other fields.
- `ConditionalResult` enforces the label `CONDITIONAL`, not the truth of its assumptions and not the validity of its certificate.
- Unchecked assumptions remain visible even when a conditional certificate is valid.
- Diagnostics explain a run but cannot overturn its Boolean outcome.
- Theorem identifiers and provenance identifiers are not automatically reconciled.
- The frozen data classes contain mutable dictionaries. Freezing is shallow.
- Presentation JSON may stringify diagnostic types. Use the portable codec when a supported typed certificate roundtrip is required.
- A portable SHA-256 digest detects payload inconsistency. It is not a digital signature or a statement of authorship.

5.8 What the shipped tests establish

The certificate contract is exercised at several levels. The focused registry tests assert that a valid certificate returns itself from `.require()`, that JSON contains the string `"exact"`, and that an invalid certificate propagates its message through `ValidationError`. They also reject construction of a `ConditionalResult` from an exact certificate and resolve the `PacketSystem` provenance identifier `PSC-I-T20`.

Export tests show that presentation serialization of a `ComputationResult` retains its nested certificate and theorem identifier. Persistence tests carry certificates inside versioned portable objects, serialize them, reconstruct them, and demand byte-stable re-encoding. The expression-calculus suite then checks the evidence-composition rule at a semantic level: numerical input evidence remains numerical, an unchecked premise imposes conditional status, and invalid child evidence remains invalid. The adversarial verifier repeats those non-promotion checks outside the ordinary unit-test path.

These tests establish the implemented finite contracts. They do not turn an arbitrary hand-written certificate into independently verified evidence. That distinction explains why examples should normally display a certificate re-

turned by a domain operation, then use manually constructed certificates only to demonstrate a controlled failure or composition rule.

> **Chapter 5 summary.** `Exactness` says what kind of finite evidence was produced. `valid` says whether the producer's declared check passed. Residuals, tolerances, and assumptions explain that decision. `ComputationResult.require()` releases a value only after the certificate passes. `ConditionalResult` preserves an explicitly conditional conclusion. Certificate composition may retain or weaken evidence but never strengthen it, and provenance records document source claims without replacing execution certificates.

The rejected result in this chapter still contained inspectable data. Chapter 6 now distinguishes that situation from an exception, where no admissible result record has crossed the public boundary.

6. Errors, assumptions, and resource guards

Komorebi Math distinguishes several kinds of failure because they call for different responses. A malformed object should be corrected. A dimension mismatch should be traced to the map or coordinate space that introduced it. A failed mathematical assumption may require a different theorem or algorithm. A missing backend is an environment problem. A resource-limit failure asks the caller to reduce the problem or explicitly authorize a larger finite budget. An invalid certificate, meanwhile, is evidence returned for inspection rather than necessarily an exception raised at the point of computation.

The central operational rule is:

> Catch only the failures that the current layer can resolve. Preserve the original type and message when passing an unresolved failure upward.

The public contract distinguishes exceptions from invalid certificates, separates checked assumptions from unchecked ones, and states the resource limits used by finite computations. The examples were executed against the delivered `1.0.0b4` source.

6.1 Public exception hierarchy

The canonical definitions live in `komorebi_math.exceptions`. Seven classes are also members of the frozen stable API:

```
from komorebi_math.stable import (
    AssumptionError,
    BackendUnavailableError,
    DimensionError,
    ExactnessError,
    KomorebiMathError,
    ResourceLimitError,
    ValidationError,
)
```

Two additional package exceptions are available from the canonical module but are not frozen stable symbols:

```
from komorebi_math.exceptions import (
    FeatureNotImplementedError,
    RelationError,
)
```

The top-level `komorebi_math` research namespace does not export the exception names. Import from `komorebi_math.stable` when the frozen contract is required, or from `komorebi_math.exceptions` when the complete canonical hierarchy is required.

Let E_K denote `KomorebiMathError`. Let $E_V, E_D, E_R, E_A, E_B, E_X, E_L$ denote validation, dimension, relation, assumption, backend, exactness, and resource-limit errors, and let E_P denote the planned-feature error. With $\preceq$ meaning "is a subclass of," the hierarchy is

$$E_D, E_R, E_L \preceq E_V \preceq E_K, \qquad E_V \preceq \texttt{ValueError},$$

$$E_A, E_B, E_X \preceq E_K, \qquad E_P \preceq E_K, \qquad E_P \preceq \texttt{NotImplementedError}.$$

The classes have these responsibilities.

Class	Meaning	Typical caller response
`KomorebiMathError`	Base of package-defined public errors	Log context and re-raise unless the boundary owns recovery
`ValidationError`	A declared validation rule failed	Correct the value, record, or parameter
`DimensionError`	Matrix, vector, packet, or binding dimensions disagree	Inspect source and target spaces or array shapes
`RelationError`	A typed grammar relation is malformed or violated	Correct endpoints, relation terms, or realization
`AssumptionError`	A required finite mathematical assumption is false	Choose a compatible theorem, transform, or algorithm
`BackendUnavailableError`	A requested optional backend is unknown or unavailable	Install the dependency or explicitly select another backend
`ExactnessError`	An exact operation was requested across an inexact boundary	Select an exact domain or accept a documented numerical path
`ResourceLimitError`	A valid explicit resource contract would be exceeded	Reduce the request or supply a reviewed larger budget
`FeatureNotImplementedError`	A declared feature is still a placeholder	Use implemented functionality. Do not emulate a result silently

The exception classes do not declare custom constructors. They inherit ordinary Python exception arguments, and the stable signature manifest records no package-specific constructor signature. Code should rely on their types and documented meanings, not parse message text as a machine protocol.

6.2 Catch policy

The inheritance structure supports progressively broader handling. Catching `DimensionError` isolates a shape problem. Catching `ValidationError` also catches `DimensionError`, `RelationError`, and `ResourceLimitError`. Because `ValidationError` is also a `ValueError`, a conventional Python value-error boundary catches those four package types. Catching `KomorebiMathError` catches every exception defined in the package hierarchy, including `FeatureNotImplementedError`.

A narrow application boundary can therefore use:

```
from komorebi_math.stable import DimensionError, ResourceLimitError

try:
    result = run_finite_problem()
except DimensionError as error:
    report_shape_problem(error)
except ResourceLimitError as error:
    request_a_smaller_problem(error)
```

A command-line front end may instead catch `KomorebiMathError` once, add the operation name and user-facing guidance, and exit. Library code should generally avoid a broad catch followed by an unrelated default result. In particular, a backend failure must not be converted silently into execution on a different backend: backend selection can change scalar domains, exactness, performance, and available operations.

`KomorebiMathError` is not a total boundary around every possible Python failure. Some APIs intentionally expose ordinary built-ins. A non-expression passed to expression preflight raises `TypeError`. A missing packet coordinate name raises `KeyError`. `OperatorGrammar.paths(max_length=-1)` raises `ValueError`, and a `ConditionalResult` paired with

a nonconditional certificate raises `ValueError`. Catch a built-in only where the surrounding Python operation gives it a well-defined recovery meaning.

6.3 Validation, dimensions, and relations

`ValidationError` covers a failed declared rule that is not better described by a more specific subclass. Examples include an empty packet family, duplicate packet names, a nonpositive budget field, an invalid exact scalar, or a noncanonical portable record. It answers the question "is this admissible input or a valid finite record?"

`DimensionError` specializes that answer when spaces or shapes disagree. A `PacketSystem` requires at least one square projector, all projectors must have one common size, and analyzed vectors must have the ambient dimension. Expression bindings, exact maps, coordinate bases, and matrix chains likewise use the type when their finite dimensions are incompatible.

`RelationError` belongs to the operator-grammar layer developed in Chapter 9. Relation terms must be parallel typed words: every word in one relation has the same source and target. Duplicate relation names, inconsistent endpoints, and a realized operator that violates a registered relation also use this type. By contrast, asking a grammar to form a path from two noncomposable arrows is an input-validation failure and raises `ValidationError` before any relation exists.

A useful abstract routing model is

$$f(x;b) \rightsquigarrow \begin{cases} \uparrow E_D, & \neg D(x), \\ \uparrow E_R, & \neg R(x), \\ \uparrow E_V, & \neg V(x), \\ \uparrow E_A, & \neg A_{\text{checked}}(x), \\ \uparrow E_L, & Q(x) > b, \\ (y, C), & \text{otherwise}, \end{cases}$$

where D, R, V are dimension, relation, and general validation predicates. A_{checked} is a finitely testable assumption. $Q(x)$ is a declared resource measure. b is its budget, and C is a certificate. This is a documentation model, not a promise of one universal check order. Each public function validates the properties relevant to its own contract.

6.4 Exceptions versus invalid certificates

An exception says that the requested operation cannot proceed under its input contract. An invalid certificate says that a finite computation or check was performed and produced inspectable negative evidence. These outcomes are not interchangeable.

For a certificate

$$C = (v, e, r, \tau, H_{\checkmark}, H_{?}, D, T, M),$$

the fields are validity v, exactness class e, residuals r, tolerance τ, checked assumptions $H_{\checkmark}$, unchecked assumptions $H_{?}$, diagnostics D, theorem identifier T, and message M. The strict conversion is

$$\text{require}(C) = \begin{cases} C, & C.\texttt{valid}, \\ \uparrow E_V(M), & \text{otherwise}. \end{cases}$$

`Certificate.require()` returns the same certificate when it is valid and raises `ValidationError` with the certificate message otherwise. `ComputationResult.require()` first enforces its certificate and then returns the contained value.

This distinction supports two legitimate workflows. A strict pipeline calls `.require()` immediately because later stages are meaningful only after acceptance. A diagnostic tool first records residuals, tolerance, assumptions, and diagnostics, then calls `.require()` only if it intends to cross into a strict stage.

Construction validation follows the same pattern. `PacketSystem(..., validate=True)`, the default under the default settings, builds its certificate and requires it. `validate=False` allows an algebraically invalid but structurally well-formed packet record to be inspected. It does not bypass empty-input, nonsquare-matrix, common-dimension, or name-validation checks.

Some iterative algorithms also return an invalid certificate for ordinary nonconvergence. For example, conjugate gradient can return `converged=False` with its final residual and an invalid numerical certificate when the iteration limit is reached. A detected nonpositive generated direction is different: it falsifies a required algorithmic assumption and raises `AssumptionError` immediately.

6.5 Checked assumptions and conditional evidence

An assumption is not automatically an error. The important division is whether the current finite data can decide it.

If a supplied declaration is finitely false, the operation raises `AssumptionError`. The separated-jump recovery routine, for example, can check that the declared minimum separation is at least one sample spacing, that the minimum jump is sufficiently larger than the smooth and noise contrast bound, and that the threshold lies in the required open gap. Failure of one of those finite inequalities prevents the theorem-backed operation from proceeding.

Other hypotheses concern an unknown generating object and cannot be proved from the finite samples alone. The same recovery routine cannot establish globally that the unknown smooth part obeys the declared Lipschitz bound, that all unknown noise obeys the uniform bound, that every unknown jump has the declared minimum magnitude, or that no sample cell contains more than one jump. It therefore returns a valid certificate with exactness `conditional` and records those hypotheses in `assumptions_unchecked`.

Consequently,

$$C.\texttt{valid} = \texttt{True} \quad \not\Rightarrow \quad H_? \text{ is proved.}$$

Validity means the implemented finite checks passed under the certificate's stated semantics. A conditional conclusion remains conditional. Published reports should preserve both the exactness label and the unchecked-assumption list instead of reducing the evidence to one Boolean.

6.6 Executed example: evidence and assumption paths

This compact program shows an inspectable invalid certificate, its conversion to an exception, a valid conditional result, and a finitely false assumption:

```
import numpy as np

from komorebi_math import recover_separated_jumps
from komorebi_math.stable import AssumptionError, PacketSystem, ValidationError

bad = PacketSystem([np.zeros((2, 2))], validate=False)
failed = bad.certificate()
print(failed.valid, failed.message)

try:
    failed.require()
except ValidationError as error:
    print(type(error).__name__ + ":", error)

recovered = recover_separated_jumps(
    [0.0, 0.0, 3.0, 3.0],
    spacing=1.0,
    lipschitz_bound=0.0,
    noise_bound=0.0,
    minimum_jump=2.0,
    minimum_separation=1.0,
)
```

```
print(recovered.cells, recovered.locations.tolist())
print(recovered.certificate.exactness.value)
print(recovered.certificate.assumptions_unchecked[0])
```

The finitely false declaration is a separate negative path:

```
try:
    recover_separated_jumps(
        [0.0, 0.0, 3.0, 3.0],
        spacing=1.0,
        lipschitz_bound=0.0,
        noise_bound=0.0,
        minimum_jump=2.0,
        minimum_separation=0.5,
    )
except AssumptionError as error:
    print(type(error).__name__ + ":", error)
```

Expected output:

```
False projectors do not form a complete packet system
ValidationError: projectors do not form a complete packet system
(1,) [1.5]
conditional
unknown smooth part obeys the declared Lipschitz bound
AssumptionError: minimum_separation must be at least one sample spacing
```

The first object is structurally admissible but fails the packet axioms. The second result passes every implemented finite recovery check, yet its conclusion retains explicit hypotheses about the unknown signal. The final call fails before producing a result because its supplied finite separation declaration is incompatible with the sampling scale.

6.7 Backend and exactness boundaries

`get_backend(name)` raises `BackendUnavailableError` for an unknown or unavailable backend. `available_backends()` reports import presence. It does not select a backend, prove that hardware is usable, or certify numerical behavior. The caller should choose a backend explicitly when scalar domain or exactness matters.

`ExactnessError` is part of the stable hierarchy and reserves the semantic boundary where an exact operation cannot be honored by an inexact backend. In this release, however, exactness is communicated mainly through `Certificate.exactness`, and the audited source contains no active `raise ExactnessError` site. The guide should document the class without inventing a current executable trigger. Invalid "exact" inputs frequently use `ValidationError`. Numerical computations retain `numerical` exactness even when their observed residual happens to print as zero.

`FeatureNotImplementedError` is similarly a real package-defined class but not a frozen stable symbol. The internal planned-feature guard can raise it for a declared placeholder. Every current registry entry is implemented, partial, or experimental, so no ordinary current public path supplies a useful executed example.

6.8 Explicit resource contracts

A resource budget makes a finite computational promise visible before a large allocation or enumeration begins. Exceeding a valid declared budget raises `ResourceLimitError`. Supplying an invalid budget, such as zero or a Boolean where a positive integer is required, raises `ValidationError`, because the contract itself is malformed.

The primary coordinate contract is:

```
CoordinateBudget(
    maximum_matrix_dimension=512,
    maximum_polynomial_degree=512,
    maximum_horizon=4096,
    maximum_exact_entries=1_000_000,
)
```

Its preflight methods are:

```
require_matrix(rows, columns, *, operation) -> None
require_degree(degree, *, operation) -> None
require_horizon(horizon, *, operation) -> None
```

For a matrix request with r rows and c columns, the default contract requires

$$0 \le r, c \le 512, \qquad rc \le 10^6.$$

The dimension bound and exact-entry bound are independent: a caller may reduce one dimension yet still exceed the total-entry contract. The `operation` label is included in the error message so that a report identifies the rejected allocation rather than merely its size.

Two other public budget families cover different domains. `GeneratingBudget` guards degree, coefficient bit length, finite-state matrices, reachable states, local combinations, modulus, serialized bytes, and recursion depth. `ExpressionBudget` preflights an expression DAG and guards node count, depth, traversal steps, polynomial degree, exact entries, coefficient bits, structural bytes, and symbol length. Expression cycles are malformed graphs and therefore raise `ValidationError`. Excess finite size raises `ResourceLimitError`.

The defaults are domain contracts, not estimates of available RAM. In particular, the generating budget uses 64 MiB, or $67{,}108{,}864$ bytes, while the expression budget uses decimal $64{,}000{,}000$ bytes. Do not merge the two values in documentation.

6.9 Executed example: `CoordinateBudget`

```
from komorebi_math import CoordinateBudget
from komorebi_math.stable import ResourceLimitError, ValidationError

budget = CoordinateBudget(
    maximum_matrix_dimension=4,
    maximum_polynomial_degree=3,
    maximum_horizon=8,
    maximum_exact_entries=12,
)

budget.require_matrix(3, 4, operation="guide transform")
print("accepted: 3 by 4")

for action in (
    lambda: budget.require_matrix(4, 4, operation="guide transform"),
    lambda: budget.require_degree(4, operation="guide polynomial"),
    lambda: CoordinateBudget(maximum_horizon=0),
):
    try:
        action()
    except (ResourceLimitError, ValidationError) as error:
        print(type(error).__name__)
        print(str(error))
```

Expected output:

```
accepted: 3 by 4
ResourceLimitError
guide transform requires 16 exact entries, exceeding the coordinate entry limit 12
ResourceLimitError
guide polynomial degree 4 exceeds the coordinate degree limit 3
ValidationError
maximum_horizon must be a positive integer
```

The first request lies exactly on the entry boundary and succeeds. The next two requests are mathematically well-formed but exceed a reviewed resource contract. The final constructor does not create a valid contract at all.

A caller may provide a larger budget when the resulting arithmetic and memory cost are acceptable. Such a change is authorization, not error suppression. It belongs near the operation that needs it and should be visible in an execution record or configuration review.

6.10 Negative contracts

These limits are part of the documentation contract:

- **No universal normalization of Python failures.** Package exceptions cover package-defined semantic failures, but built-in `TypeError`, `ValueError`, and `KeyError` remain possible where ordinary Python semantics are appropriate.
- **No structural bypass through `validate=False`.** The flag can defer selected mathematical axiom enforcement. It cannot make empty, ill-shaped, or inconsistently dimensioned input admissible.
- **No theorem from a Boolean alone.** A valid certificate must be read together with its exactness, tolerance, residuals, and checked and unchecked assumptions.
- **No convergence implication from receiving a result object.** Algorithms may return values and diagnostic histories with invalid certificates.
- **No silent backend substitution.** Availability, selection, exactness, and hardware qualification are separate claims.
- **No guarantee that every historical `max_*` parameter raises `ResourceLimitError`.** The coordinate, generating, and expression budgets use the typed resource contract, but some older domain-specific guards still raise `ValidationError`. Consult the individual function contract.
- **No promise that a resource budget predicts wall-clock time.** It bounds declared structural quantities. Scalar growth, backend behavior, and machine characteristics can still affect cost.
- **No programmatic dependence on message text.** Catch by type and inspect structured result or certificate fields. Messages are for diagnosis and may become more precise without changing the exception contract.

Applications should therefore use this pattern:

1. Validate structural input and dimensions.
2. State the exact, numerical, or conditional domain explicitly.
3. Provide an explicit budget where expensive finite work is possible.
4. Catch only errors that the current layer can repair.
5. Inspect the complete certificate.
6. Call `.require()` before crossing into a stage that requires accepted evidence.
7. Retain the original exception type, certificate, and environment context in diagnostic records.

> **Chapter 6 summary.** The object is an input contract, a finite resource budget, or a returned certificate. The operation either raises a typed failure or returns inspectable evidence. Checked assumptions may fail immediately, while unchecked hypotheses remain explicit in conditional certificates. The safe caller catches narrowly, never treats `validate=False` as a shape bypass, and calls `.require()` only when invalid evidence must become a hard boundary.

Failure behavior is part of an interface's public meaning. Chapter 7 therefore moves from one execution to the longer-lived question: which names, signatures, semantics, and portable records may downstream code rely on across releases?

7. Public API tiers

Komorebi Math makes a deliberate distinction between *availability* and *compatibility commitment*. A name can be importable and useful without being promised for the whole 1.x line. Conversely, a stable import path says that the project has accepted additional obligations: the exported name, broad object kind, documented signature, selected finite behavior, and portable identity must continue to agree with committed contracts.

The recorded `1.0.0b4` reference baseline is a beta package. Its release contract describes the line from `1.0.0b1` through `1.0.0rc1`, with `1.0.0b3` as the direct predecessor. The release observations and literal outputs below belong to that baseline. The word *stable* names its frozen compatibility surface; a tier label alone does not establish the publication or qualification status of any later package.

The public tiers are:

Tier	Public namespace	Current manifest size	Compatibility policy
`[STABLE]`	`komorebi_math.stable` plus two aliases	131	frozen structure, semantics, and persistence
`[BETA]`	`komorebi_math.beta`	83	additive surface with strict signatures
`[RESEARCH]`	top-level and selected domain namespaces	1,312	additive. Signatures non-blocking by default

The release machinery also recognizes an `internal` tier, but internal modules do not form a public compatibility surface. The three documented tiers can be summarized by the implication boundary

$$\text{importable} \not\Rightarrow \text{beta contracted} \not\Rightarrow \text{stable contracted}.$$

This separation allows new finite mathematics to be implemented and tested without silently freezing every experimental spelling. It also gives users a clear choice: exploratory code may use research namespaces, reusable beta pipelines may accept the stricter beta contract, and long-lived integrations should prefer the stable aliases.

A practical dependency rule is to import from the narrowest tier that contains the required operation. If a program only needs stable coordinate transforms, polyphase refinement, certificates, and portable records, importing those names from `komorebi_math.stable` makes its expectations explicit. If it needs the resumable packet-jet stream machinery, `komorebi_math.beta` is the appropriate facade. If it needs `komorebi_math.integration`, `komorebi_math.expression`, or another recently added domain, it is intentionally accepting a research-tier dependency. Mixing tiers is legal, but the weakest selected tier determines the compatibility expectation for that part of the program.

Tier membership is about the exported path, not a second copy of the implementation. A class may be defined in a domain module and re-exported by a curated facade. The guide records both facts: the domain module is the canonical implementation location, while the stable or beta namespace is the public compatibility commitment.

7.1 Research namespace

The research API is the broad executable workspace. Its current manifest is built from explicit `__all__` lists in six namespaces:

$$\mathcal{N}_R = \{\texttt{komorebi_math}, \texttt{komorebi_math.nonlinear}, \texttt{komorebi_math.export}, \texttt{komorebi_math.signals}, \texttt{komorebi_math.generating}, \texttt{komorebi_math.coordinates}\}.$$

The 1,312 manifest entries are namespace/name pairs, so the same implementation may appear more than once when it is intentionally re-exported. Their current distribution is:

Namespace	Manifest entries
`komorebi_math`	516
`komorebi_math.coordinates`	237
`komorebi_math.generating`	181
`komorebi_math.signals`	171
`komorebi_math.nonlinear`	149
`komorebi_math.export`	58

The research stability label is `pre-beta-additive`. In ordinary compatibility mode, a later manifest may add names. It may not remove a committed export or change its broad kind from, for example, a class to a function. Reflected signature changes are reported, but they become compatibility failures only when strict signature checking is requested.

Let M_0 be the reference manifest and M_1 the observed manifest. If s denotes strict-signature mode, the implemented structural decision is

$$\text{Compatible}(M_0, M_1; s) \iff \Delta_{\text{removed}} = \emptyset \wedge \Delta_{\text{kind}} = \emptyset \wedge (\neg s \vee \Delta_{\text{signature}} = \emptyset).$$

Additions Δ_{added} are always reported but do not make this comparison fail. The default research command is therefore useful when asking whether earlier imports still exist:

```
komorebi api check
```

The current publication gate uses the stronger release-time signature check:

```
komorebi api check --strict-signatures
```

This strict command does not turn the research tier into the stable tier. It pins the signatures of the release being qualified. It does not promise that a future research release can never make a reviewed signature change.

The research surface has grown while the curated tiers have remained fixed:

Version	Research entries	Beta entries	Stable entries
`1.0.0b1`	1,179	83	131
`1.0.0b2`	1,191	83	131
`1.0.0b3`	1,229	83	131
`1.0.0b4`	1,312	83	131

This is the intended pattern. The finite measure and integration API and the typed finite expression API are research features. They are tested and documented, but they were not silently inserted into either curated contract.

Research boundary. The manifest checks public structure. It does not prove mathematical equivalence, numerical stability, performance, exception compatibility, thread safety, or the behavior of undocumented internals. Those claims need their own tests, certificates, and domain documentation.

7.2 Beta namespace

`komorebi_math.beta` is a smaller compatibility facade for finite packet-jet execution and persistence. Its 83 exports cover certificates and errors, packet systems, derivative providers, packet jets, sparse tensors, execution plans, snapshots, resumable streams, profiling records, portable codecs, migrations, and compatibility tools.

The beta stability label is `1.0-beta-additive-strict-signatures`. The word *additive* means that new names may be introduced. Existing names may not be removed, change broad kind, or change reflected signature without an explicit compatibility decision. The tier-specific check always enables strict signatures:

```
komorebi api check --beta
```

Structural compatibility is supplemented by a closed behavioral golden fixture. The current fixture executes 15 cases involving packet jets, snapshots, streaming records, migrations, canonical serialization, and related finite behavior. It can be run separately:

```
komorebi golden
```

The golden cases protect the behavior they state. They are not an exhaustive proof of every input or optional backend. In particular, a live arbitrary Python derivative provider cannot acquire a cross-process semantic identity merely because a stream record contains metadata. Frozen snapshots can make a stronger claim because their retained coefficient content is itself fingerprinted.

A user should select the beta tier when the packet-jet and streaming facade is the desired contract but the broader stable workflow is either unnecessary or too restrictive. Importing a beta object from its implementation module remains possible, but importing it from `komorebi_math.beta` states the intended compatibility dependency explicitly.

7.3 Frozen stable namespace and aliases

The stable candidate contains 131 exported names selected to support one complete finite workflow:

$$\text{construct} \to \text{decompose} \to \text{operate} \to \text{refine} \to \text{certify} \to \text{persist} \to \text{render}.$$

It includes core operator and packet objects, exact and numerical coordinate transforms, analysis/synthesis systems, polyphase and residue refinement, certificates and errors, portable persistence, document rendering, settings, and the stable-contract checks themselves. Domain-specific research objects remain available elsewhere without inheriting this promise.

Three import paths expose the same exported objects:

```
import komorebi_math.stable as stable
import komorebi_math.v1 as v1
import komorebi_math.api.v1 as api_v1

print(len(stable.__all__))
print(stable.__all__ == v1.__all__ == api_v1.__all__)
print(all(
    getattr(stable, name) is getattr(v1, name) is getattr(api_v1, name)
    for name in stable.__all__
))
print(stable is v1, stable is api_v1)
```

Expected output:

```
131
True
True
False False
```

The last line matters. These are distinct module objects, not one module assigned three names. Their `__all__` lists agree, and every public value they re-export is object-identical. There is no second implementation hiding behind either versioned path.

Readable polyphase names are also retained as direct object aliases:

```
assert stable.polyphase_refine is stable.refine_polyphase
assert stable.polyphase_coarsen is stable.coarsen_polyphase
assert stable.lattice_polyphase_refine is stable.refine_lattice_polyphase
assert stable.lattice_polyphase_coarsen is stable.coarsen_lattice_polyphase
```

Similarly, a stable class is the same class exported by its defining domain module. The facade selects and names implementations. It does not fork them.

The stable symbol array is exactly unchanged across the committed `0.16`, `1.0.0b1`, `1.0.0b2`, `1.0.0b3`, and `1.0.0b4` manifests. That historical identity is stronger evidence than the count alone: 131 differently defined objects would not satisfy the upgrade contract.

7.4 Manifest identity, reflected signatures, and semantic fixtures

Every API manifest is a deterministic collection of `PublicApiSymbol` records. One symbol has the form

$$S = (N, n, k, m, q, \sigma),$$

where N is the export namespace, n the public name, k the broad kind, m the implementation module, q the qualified implementation name, and σ the reflected callable signature or `null`.

For example, the stable `PolyphaseRefinement` entry records:

```
{
  "implementation_module": "komorebi_math.refinement.polyphase",
  "kind": "class",
  "name": "PolyphaseRefinement",
  "namespace": "komorebi_math.stable",
  "qualname": "PolyphaseRefinement",
  "signature": "(coarse_order: 'int', fine_order: 'int') -> None"
}
```

Manifest construction rejects empty namespace lists, duplicate namespaces, duplicate exports, absent exported attributes, and nondeterministic symbol ordering. It also normalizes two interpreter-dependent cases. Concrete POSIX and Windows path values are recorded as the public `pathlib.Path` abstraction, and generic-alias constructors receive a portable variadic signature across the supported Python 3.11 through 3.13 matrix.

The manifest's `digest` property hashes canonical compact JSON. It is not the same quantity as the SHA-256 hash of the indented JSON file stored on disk. The first binds the validated mapping. The release contract separately binds the exact artifact bytes. Current canonical manifest digests are:

```
research  473c73e1a0563fe0b2569c8be384f7c9f947570bea2f300ef611db351136847a
beta      311f2bf7cbcf0a45bcbe2af433d73a8f597c0fbf7133750882314d6e0edb16b2
stable    23cd9e47a1663f2d4b3c0fef50f9f7d8c88d4af2f8bbc57e7ba76461e6e69276
```

Structural identity alone is not enough for the stable tier. The aggregate contract is

$$C_{\text{stable}} = C_{\text{API}} \wedge C_{\text{semantics}} \wedge C_{\text{persistence}}.$$

`check_stable_api()` performs the strict structural comparison. `run_stable_semantics_fixture()` executes ten committed mathematical cases. `check_portable_codec_contract()` verifies the 51 package-owned codec tags, their represented implementation types, nondecreasing versions, and every required adjacent migration. `check_stable_contract()` combines the three reports into one `StableContractReport`.

```python
from komorebi_math.stable import check_stable_contract

report = check_stable_contract()

print(report.compatible)
print(sum(case.passed for case in report.semantics.results))
print(len(report.semantics.results))
print(report.persistence.current_version)
print(report.certificate.message)
```

Expected output:

```
True
10
10
1.0.0b4
the complete 1.0-candidate compatibility contract passed
```

The semantic fixture covers general analysis/synthesis reconstruction, one-dimensional and lattice polyphase refinement, exact arithmetic polyphase coordinates, an operator relation, exact basis coordinates, a factorial-power series product, document rendering, settings restoration, and a portable refinement-tower roundtrip. Its ten cases are representative and closed, not exhaustive.

Stable semantic case	Principal observation
General analysis/synthesis	reconstruction and transfer-block certificates
Signal polyphase	direct refinement match and coarsening roundtrip
Arithmetic polyphase	exact rational reconstruction
Lattice polyphase	rectangular address set and roundtrip
Operator grammar	exact relation residual
Coordinate basis	exact connection matrix and inverse roundtrip
Normalized series	factorial-power product coefficients
Document rendering	deterministic Markdown and LaTeX digests
Settings scope	active values and restoration after the context
Portable refinement	codec tag, version, type, and equality

The fixture is finite by design and readable. Its certificate lists "fixture coverage is representative rather than exhaustive" and optional hardware equivalence among the unchecked assumptions. A passing fixture cannot be used to infer behavior for an arbitrary dimension, backend, tolerance, or unrepresented mathematical family.

Version identity is also a separate concern. Manifest comparison requires the same namespace set, but its compatibility Boolean is decided from symbol differences rather than from the package-version strings alone. This permits a reference manifest to be compared with a later release. The release contract then checks that runtime `__version__`, the current manifests, citation metadata, and packaged artifacts all identify `1.0.0b4`. In other words, an API checker answers "Is this surface compatible?" A release gate additionally answers "Is this the artifact and version we intended to ship?"

The installed stable verification suite adds two important release assertions: the newly constructed manifest must equal the committed manifest in every recorded field, and all 131 exports must retain tri-alias object identity. This is why a release decision should use the suite rather than treating one structural Boolean as the whole contract:

```
komorebi verify stable
```

The current terminal summary is:

```
[PASS] strict stable API manifest
[PASS] deterministic stable API snapshot
[PASS] closed stable semantic fixture
[PASS] portable codec migration contract
[PASS] aggregate 1.0-candidate contract
[PASS] versioned stable namespace identity
verification passed 6/6 checks
```

The distinction between loose and strict signatures is executable without changing the installed package. This code constructs an in-memory candidate whose `check_stable_contract` signature has been altered:

```
from dataclasses import replace
from komorebi_math.compatibility import (
    PublicApiManifest,
    compare_public_api,
    load_stable_api_manifest,
)

reference = load_stable_api_manifest()
symbols = list(reference.symbols)
index = next(
    i for i, symbol in enumerate(symbols)
    if symbol.name == "check_stable_contract"
)
symbols[index] = replace(
    symbols[index],
    signature="() -> 'StableContractReport'",
)

changed = PublicApiManifest(
    package_version="demonstration",
    namespaces=reference.namespaces,
    symbols=tuple(sorted(symbols)),
    stability_level=reference.stability_level,
)
```

Now compare the same in-memory candidate under both policies:

```

loose = compare_public_api(reference, changed)
strict = compare_public_api(
    reference,
    changed,
    strict_signatures=True,
)
```

```
print("loose:", loose.compatible, len(loose.signature_changed))
print("strict:", strict.compatible, len(strict.signature_changed))
```

Expected output:

```
loose: True 1
strict: False 1
```

This example changes only a manifest value in memory. It does not monkey-patch or overwrite the package. It shows exactly why the beta and stable tier helpers always request strict comparison.

7.5 Deprecation and migration discipline

Compatibility sometimes requires a name to remain available while users move to a replacement. The `deprecated` decorator retains the call, emits `KomorebiDeprecationWarning`, and attaches a machine-readable record

$$D = (\text{since}, \text{replacement}, \text{remove_in}, \text{reason}).$$

```
import warnings
from komorebi_math import KomorebiDeprecationWarning, deprecated

@deprecated(
    since="1.0.0b4",
    replacement="new_square",
    remove_in="2.0",
    reason="demonstration",
)
def old_square(value: int) -> int:
    return value * value

with warnings.catch_warnings(record=True) as caught:
    warnings.simplefilter("always", KomorebiDeprecationWarning)
    print("value:", old_square(5))

record = old_square.__komorebi_deprecation__
print("warning emitted:", len(caught) == 1)
print("since:", record.since)
print("replacement:", record.replacement)
print("remove in:", record.remove_in)
print("reason:", record.reason)
```

Expected output:

```
value: 25
warning emitted: True
since: 1.0.0b4
replacement: new_square
remove in: 2.0
reason: demonstration
```

The example defines its own demonstration function. It does not claim that `old_square` is a package export. At `1.0.0b4`, the exact stable documentation contract covers all 131 stable exports and reports zero deprecated stable names.

Unambiguous spelling or discovery aliases may be retained without a warning. The polyphase aliases above are examples. A compatibility alias must not be used to conceal changed mathematics: the analysis/synthesis methods `projector()` and `projectors()` remain for compatibility, but in a redundant system their returned reconstruction components need not be idempotent. New code should use `component()` and `components()` unless projector hypotheses have been established independently.

Portable data has a separate migration discipline. A Python deprecation does not authorize reinterpretation of serialized records. If a codec advances from version v to $v + k$, every adjacent step must exist:

$$J_v \xrightarrow{\mu_{v\to v+1}} J_{v+1} \xrightarrow{\mu_{v+1\to v+2}} \cdots \xrightarrow{\mu_{v+k-1\to v+k}} J_{v+k}.$$

Unknown tags, unsupported future versions, type-identity changes, decreasing versions, and missing adjacent migrations fail closed. Users should retain original payloads while upgrading and must not hand-edit `__komorebi_type__` or `__version__` fields.

The current upgrade contract checks the stable API against `0.15.0a2`, `0.16.0a2`, `1.0.0b1`, `1.0.0b2`, and `1.0.0b3`. It also validates and loads seven historical portable fixtures. Run it before accepting an upgrade:

```
komorebi release upgrade
```

For a complete current release decision, the useful sequence is:

```
komorebi api check --stable
komorebi api check --beta
komorebi api check --strict-signatures
komorebi verify stable
komorebi release documentation
komorebi release upgrade
komorebi release contract
```

The API commands answer structural questions. `verify stable` adds semantic, persistence, snapshot, and alias checks. The documentation and upgrade commands close their respective inventories. The release contract binds those layers to the current package version and committed artifact hashes.

Maintainers can exercise the focused source contracts directly:

```
python -m pytest -q `
  tests/test_block15_stable_api.py `
  tests/test_block16_contracts.py `
  tests/test_block16_release_contract.py `
  tests/test_block17_upgrade_contract.py
```

These tests cover deterministic manifest construction, platform-neutral path identity, strict signature rejection, all three stable aliases, the aggregate semantic and persistence contract, release artifact counts, frozen CLI route names, predecessor manifests, and historical portable fixtures. The recorded publication tests add strict research-signature portability across the declared Python versions. A focused test pass is useful during development, but the publication decision still belongs to the complete gate because documentation, platform evidence, distribution artifacts, and the rest of the source suite lie outside this chapter's focused selection.

Chapter 7 summary. Use research namespaces to explore the broad executable library, `komorebi_math.beta` when depending on the curated packet-jet and streaming facade, and one of the three stable aliases for long-lived 1.x code. A manifest proves selected public structure, not mathematics. The stable promise is therefore layered: strict API identity, ten committed semantic cases, 51 portable-codec contracts, exact tri-alias identity, one-to-one documentation, and explicit adjacent migrations.

An API tier states how a public interface may evolve. It does not choose the scalar arithmetic used by a particular run. Chapter 8 supplies that second axis: backend selection, coercion, exact domains, and optional runtimes.

8. Backends, scalar domains, and coercion

Komorebi Math uses the word *backend* in more than one setting, but those settings are not interchangeable. The finite-dimensional core has a small linear-algebra backend interface, currently realized by NumPy and, when the optional dependency is installed, SymPy. Other subsystems use optional feature adapters: SciPy supplies selected scientific routines, JAX and PyTorch supply directional automatic differentiation, and CuPy supplies selected device executors. Finally, several exact coordinate and arithmetic modules use Python integers and `fractions.Fraction` directly and do not need any matrix backend at all.

That separation is the central rule of this chapter:

$$\text{core matrix backend} \neq \text{optional feature runtime} \neq \text{exact scalar domain}.$$

Selecting one does not silently select the others. In particular, `get_backend("numpy")` says nothing about whether SciPy is installed, `get_backend("sympy")` does not enable JAX, and the exact rational coordinate layer works without SymPy.

8.1 The core linear-algebra backend contract

The abstract type is `komorebi_math.backends.LinearAlgebraBackend`. A backend declares a name and whether its arithmetic is treated as exact:

```
class LinearAlgebraBackend(ABC):
    name: str
    exact: bool
```

Its operational contract is:

Operation	Signature	Meaning
conversion	`as_matrix(value) -> Any`	convert a matrix-like value
conversion	`as_vector(value) -> Any`	convert and normalize a vector-like value
inspection	`shape(value) -> tuple[int, ...]`	report dimensions
constructors	`zeros(rows, cols)`, `eye(size)`	additive and multiplicative identities
arithmetic	`matmul`, `add`, `subtract`, `scale`	finite linear algebra
dual operations	`transpose`, `adjoint`	transpose and conjugate transpose
inversion	`inverse(value)`	inverse of a nonsingular square matrix
diagnostics	`rank(value, *, tolerance=None)`	exact or thresholded rank
diagnostics	`norm(value) -> float`	a floating diagnostic norm
diagnostics	`is_zero(value, *, tolerance=None)`	exact or tolerance-aware zero test
basis construction	`column_stack(values)`	assemble column vectors
kernel	`nullspace(value, *, tolerance=None)`	a basis for the right nullspace
tensor product	`kron(left, right)`	Kronecker product
copying	`copy(value)`	backend-native copy

The public selection functions are:

```
get_backend(
    backend: str | LinearAlgebraBackend | None = None,
) -> LinearAlgebraBackend

register_backend(
    backend: LinearAlgebraBackend,
    *,
    replace: bool = False,
) -> None

available_backends() -> dict[str, bool]
backend_name(value: Any) -> str
```

The `exact` flag is semantically important. Core objects such as `OperatorAlgebra`, `PacketSystem`, `OperatorRealization`, and `SeedSystem` label their certificates `Exactness.EXACT` when `backend.exact` is true and `Exactness.NUMERICAL` otherwise. For a numerical certificate, the active tolerance is recorded. For an exact certificate, the recorded tolerance is `None`. Chapters 9 through 11 give the full object contracts. Only their backend-dependent evidence behavior is covered here.

This is a declaration by the backend, not an independent proof of its scalar field. A custom backend must therefore set `exact` honestly. Marking floating arithmetic exact would produce misleading certificate labels.

8.2 Registry, discovery, selection, and classification

Four public functions answer four different questions.

Function	Question answered	Important limitation
`get_backend(name)`	Which core linear-algebra backend object will execute?	Only registered names work. `None` means NumPy.
`register_backend(obj)`	Add or replace a process-global registry entry.	No public unregister operation. Registration is not context-local.
`available_backends()`	Which named optional packages can be discovered?	Presence is not registration, successful import, hardware readiness, or execution.
`backend_name(value)`	Does the value's defining module begin with `sympy`?	Everything else is reported as `numpy`. This is a heuristic, not dispatch.

At import time the registry contains one object, a default `NumpyBackend()`. `get_backend()` and `get_backend(None)` always return that NumPy object. The string `"sympy"` is special: if SymPy can be discovered, the library lazily registers a `SympyBackend`. The actual `import sympy` is deferred until the first matrix operation. Backend names are case-sensitive and are not normalized.

`available_backends()` always returns exactly the keys `numpy`, `sympy`, `scipy`, `mpmath`, and `cupy`. Except for NumPy, each Boolean is based on module discovery. Thus this is possible and intentional:

```
from komorebi_math.backends import available_backends, get_backend
from komorebi_math.exceptions import BackendUnavailableError

print(available_backends()["scipy"])  # may be True
try:
    get_backend("scipy")
except BackendUnavailableError as exc:
    print(type(exc).__name__ + ":", exc)
```

Possible output when SciPy is installed:

```
True
BackendUnavailableError: unknown or unavailable backend: scipy
```

There is no contradiction. SciPy is an optional feature dependency, not an implementation of `LinearAlgebraBackend` in this release. The same warning applies to mpmath and CuPy. JAX and PyTorch use their own diagnostic API and do not appear in `available_backends()`.

A deterministic unknown-name failure is useful in examples and installation checks:

```python
from komorebi_math.backends import get_backend
from komorebi_math.exceptions import BackendUnavailableError

try:
    get_backend("not-a-komorebi-backend")
except BackendUnavailableError as exc:
    print(f"{type(exc).__name__}: {exc}")
```

Output:

```
BackendUnavailableError: unknown or unavailable backend: not-a-komorebi-backend
```

Custom registration is intentionally low level. A duplicate name raises `ValueError` unless `replace=True`. Replacement can overwrite even a built-in entry for the remainder of the process. The implementation does not perform a full protocol audit during registration. Extension authors should subclass `LinearAlgebraBackend`, implement every abstract method, use a private unique name, and test in an isolated process.

8.3 NumPy: the default numerical realization

The constructor is:

```
NumpyBackend(*, dtype: Any = numpy.complex128)
```

The default scalar field is therefore represented numerically by complex double precision, even when the input contains only real integers. `as_matrix` requires a genuinely two-dimensional array. `as_vector` accepts a one-dimensional value or a two-dimensional row or column and flattens it. Shape failures raise `DimensionError`.

`transpose(A)` computes A^T. `adjoint(A)` computes $A^* = \overline{A}^T$. They differ for complex matrices. `norm` delegates to `numpy.linalg.norm` without an `ord` argument, so it is the Euclidean norm for a vector and the Frobenius norm for a matrix. Consequently,

$$\text{is_zero}(A;\tau) \iff \|A\| \le \tau,$$

with `1e-10` used when no tolerance is passed directly to `is_zero`. This is a whole-object norm test, not an element-by-element comparison. A large matrix whose individual entries are all below τ may still have Frobenius norm above τ.

NumPy rank and nullspace are numerical decisions. `rank` delegates to `numpy.linalg.matrix_rank`. `nullspace` performs a full singular-value decomposition and treats singular values above the threshold as nonzero. Its default threshold is

$$\tau_{\text{svd}} = \max(m,n)\,\epsilon_{64}\,\sigma_{\max},$$

where the implementation uses `numpy.finfo(float).eps`. An explicit tolerance overrides that threshold.

The rank boundary can be seen with a nearly singular diagonal matrix:

```
from komorebi_math.backends import get_backend

b = get_backend("numpy")
A = b.as_matrix([[1.0, 0.0], [0.0, 1e-12]])

print(b.rank(A))
print(b.rank(A, tolerance=1e-10))
print(b.is_zero(A, tolerance=1e-10))
```

Output:

```
2
1
False
```

The explicit threshold changes the estimated rank. It does not make the matrix exactly singular. The zero test remains false because the matrix norm is approximately one.

NumPy also coerces exact-looking input to the chosen dtype:

```
from fractions import Fraction
from komorebi_math.backends import get_backend

b = get_backend("numpy")
v = b.as_vector([Fraction(1, 3)])
print(v.dtype)
print(v[0])
print(v[0] == Fraction(1, 3))
```

Output:

```
complex128
(0.3333333333333333+0j)
False
```

Inversion and SVD failures are not wrapped in package exceptions. For example, inverting a singular NumPy matrix raises `numpy.linalg.LinAlgError`. The backend conversion boundary also does not reject `NaN` or infinity. Individual higher-level algorithms may impose stronger finite-value checks.

8.4 SymPy: the optional symbolic and exact realization

The supported public selection path is `get_backend("sympy")`. The concrete class is loaded lazily. Install the optional dependency with the package's `exact` extra before relying on it.

```
from fractions import Fraction
from komorebi_math.backends import available_backends, get_backend

if not available_backends()["sympy"]:
    print("SymPy unavailable; install komorebi-math[exact]")
else:
    b = get_backend("sympy")
    A = b.as_matrix([[1, Fraction(1, 2)], [0, 1]])
    print(b.exact)
    print(b.inverse(A))
```

Installed-branch output:

```
True
Matrix([[1, -1/2], [0, 1]])
```

SymPy rank and nullspace are exact symbolic operations. Their `tolerance` arguments are accepted for interface compatibility and ignored. The zero test is structural equality with a SymPy zero matrix. It does not call a general simplifier. A mathematically zero expression that SymPy has not normalized may therefore test false until the caller simplifies it.

There are three more boundaries worth stating explicitly.

First, SymPy and NumPy do not interpret every input shape identically. `NumpyBackend.as_matrix([1, 2])` rejects a one-dimensional list, whereas SymPy's `Matrix([1, 2])` constructs a 2×1 matrix and is accepted. Second, `SympyBackend.norm` ultimately converts a SymPy norm to Python `float`. An unresolved symbolic norm may raise a conversion error. Exact core certificates still store floating residual fields, even though a SymPy-backed zero residual must equal `0.0`. Third, passing an existing mutable SymPy matrix to `as_matrix` returns that matrix rather than an immutable copy. Mutation by the caller can therefore change an object retained by a higher-level construction.

SymPy import readiness is weaker than the crash-isolated JAX and PyTorch checks described below. Discovery can succeed even if a damaged installation later fails during import. A normal missing import is translated to `Backend UnavailableError`. Other third-party initialization failures need not be wrapped.

8.5 Exact rational and modular scalar domains

Some exact computations do not use `LinearAlgebraBackend` at all. The module `komorebi_math.coordinates.exact` represents vectors and matrices as immutable tuples of `Fraction` values:

```
from fractions import Fraction
from komorebi_math.coordinates.exact import (
    as_matrix,
    identity_matrix,
    inverse_matrix,
    matrix_multiply,
)

Q = as_matrix([[1, Fraction(1, 2)], [0, 1]])
Q_inv = inverse_matrix(Q)
print(Q_inv)
print(matrix_multiply(Q, Q_inv) == identity_matrix(2))
```

Output:

```
((Fraction(1, 1), Fraction(-1, 2)), (Fraction(0, 1), Fraction(1, 1)))
True
```

This layer supplies exact rank, determinant, inverse, reduced row-echelon form, linear-system solving, nullspace, powers, and Kronecker products using only the standard library. It rejects booleans as coefficients. Singular inversion raises `ValidationError("matrix is singular")`.

Runtime coercion is slightly broader than the public `int | Fraction` type annotation because it delegates to `Fraction(value)`. That makes strings such as `"1/3"` exact, but it also preserves the binary value of a raw float:

```
from komorebi_math.coordinates.exact import as_vector

print(as_vector(["1/3"]))
print(as_vector([0.1]))
```

Output:

```
(Fraction(1, 3),)
(Fraction(3602879701896397, 36028797018963968),)
```

Use `Fraction(1, 10)` or a deliberate string when decimal intent must remain exact. Do not pass `0.1` and expect $1/10$.

The arithmetic package provides additional exact finite domains: `ModularRing(n)` for $\mathbb{Z}/n\mathbb{Z}$, `PrimeField(p)` for canonical residues in $\mathbb{F}_p$, and `TruncatedPadic(p, k)` for arithmetic modulo p^k. These classes accept integers, reject booleans, and raise `ValidationError` for a nonunit inverse. `TruncatedPadic` is a finite precision residue ring, not an implementation of an infinite complete p-adic field.

8.6 Runtime settings: tolerance is active. Backend is descriptive

The settings API is:

```
Settings(
    backend: str = "numpy",
    tolerance: float = 1e-10,
    validate_on_construction: bool = True,
)

get_settings() -> Settings
configure(*, backend=None, tolerance=None,
          validate_on_construction=None) -> Settings
settings_context(**changes) -> Iterator[Settings]
```

Settings are stored in a `ContextVar`. `configure` updates the current context. `settings_context` temporarily replaces it and restores the previous record, even when the body raises an exception. The record is frozen, so callers replace settings rather than mutating fields.

Only part of the record currently controls core construction. When explicit arguments are absent, `OperatorAlgebra`, `OperatorRealization`, `PacketSystem`, and `SeedSystem` read the active tolerance. `PacketSystem` also reads `validate_on_construction`. No production constructor consults `get_settings().backend`. `get_backend(None)` remains NumPy.

```
from komorebi_math.backends import get_backend
from komorebi_math.config import get_settings, settings_context

with settings_context(backend="sympy"):
    print(get_settings().backend, get_backend().name)
```

Output:

```
sympy numpy
```

To execute with SymPy, pass `backend="sympy"` explicitly to the construction. The backend settings field is retained as configuration metadata, not as a global dispatcher in version `1.0.0b4`.

Tolerance changes do affect constructors that consult them:

```
from komorebi_math.config import get_settings, settings_context
from komorebi_math.core import PacketSystem
from komorebi_math.exceptions import ValidationError

P0 = [[1, 0], [0, 0]]
P1 = [[0, 0], [0, 1 + 1e-8]]

try:
    PacketSystem([P0, P1])
except ValidationError as exc:
```

```
    print(f"{type(exc).__name__}: {exc}")

with settings_context(tolerance=1e-7):
    system = PacketSystem([P0, P1])
    print(system.certificate().valid, system.tolerance)

print(get_settings().tolerance)
```

Output:

```
ValidationError: projectors do not form a complete packet system
True 1e-07
1e-10
```

The settings constructors do not fully validate policy. `configure` converts a tolerance to `float` but accepts negative, infinite, or `NaN` values, and `bool(value)` means the string `"false"` becomes true. `settings_context` uses raw dataclass replacement and performs no conversion. Applications should pass a finite nonnegative tolerance and actual Boolean values.

8.7 Optional feature adapters

Optional feature adapters have their own contracts and must not be passed to `get_backend`.

Dependency	Role in this release	Readiness test
SciPy	selected routines such as `matrix_exponential(..., method="scipy")`	import at point of use. `auto` can fall back to NumPy
mpmath	selected analytic high-precision features	import at point of use
JAX	nested forward-mode directional derivatives	crash-isolated child import plus `jax.jvp` capability
PyTorch	nested `torch.func.jvp` directional derivatives	crash-isolated child import plus `torch.func.jvp` capability
CuPy	selected packet and snapshot device execution	package discovery, then separate CUDA runtime and device checks

JAX and PyTorch expose:

```
ad_framework_diagnostics(*, refresh: bool = False)
available_ad_frameworks() -> dict[str, bool]
```

Provider selection uses:

```

autodiff_provider(
    framework,
    function,
    source_dimension,
    target_dimension,
    *,
    max_order=4,
    **options,
)
```

Provider constructors are:

```
JaxDerivativeProvider(..., max_order=4, dtype=None, ...)
TorchDerivativeProvider(..., max_order=4,
                        dtype="float64", device=None, ...)
```

Provider construction is lazy. The first value or derivative request checks a cached child-process probe before importing the framework into the application process. The probe has a 60-second timeout and records discovery, availability, version, return code, and a bounded diagnostic. Use `ad_framework_diagnostics(refresh=True)` after changing an environment in the same Python process.

Both providers compute higher directional derivatives through nested JVP calls, label results numerical, and convert outputs back to host NumPy arrays. JAX's default `dtype=None` respects the external JAX precision configuration. The PyTorch adapter defaults to `float64` and accepts a device string. The function must be traceable by the selected framework. A scalar-valued map must return a length-one vector, not a zero-dimensional scalar.

```
from komorebi_math.nonlinear import (
    autodiff_provider,
    available_ad_frameworks,
)

def square(x):
    return x * x

for framework, ready in available_ad_frameworks().items():
    if not ready:
        print(framework, "unavailable")
        continue
    provider = autodiff_provider(
        framework, square, source_dimension=2,
        target_dimension=2, max_order=2,
    )
    value = provider.derivative(1, [1.0, 2.0], ([3.0, 4.0],))
    print(framework, value.tolist())
```

Each installed and usable branch prints:

```
jax [6.0, 16.0]
torch [6.0, 16.0]
```

An absent branch prints `jax unavailable` or `torch unavailable` without breaking the NumPy core. Framework tracing errors, unsupported operations, and device failures are not converted into a numerical fallback.

8.8 Scalar and backend decision table

Choose the scalar domain before choosing an optional package. If the input is intended to be rational, construct that rational value explicitly. If the workflow is numerical, choose and record its dtype and tolerance. Then consult the operation's backend field: installing a dependency and selecting it for a particular calculation are separate steps.

Need	Recommended path	Exactness	Main caution
default dense finite linear algebra	`get_backend("numpy")`	numerical	default dtype is `complex128`. Rank depends on thresholds
symbolic or rational matrix identities	`get_backend("sympy")`	declared exact	optional dependency. Structural zero test. Symbolic norms may not convert
immutable rational coordinate algebra	`komorebi_math.coordinates.exact`	exact	construct decimals explicitly with `Fraction`

Need	Recommended path	Exactness	Main caution
finite modular arithmetic	`ModularRing`, `PrimeField`	exact	only units are invertible in a composite-modulus ring
finite local precision modulo p^k	`TruncatedPadic`	exact finite quotient	not an infinite p-adic field
selected scientific matrix routines	feature API with SciPy	numerical	SciPy presence does not register a core backend
directional AD	JAX or PyTorch provider	numerical	runtime capability and traceability are separate from installation
selected CUDA execution	CuPy executor	numerical	package presence does not prove a working device

8.9 Failure boundaries and practical cautions

Keep these distinctions visible in examples and error handling:

1. An unknown or absent core backend raises `BackendUnavailableError`. Duplicate registry insertion raises ordinary `ValueError`.
2. Matrix and vector shape violations raise `DimensionError`, a subclass of `ValidationError`. Low-level NumPy and SymPy algebra failures may retain their framework-native exception types.
3. `available_backends()` reports discovery, not successful execution. `available_ad_frameworks()` is stronger because it performs an isolated capability probe, but even that does not prove a user's particular function is traceable.
4. `backend_name` recognizes SymPy by module name and calls every unfamiliar value NumPy. Python lists, JAX arrays, Torch tensors, and CuPy arrays should not be dispatched through this heuristic.
5. Tolerance changes can alter numerical rank, nullspace dimension, support, closure, and certificate validity. Report the tolerance with every numerical claim.
6. Exactness follows the executed path. A rational number coerced into NumPy is numerical. A `Fraction` tuple in the exact coordinate layer remains exact. A JAX or Torch derivative remains numerical.
7. `ExactnessError` is part of the public exception hierarchy, but the current backend and coercion modules do not raise it. Do not promise it as the generic response to every exact/numerical mismatch.

The focused tests cover NumPy linear algebra and nullspace, SymPy rank and nullspace, the fixed availability-report keys, settings-context restoration, exact rational inverse and solvers, modular-domain units and valuations, crash-isolated optional-runtime aborts and timeouts, and JAX/PyTorch directional derivatives through third order when those runtimes are usable. The current suite does not make custom registry replacement, the `backend_name` heuristic, invalid global tolerance policy, or symbolic simplification completeness part of a strong public contract. Treat those as documented implementation boundaries rather than extension guarantees.

> **Chapter 8 summary.** The core matrix protocol uses NumPy by default and optional SymPy for symbolic/exact matrices. `get_backend` selects execution. `available_backends` reports discovery. `backend_name` is only a two-way module heuristic. SciPy, mpmath, JAX, PyTorch, and CuPy remain feature dependencies, while exact rational coordinates and modular domains are independent scalar systems. Exactness follows the path that actually ran. Numerical claims retain their dtype, tolerance, runtime, and certificate assumptions. Chapter 9 now applies these rules to typed operator realizations and declared path relations.

Part III. Operator, packet, and refinement foundations

Reading route. This part builds a finite operator model in layers. You can enter at the layer that matches the data you already have.

Your starting point	Start here	What to keep for the next step
Named spaces and permitted operations	Chapter 9	A grammar, its realized matrices, and registered relations
Square matrices and candidate generating vectors	Chapter 10	The algebra or orbit basis and the corresponding certificate
A decomposition into labeled subspaces	Chapter 11	Packet names, projectors, and the source/target order of blocks
Several resolutions of one decomposition	Chapter 12	The fine-to-coarse parent maps and compatible endpoint systems
Residues, rational lattices, or modular linear equations	Chapter 13	Address conventions, prime, and exact arithmetic data
Signal or arithmetic channels to refine	Chapter 14	Channel order, original shape, and the compatible refinement plan

For a first pass, read the opening of each chapter and run its first small example. Return to the method tables when adapting that example. The common prerequisites are matrix multiplication on column vectors, finite-dimensional span and rank, and the certificate and backend conventions of Chapters 5 and 8. The arithmetic sections state their additional prime and divisibility requirements locally. Keep the labels attached to matrices and coordinates: matching numerical dimensions alone does not establish that two named objects can be composed.

9. Typed operator grammars

First route. Sections 9.1 to 9.3 separate the declarations from their execution. If you prefer to begin with a complete program, use the numerical factorization in Section 9.4.1, then trace its names back through those sections. Use Section 9.4.2 for the SymPy variant. When a path fails, inspect its endpoints before changing a matrix or a tolerance.

Typed operator grammars are the first executable layer of the guide's operator language. They answer three questions before any matrix calculation is allowed to begin:

1. Which spaces, or *types*, exist?
2. Which named operators may act between those spaces?
3. Which sequences of named operators form legal paths?

Only after those structural questions have been answered does an `OperatorRealization` attach dimensions and matrices. This division is useful because the same formal grammar can have several realizations: an exact rational realization, a floating-point approximation, a lower-dimensional model, or a failed candidate whose declared relations can be inspected.

The implemented picture is a finite directed multigraph, or quiver,

$$\mathsf{G} = (V, A, s, t), \qquad a : s(a) \longrightarrow t(a),$$

together with finitely many linear relations among parallel paths. A realization assigns a finite-dimensional space of dimension d_X to each vertex X, and a matrix

$$\rho(a) \in \mathbb{F}^{d_{t(a)} \times d_{s(a)}}$$

to every arrow. The target dimension is the row count and the source dimension is the column count. This shape convention is what makes the grammar's type checking agree with ordinary matrix action on column vectors.

The `[STABLE]` manifest for the reference version `1.0.0b4` contains the six objects used here:

```
from komorebi_math.stable import (
    Arrow,
    OperatorGrammar,
    OperatorRealization,
    OperatorRelation,
    OperatorWord,
    RelationResidual,
)
```

`Arrow`, `OperatorGrammar`, `OperatorRealization`, `OperatorRelation`, and `OperatorWord` are also top-level research exports. `RelationResidual` is not a top-level export in this release. Import it from `komorebi_math.stable` or `komorebi_math.core`. Long-lived code should use the stable import shown above.

The provenance records distinguish the two layers:

Identifier	Object	Status	Implemented scope
`PSC-I-D01`	`OperatorGrammar`	definition	finite vertices, typed arrows, and finite linear path relations
`PSC-I-T01`	`OperatorRealization`	proved	finite-dimensional matrix realization and verification of the declared relations

These labels do not claim that the software constructs an abstract quotient algebra, finds a normal form, or proves a relation for every possible realization. It checks the supplied finite realization.

9.1 `Arrow`, `OperatorWord`, `OperatorRelation`, `OperatorGrammar`

The small records are frozen, slotted dataclasses. Their stable constructor signatures are:

```
Arrow(name: str, source: str, target: str) -> None

OperatorWord(
    arrows: tuple[str, ...],
    source: str,
    target: str,
) -> None

OperatorRelation(
    name: str,
    terms: tuple[tuple[Any, OperatorWord], ...],
) -> None

RelationResidual(
    name: str,
    residual: float,
    satisfied: bool,
) -> None
```

Their fields have these meanings:

Record	Field	Meaning
`Arrow`	`name`	name used to retrieve and compose the generator
	`source`	input vertex
	`target`	output vertex
`OperatorWord`	`arrows`	arrow names in the order in which they act
	`source`	initial vertex
	`target`	final vertex
`OperatorRelation`	`name`	unique name after registration in a grammar
	`terms`	coefficient-word pairs (c_j, w_j)
`RelationResidual`	`name`	registered relation name
	`residual`	backend norm, returned as a Python `float`
	`satisfied`	result of the backend's zero test

An `OperatorWord` also provides two derived properties:

```
OperatorWord.length: int
OperatorWord.is_identity: bool
```

`length` is the number of arrow names. `is_identity` is true exactly when the arrow tuple is empty and the two stored endpoints are equal. Converting a word to text produces `id_X` for the identity at `X`, and joins nonempty words with the centered-dot string `·`.

The preferred way to obtain all three structural records is through an `OperatorGrammar`, not by assembling dataclasses manually. The grammar checks that arrows use known vertices, paths compose, identities name known vertices, and registered relations contain words that agree with the grammar.

9.1.1 Constructing a grammar

The stable grammar constructor is:

```
OperatorGrammar(
    vertices: Iterable[str],
    arrows: Mapping[str, tuple[str, str]] | Iterable[Arrow],
    relations: Iterable[OperatorRelation] = (),
) -> None
```

The common mapping form is concise:

```
grammar = OperatorGrammar(
    ["X", "Y", "Z"],
    {
        "a": ("X", "Y"),
        "b": ("Y", "Z"),
        "c": ("X", "Z"),
    },
)
```

This defines

$$X \xrightarrow{a} Y \xrightarrow{b} Z, \qquad X \xrightarrow{c} Z.$$

The alternative form is useful when arrows have already been constructed:

```
grammar = OperatorGrammar(
    ["X", "Y", "Z"],
    [
        Arrow("a", "X", "Y"),
        Arrow("b", "Y", "Z"),
        Arrow("c", "X", "Z"),
    ],
)
```

The constructor enforces this finite structural contract:

- At least one vertex is required.
- The normalized vertex names must be nonempty.
- Arrow names must be nonempty and unique.
- Every arrow source and target must occur in the vertex tuple.
- Relations passed to the constructor are registered through the same validation path as later relations.

The public read-only views are:

```
OperatorGrammar.vertices  -> tuple[str, ...]
OperatorGrammar.arrows    -> tuple[Arrow, ...]
OperatorGrammar.relations -> tuple[OperatorRelation, ...]
```

Their order is deterministic under ordinary ordered Python inputs. Vertices preserve first occurrence, arrows preserve mapping or iterable order, and relations preserve registration order.

There is one subtle normalization rule. Vertex inputs are converted with `str`, and repeated normalized values are silently collapsed while preserving the first occurrence. Thus `OperatorGrammar(["X", "X", 1], {})` has vertices `("X", "1")`. The source does **not** reject repeated vertex inputs. Arrow names, by contrast, must be unique and are rejected if repeated. Programs that use names as external identifiers should normalize and reject collisions before calling the constructor rather than depending on this permissive vertex rule.

Individual arrows are retrieved with:

```
OperatorGrammar.arrow(self, name: str) -> Arrow
```

An unknown name raises `ValidationError` rather than returning `None`.

9.2 Composition legality and relation syntax

The grammar creates words through:

```
OperatorGrammar.identity(
    self,
    vertex: str,
) -> OperatorWord

OperatorGrammar.word(
    self,
    *arrow_names: str,
    vertex: str | None = None,
) -> OperatorWord
```

For a nonempty word, the arrow names are listed in **application order**. If

$$a : X \to Y, \qquad b : Y \to Z,$$

then:

```
word = grammar.word("a", "b")
```

stores `word.arrows == ("a", "b")`, has endpoints `X -> Z`, prints as `a · b`, and means "apply `a`, then apply `b`." If the realized matrices are $A = \rho(a)$ and $B = \rho(b)$, evaluation is

$$\rho(\texttt{word("a","b")}) = BA,$$

not AB. More generally, for the stored tuple

$$w = (a_1, a_2, \dots, a_k),$$

the implemented product is

$$\rho(w) = \rho(a_k)\rho(a_{k-1}) \cdots \rho(a_1).$$

The implementation starts with the identity on the source space and left multiplies once for each arrow. This convention is consistent with column vectors:

$$x \longmapsto A_1 x \longmapsto A_2 A_1 x \longmapsto \cdots \longmapsto A_k \cdots A_1 x.$$

Adjacent names are legal exactly when

$$t(a_j) = s(a_{j+1}).$$

A failure is reported at the first noncomposable pair. The `vertex` keyword is not used to override or constrain a nonempty word. It supplies the object for the empty word only. These two expressions are equivalent:

```
grammar.identity("X")
grammar.word(vertex="X")
```

Both return the empty path $1_X : X \to X$. Calling `grammar.word()` without a vertex is ambiguous and raises `ValidationError`.

> **Order rule.** Read `word("a", "b")` from left to right as execution, but read its matrix from right to left as multiplication: first A, then B, hence BA.

9.2.1 Linear path relations

A relation is a named finite linear combination of parallel words:

$$R = \sum_{j=1}^{m} c_j w_j : X \to Y.$$

Every word in the sum must have the same source X and target Y. The factory signature is:

```
OperatorGrammar.relation(
    self,
    name: str,
    terms: Sequence[tuple[Any, OperatorWord]],
    *,
    add: bool = True,
) -> OperatorRelation
```

For the three-arrow grammar above, the factorization relation

$$b \circ a - c = 0$$

is entered as:

```
factorization = grammar.relation(
    "factorization",
    [
        (1, grammar.word("a", "b")),
        (-1, grammar.word("c")),
    ],
)
```

Because the stored words are in application order, the first term evaluates as BA. The factory converts the term sequence to a tuple. By default it also registers the relation in the grammar. `add=False` creates and validates the parallel relation record without registering it:

```
candidate = grammar.relation(
    "candidate",
    [(1, grammar.word("c"))],
    add=False,
)
```

An unattached relation can be evaluated explicitly with `realization.relation_matrix(candidate)`, but it is not included in `grammar.relations`, `relation_residuals()`, constructor validation, or the relation certificate until it is registered.

Existing records are registered through:

```
OperatorGrammar.add_relation(
    self,
    relation: OperatorRelation,
) -> None
```

Registration checks that the name has not already been used and that every word is reconstructible in this grammar with consistent endpoints. Identity terms must name known vertices. A relation must have a nonempty name, at least one term, and parallel endpoints.

Coefficients are intentionally backend-generic and annotated `Any`. The grammar does not prove that a coefficient belongs to a field, coerce it, or reject a zero coefficient. Compatibility is tested only when a realization asks its backend to scale and add matrices. Use ordinary numerical scalars with NumPy and exact SymPy scalars with the SymPy backend. A coefficient accepted by one backend need not be accepted by another.

9.2.2 Enumerating finite paths

Legal paths can be enumerated with:

```
OperatorGrammar.paths(
    self,
    *,
    source: str | None = None,
    target: str | None = None,
    max_length: int = 1,
    include_identities: bool = True,
) -> tuple[OperatorWord, ...]
```

The method performs a finite breadth-by-length enumeration:

1. Accepted identities are emitted first when requested.
2. All length-one arrows are considered in arrow order.
3. Each frontier word is extended by every type-compatible arrow.
4. Source and target filters control which words are returned, not which legal intermediate words may be extended.

For the factorization grammar,

```
grammar.paths(source="X", target="Z", max_length=2)
```

returns the direct path `c` followed by the two-step path `a · b`. An identity is included only when its vertex meets both endpoint filters. With `max_length=0`, the result contains only accepted identities, or is empty when `include_identities=False`.

`max_length` must be nonnegative. Unknown source and target filters raise `ValidationError`. Relations do not alter enumeration: declaring `a · b - c = 0` does not remove either path, identify their `OperatorWord` objects, or choose a canonical representative. In a graph with branching or loops, the number of paths can grow exponentially with `max_length`. This method has no separate path-count resource guard. Keep the length bound small unless growth has been estimated.

9.3 `OperatorRealization` and relation residuals

The realization constructor is:

```
OperatorRealization(
    grammar: OperatorGrammar,
    spaces: Mapping[str, int],
    operators: Mapping[str, Any],
    *,
    backend: str | LinearAlgebraBackend | None = None,
    validate_relations: bool = True,
    tolerance: float | None = None,
) -> None
```

The construction contract is exact at the level of keys and dimensions:

- `spaces` must have exactly the grammar's vertex names as keys.
- Every space dimension must be positive after conversion with `int`.
- `operators` must have exactly the grammar's arrow names as keys.
- The matrix for $a : X \to Y$ must have shape (d_Y, d_X).
- Each matrix is converted by the selected backend.
- If registered relations exist and `validate_relations=True`, all must pass before construction returns.

The selected backend is obtained through the mechanism described in Chapter 8. `backend=None` selects NumPy. A registered backend name or a concrete `LinearAlgebraBackend` instance may also be supplied. The default NumPy backend converts matrices to `complex128`. `backend="sympy"` requests the optional exact SymPy backend.

If `tolerance` is omitted, the realization snapshots the current global setting when it is constructed. An explicit value is converted to `float` and stored as `realization.tolerance`. Changing the settings context afterward does not alter an existing realization.

The main evaluator is:

```
OperatorRealization.evaluate(
    self,
    word: OperatorWord,
) -> Any
```

For an identity it returns the backend identity matrix of the realized vertex dimension. For a nonempty word it reconstructs the arrow sequence through the grammar, verifies the stored endpoints, and left multiplies the matrices in application order.

The evaluator does not infer dimensions or repair a manually forged word. Use `grammar.word(...)` and `grammar.identity(...)` so that the path has already crossed the structural boundary.

9.3.1 Relation matrices, residuals, and certificates

For a parallel relation

$$R = \sum_j c_j w_j : X \to Y,$$

the realized relation matrix is

$$\rho(R) = \sum_j c_j \rho(w_j) \in \mathbb{F}^{d_Y \times d_X}.$$

The relevant methods are:

```
OperatorRealization.relation_matrix(
    self,
    relation: OperatorRelation,
) -> Any

OperatorRealization.relation_residuals(
    self,
) -> tuple[RelationResidual, ...]

OperatorRealization.relation_certificate(
    self,
) -> Certificate
```

`relation_matrix` accepts either a registered relation or an unattached parallel relation. It starts from a backend zero matrix of typed shape and adds each scaled word matrix.

`relation_residuals()` processes only the registered relations, in registration order. For each relation it computes

$$r_R = \|\rho(R)\|$$

through `backend.norm`, then asks `backend.is_zero` whether the matrix is satisfied. The returned residual is always a Python `float`, even when the backend is exact.

The NumPy backend uses `numpy.linalg.norm`, which is the Frobenius norm for the two-dimensional matrices used here, and accepts the relation when

$$r_R \leq \tau.$$

The SymPy backend ignores the tolerance and tests exact equality with the zero matrix. Consequently the two evidence modes are:

Backend path	Certificate exactness	Satisfaction rule	Stored tolerance
NumPy	`[NUMERICAL]`	matrix norm at most τ	explicit float
SymPy	`[EXACT]`	exact zero-matrix equality	`None`

The certificate has:

- `valid=True` exactly when every registered residual record is satisfied.
- Residuals mapped by relation name.
- The fixed assumptions-checked tuple `("operator shapes", "typed path composition", "declared relations")`.
- Diagnostics containing the backend name and relation count.
- Theorem identifier `PSC-I-T01`.
- Message `all grammar relations are satisfied` or `one or more grammar relations fail`.

If the grammar has no registered relations, the certificate is vacuously valid, has an empty residual mapping, and reports a relation count of zero. Such a certificate confirms the typed realization boundary. It does not provide evidence for a relation that was never declared.

With the default `validate_relations=True`, an invalid certificate is converted into `RelationError` inside the constructor. Use `validate_relations=False` only when the intended workflow is to retain a failed candidate and inspect its matrix, residual, and certificate. This flag does not bypass missing keys, nonpositive dimensions, wrong operator shapes, or invalid grammar paths.

9.4 Grammar examples and invalid paths

9.4.1 Worked numerical factorization

This example realizes two routes from X to Z: the direct arrow c and the composed path obtained by applying a and then b. It declares that the routes agree.

```
import numpy as np

from komorebi_math.stable import OperatorGrammar, OperatorRealization

grammar = OperatorGrammar(
    ["X", "Y", "Z"],
    {
        "a": ("X", "Y"),
        "b": ("Y", "Z"),
        "c": ("X", "Z"),
    },
)

ab = grammar.word("a", "b")
grammar.relation(
    "factorization",
    [(1, ab), (-1, grammar.word("c"))],
)

A = np.array([[1, 0], [0, 1], [1, 1]], dtype=float)
B = np.array([[1, 2, 0], [0, 1, 1]], dtype=float)
C = B @ A

realization = OperatorRealization(
    grammar,
    {"X": 2, "Y": 3, "Z": 2},
    {"a": A, "b": B, "c": C},
)

print("word:", str(ab), ab.source, "->", ab.target, "length=", ab.length)
print("B @ A:")
print(np.real_if_close(realization.evaluate(ab)))
print(
    "paths X -> Z, length <= 2:",
    [
        str(word)
        for word in grammar.paths(source="X", target="Z", max_length=2)
    ],
)
print("residuals:", realization.relation_residuals())

certificate = realization.relation_certificate()
print(
    "certificate:",
    certificate.valid,
    certificate.exactness.value,
    certificate.residuals,
    certificate.tolerance,
    certificate.theorem_id,
)
```

Expected output under the shipped default tolerance:

```
word: a · b X -> Z length= 2
B @ A:
[[1. 2.]
 [1. 2.]]
paths X -> Z, length <= 2: ['c', 'a · b']
residuals: (RelationResidual(name='factorization', residual=0.0, satisfied=True),)
certificate: True numerical {'factorization': 0.0} 1e-10 PSC-I-T01
```

Three distinct contracts are visible. The grammar establishes that the two routes are parallel. The realization shape-checks A, B, and C. The certificate then verifies numerically that $BA - C$ has zero residual at the stored tolerance.

9.4.2 Exact nilpotent realization

The same interface can use the optional SymPy backend. Here the single loop $N : X \to X$ obeys $N^2 = 0$:

```python
import sympy as sp

from komorebi_math.stable import OperatorGrammar, OperatorRealization

grammar = OperatorGrammar(["X"], {"N": ("X", "X")})
square = grammar.word("N", "N")
grammar.relation("square_zero", [(1, square)])

realization = OperatorRealization(
    grammar,
    {"X": 2},
    {"N": sp.Matrix([[0, 1], [0, 0]])},
    backend="sympy",
)

print("N^2 =")
print(realization.evaluate(square))
print(
    "loops:",
    [
        str(word)
        for word in grammar.paths(
            source="X",
            target="X",
            max_length=2,
        )
    ],
)
print("residual:", realization.relation_residuals()[0])

certificate = realization.relation_certificate()
print(
    "certificate:",
    certificate.valid,
    certificate.exactness.value,
    certificate.residuals,
    certificate.tolerance,
    certificate.theorem_id,
)
```

Expected output:

```
N^2 =
Matrix([[0, 0], [0, 0]])
loops: ['id_X', 'N', 'N · N']
residual: RelationResidual(name='square_zero', residual=0.0, satisfied=True)
certificate: True exact {'square_zero': 0.0} None PSC-I-T01
```

`[EXACT]` here means that the supplied SymPy matrix satisfies the supplied finite relation by exact matrix equality. It does not mean that every operator called N is nilpotent, or that an abstract nilpotent algebra has been classified.

9.4.3 Tolerance is part of a numerical claim

A numerical relation can pass at one tolerance and fail at another. The realized matrix and its residual do not change. The acceptance boundary does:

```python
import numpy as np

from komorebi_math.stable import OperatorGrammar, OperatorRealization

grammar = OperatorGrammar(["X"], {"T": ("X", "X")})
grammar.relation("approximately_zero", [(1, grammar.word("T"))])
matrix = np.array([[5.0e-9]])

loose = OperatorRealization(
    grammar,
    {"X": 1},
    {"T": matrix},
    tolerance=1.0e-8,
)
strict = OperatorRealization(
    grammar,
    {"X": 1},
    {"T": matrix},
    tolerance=1.0e-10,
    validate_relations=False,
)

for name, realization in (("loose", loose), ("strict", strict)):
    residual = realization.relation_residuals()[0]
    print(name, residual.residual, residual.satisfied)
```

Expected output:

```
loose 5e-09 True
strict 5e-09 False
```

If the strict realization had retained the default `validate_relations=True`, its constructor would have raised `RelationError`. Reporting only "the relation passed" without its backend and tolerance would discard part of the mathematical statement.

9.4.4 Path and loop operator helpers

The realization can evaluate a bounded family of grammar paths in one call:

```
OperatorRealization.path_operators(
    self,
    *,
    source: str | None = None,
    target: str | None = None,
    max_length: int = 1,
    include_identities: bool = True,
) -> dict[OperatorWord, Any]

OperatorRealization.loop_operators(
    self,
    vertex: str,
    *,
    max_length: int,
) -> tuple[Any, ...]
```

`path_operators` preserves the `OperatorWord` objects as dictionary keys, so a caller can retain type and path labels beside each matrix. It delegates all enumeration rules to `grammar.paths` and evaluates every returned word.

`loop_operators` is a narrower convenience method. It returns matrices for all paths from a vertex back to itself through the requested length, always including the identity. It discards the word labels. When labels matter, use `path_operators(source=vertex, target=vertex, ...)` instead.

Neither helper removes duplicate matrices. Distinct formal paths remain distinct dictionary keys even when a declared relation or the particular realization makes their matrices equal. This is the correct boundary for the next chapter: an `OperatorAlgebra` can study the span and closure of realized matrices, while the grammar continues to preserve their formal addresses.

9.4.5 Controlled failures

This example exercises the main structural and relation failures:

```
import numpy as np

from komorebi_math.stable import OperatorGrammar, OperatorRealization

def show_failure(label, action):
    try:
        action()
    except Exception as error:
        print(f"{label}: {type(error).__name__}: {error}")

paths = OperatorGrammar(
    ["X", "Y"],
    {"a": ("X", "Y"), "b": ("X", "Y")},
)

show_failure("noncomposable", lambda: paths.word("a", "b"))
show_failure("empty word", lambda: paths.word())
show_failure(
    "nonparallel",
    lambda: paths.relation(
        "bad",
        [(1, paths.word("a")), (-1, paths.identity("X"))],
    ),
)
```

```
grammar = OperatorGrammar(["X"], {"T": ("X", "X")})
grammar.relation("square_zero", [(1, grammar.word("T", "T"))])

show_failure(
    "failed relation",
    lambda: OperatorRealization(
        grammar,
        {"X": 2},
        {"T": np.eye(2)},
    ),
)

candidate = OperatorRealization(
    grammar,
    {"X": 2},
    {"T": np.eye(2)},
    validate_relations=False,
)
print("inspection:", candidate.relation_residuals(), candidate.relation_certificate().valid)

typed = OperatorGrammar(["X", "Y"], {"a": ("X", "Y")})
show_failure(
    "wrong shape",
    lambda: OperatorRealization(
        typed,
        {"X": 2, "Y": 3},
        {"a": np.eye(2)},
    ),
)
```

Expected output:

```
noncomposable: ValidationError: path is not composable at 'a', 'b': 'Y' != 'X'
empty word: ValidationError: an empty word requires its identity vertex
nonparallel: RelationError: all words in a relation must have the same source and target
failed relation: RelationError: one or more grammar relations fail
inspection: (RelationResidual(name='square_zero', residual=1.4142135623730951, satisfied=False),) False
wrong shape: DimensionError: operator 'a' has shape (2, 2), expected (3, 2)
```

The failure order is intentional. Grammar errors are caught before matrix work. Key and dimension errors are caught while constructing a realization. Declared relation failures are caught last, after matrices have valid typed shapes. `validate_relations=False` changes only that final relation gate.

The relevant exceptions are:

Failure	Exception
empty vertex set, empty vertex name, duplicate arrow, unknown arrow vertex	`ValidationError`
unknown arrow or identity vertex, illegal composition, inconsistent word endpoints	`ValidationError`
empty or nonparallel relation, duplicate relation name, unknown identity vertex, inconsistent stored endpoints	`RelationError`
unknown arrow or illegal composition inside a manually forged relation word	`ValidationError`
nonpositive space dimension or wrong operator shape	`DimensionError`
space or operator key mismatch	`ValidationError`
unavailable backend	`BackendUnavailableError`
failed registered relation during default construction	`RelationError`
negative `max_length`	built-in `ValueError`

Failure	Exception

As in Chapter 6, callers should catch by exception type rather than depending on exact diagnostic strings.

9.4.6 Contract boundaries and source-audit corrections

The implementation is finite by design and smaller than a general symbolic rewriting system. These boundaries prevent common overclaims:

1. **The grammar is not a parser.** It accepts Python objects and named arrows. It does not parse a free-form algebraic expression such as `b*a-c=0`.
2. **Relations are checked, not used as rewrite rules.** There is no Gröbner basis, reduction order, canonical word, or quotient-path enumeration.
3. **A valid certificate concerns one realization.** It verifies the matrices, relations, backend zero test, and tolerance supplied to that object. It does not prove a universal identity over all representations.
4. **Path enumeration is syntactic.** Equal realized matrices do not merge paths, and declared relations do not shorten the enumeration.
5. **Dimensions are supplied, not inferred.** Every vertex dimension and every arrow matrix must be present.
6. **Coefficients are backend-dependent.** The grammar does not validate a scalar domain or transport coefficients between NumPy and SymPy.
7. **Exact symbolic completeness is not promised.** The SymPy path uses exact matrix equality, but arbitrary unsimplified or parameter-dependent symbolic expressions may not reduce to a decidable zero and may not convert to the floating residual required by `RelationResidual`.
8. **A direct dataclass constructor is not the complete validator.** `Arrow` and `OperatorWord` records do not validate themselves. `OperatorRelation` checks name, nonemptiness, and parallel endpoints, while grammar membership is checked only when the relation is added. Prefer grammar factories.
9. **Repeated vertex inputs are normalized away.** Nonempty normalized vertex names are enforced, and duplicates are silently collapsed. Arrow names must be unique.
10. **`RelationResidual` has a narrower top-level import story.** It is stable and exported by `komorebi_math.stable` and `komorebi_math.core`, but not by the top-level `komorebi_math` namespace in `1.0.0b4`.
11. **The theorem identifier is provenance, not a proof transcript.** The certificate records `PSC-I-T01` and finite diagnostics. It does not contain a derivation of the abstract quotient correspondence.
12. **Finite does not mean automatically cheap.** A bounded path call always terminates, but branching and loops can make the result exponentially large in the length bound.

The focused source tests establish typed endpoints and identities, rejection of noncomposable paths and nonparallel relations, a valid numerical cubic relation, constructor rejection of a failed relation, exact SymPy nilpotence, and bounded loop enumeration. The stable semantic fixture additionally freezes one idempotent operator case with a valid certificate, one registered relation, and maximum residual zero. The installed core verifier checks the cubic relation $T^3 - T = 0$ for $T = \mathrm{diag}(-1, 0, 1)$.

The tests do not promise coefficient-field validation, quotient normal forms, large path-enumeration performance, arbitrary symbolic simplification, or special behavior for manually forged dataclass records. Those remain outside the chapter's public claim.

> **Chapter 9 summary.** Vertices are types, arrows are named generators, and `OperatorWord` stores a legal path in application order. Parallel paths form finite `OperatorRelation` records. `OperatorRealization` attaches a positive dimension to every vertex and a target-by-source matrix to every arrow, evaluates `word("a", "b")` as BA, and checks each registered relation exactly with SymPy or numerically with a declared tolerance under NumPy. The certificate is evidence about the supplied finite realization. Formal quotient reduction and generated matrix-algebra closure belong to later layers.

10. Operator algebras and seed systems

Choose the question first. To find the span of products of your matrices, use Section 10.1. To find the vectors reached from supplied seeds, use Section 10.2. These computations return bases of different spaces. Begin with the nilpotent example to see both together, then read Section 10.3 only when your problem meets the structural assumptions of a seed-rank formula.

Chapter 9 separates a symbolic operator grammar from a concrete realization. This chapter takes the next finite step. Once the generators have been realized as square matrices, Komorebi Math can close them under linear combination and multiplication, then ask whether a finite family of vectors generates the whole representation under that algebra.

The two central objects answer different questions:

Object	Finite question
`OperatorAlgebra`	Which independent matrices are produced by multiplying the realized generators?
`SeedSystem`	Which independent vectors are reached by applying the realized operators to the supplied seeds?

Both questions are finite because an algebra of $n \times n$ matrices has dimension at most n^2, while an orbit hull inside K^n has dimension at most n. The numerical backend decides independence relative to a tolerance. The SymPy backend decides it exactly.

> **Implementation map.** Generated matrix algebras are implemented in `komorebi_math.core.algebra`, and seed systems are implemented in `komorebi_math.core.seeds`. Despite its filename, `komorebi_math.core.operators` implements `PacketOperator`. That object belongs to Chapter 11 rather than the generated-algebra layer described here.

10.1 Finite generated algebras

Let K be the scalar domain, let $V = K^n$, and let

$$\mathcal{G} = \{A_1, \dots, A_m\} \subseteq \mathrm{End}_K(V).$$

With the identity included, the realized generated algebra is

$$\mathrm{Alg}_K(\mathcal{G}) = \mathrm{span}_K \left\{ I, A_{i_1}, A_{i_2}A_{i_1}, \dots \right\}.$$

It is the smallest unital linear subspace of $M_n(K)$ that contains the generators and is closed under matrix multiplication. Since

$$\dim_K M_n(K) = n^2,$$

the independent-product search must stabilize after adding at most n^2 basis matrices.

The executable constructor is

```
OperatorAlgebra(
    generators: Mapping[str, Any] | Sequence[Any],
    *,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float | None = None,
```

```
    include_identity: bool = True,
) -> None
```

If `generators` is a mapping, its keys are converted to strings and retained as generator names. A sequence is named `A0`, `A1`, and so on. Every value is converted by the selected backend and must have the same square shape. The common row dimension becomes `degree`.

The public state relevant to computation is:

Attribute	Meaning
`backend`	Active `LinearAlgebraBackend` instance
`tolerance`	Explicit tolerance or the active global setting at construction time
`generators`	Dictionary of backend matrices
`degree`	Common matrix size n
`include_identity`	Whether I_n is inserted before closure
`dimension`	Number of matrices in the computed basis

The closure algorithm

`basis()` uses a rank-increment closure rather than enumerating words. It can be written schematically as follows.

1. Start with an empty list B.
2. If `include_identity=True`, add I_n when it is nonzero and independent.
3. Process the generators in insertion order, retaining only rank-increasing matrices.
4. Freeze the current basis as a snapshot and test every product XY with X, Y in that snapshot.
5. Add each product that increases the flattened matrix rank.
6. Repeat from step 4 until a whole sweep adds nothing or $|B| = n^2$.

For numerical matrices, a matrix X is independent of $B = (B_1, \dots, B_d)$ precisely when the backend reports

$$\operatorname{rank}_\tau \begin{bmatrix} \operatorname{vec}(B_1) & \cdots & \operatorname{vec}(B_d) & \operatorname{vec}(X) \end{bmatrix} > \operatorname{rank}_\tau \begin{bmatrix} \operatorname{vec}(B_1) & \cdots & \operatorname{vec}(B_d) \end{bmatrix}.$$

Here τ is `tolerance`. The NumPy backend flattens in row-major order and uses `numpy.linalg.matrix_rank(..., tol=tolerance)`. The SymPy backend reshapes to an $n^2 \times 1$ column and computes exact rank. Its rank calculation ignores the numerical tolerance.

The basis is cached after its first construction. Repeated calls to `basis()` or `dimension` therefore do not repeat the closure search.

Methods

```
basis(self) -> tuple[Any, ...]
contains(self, matrix: Any) -> bool
certificate(self) -> Certificate
seed_system(self, seeds: Sequence[Any]) -> SeedSystem
transfer_graph(self, packets: PacketSystem) -> TransferGraph
```

`contains(X)` tests whether adjoining X changes the flattened basis rank. A shape other than `(degree, degree)` returns `False`. `seed_system(seeds)` uses the computed algebra basis itself as an acting operator family, named `B0`, `B1`, and so on. `transfer_graph(packets)` is the bridge into Chapter 11: it builds packet operators from the original generators, not from every matrix in the closed basis.

Executed example: a nilpotent algebra and a cyclic seed

```python
import numpy as np

from komorebi_math import OperatorAlgebra

N = np.array([[0.0, 1.0], [0.0, 0.0]])
algebra = OperatorAlgebra({"N": N})

basis = [
    np.real_if_close(value).astype(int).tolist()
    for value in algebra.basis()
]

seeds = algebra.seed_system([np.array([0.0, 1.0])])

print("algebra dimension:", algebra.dimension)
print("basis:", basis)
print("contains 3I+4N:", algebra.contains(3 * np.eye(2) + 4 * N))
print("contains N.T:", algebra.contains(N.T))
print("hull dimension:", seeds.hull_dimension())
print("orbit layers:", [len(layer) for layer in seeds.orbit_layers()])
print("algebra certificate:", algebra.certificate().valid)
print("seed certificate:", seeds.generation_certificate().valid)
```

Output:

```
algebra dimension: 2
basis: [[[1, 0], [0, 1]], [[0, 1], [0, 0]]]
contains 3I+4N: True
contains N.T: False
hull dimension: 2
orbit layers: [1, 1]
algebra certificate: True
seed certificate: True
```

Because $N^2 = 0$, the algebra is exactly

$$\mathcal{A} = \operatorname{span}\{I, N\}.$$

The seed e_2 produces $Ne_2 = e_1$, so one seed generates the two-dimensional representation. The NumPy certificates are still *numerical*: validity means the finite rank tests passed at the declared tolerance, not that an exact symbolic calculation was performed.

Exact backend variant

With the optional exact dependency installed, the same algebra can be computed over SymPy:

```
import sympy as sp

from komorebi_math import OperatorAlgebra

N = sp.Matrix([[0, 1], [0, 0]])
algebra = OperatorAlgebra({"N": N}, backend="sympy")

print("dimension:", algebra.dimension)
print("basis:", [value.tolist() for value in algebra.basis()])
print("exactness:", algebra.certificate().exactness.value)
```

Output:

```
dimension: 2
basis: [[[1, 0], [0, 1]], [[0, 1], [0, 0]]]
exactness: exact
```

Matrix units and the full algebra

```
matrix_units(
    size: int,
    *,
    backend: str | LinearAlgebraBackend | None = None,
) -> tuple[Any, ...]
```

`matrix_units(n)` returns the n^2 standard matrices E_{ij}, in row-major `(row, column)` order. They satisfy

$$E_{ij}E_{k\ell} = \delta_{jk}E_{i\ell}$$

and span $M_n(K)$. Consequently,

```
len(matrix_units(2))                        # 4
OperatorAlgebra(matrix_units(2)).dimension   # 4
```

Both values are `4` in the current implementation.

Identity boundary

`include_identity=False` is a genuine semantic switch. It does not merely hide the identity from the returned basis. It asks for the multiplicatively closed linear span of the supplied generators without forcing a unit. For the nilpotent matrix above,

```
nonunital = OperatorAlgebra([N], include_identity=False)
print(nonunital.dimension, nonunital.certificate().valid)
```

prints

```
1 True
```

because span$\{N\}$ is closed under multiplication. Thus the class docstring's phrase "unital … algebra" applies to the default configuration. A certificate with `include_identity=False` does not require that I_n be present.

10.2 `SeedSystem` and cyclic hulls

For an acting operator family

$$\mathcal{T} = \{T_1, \dots, T_m\} \subseteq \mathrm{End}_K(V)$$

and seeds $S = \{s_1, \dots, s_r\} \subseteq V$, the finite cyclic hull is

$$\mathcal{H}_{\mathcal{T}}(S) = \mathrm{span}_K \left\{ T_{i_k} \cdots T_{i_1} s_j : k \geq 0, 1 \leq j \leq r \right\}.$$

The length-zero words include the seeds themselves. The system is generating when

$$\mathcal{H}_{\mathcal{T}}(S) = V.$$

The constructor is

```
SeedSystem(
    operators: Mapping[str, Any] | Sequence[Any],
    seeds: Sequence[Any],
    *,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float | None = None,
) -> None
```

At least one seed is required. Empty operator families are allowed. In that case the hull is simply the linear span of the seeds. Mapping keys are converted to strings, while a sequence receives the names `A0`, `A1`, and so on. Every seed must have one common dimension n, and every operator must have shape $n \times n$.

The main state is:

Attribute or property	Meaning
`backend`	Active backend
`tolerance`	Rank and zero threshold captured at construction
`operators`	Named acting matrices
`seeds`	Backend vectors
`dimension`	Ambient vector-space dimension
`exact`	`True` exactly when the backend declares exact arithmetic

Independent frontier closure

`hull_vectors()` carries out a breadth-first independence search.

1. Add each nonzero, rank-increasing seed to a basis and to a queue.
2. Treat the current queue length as one orbit layer.
3. Apply every operator, in insertion order, to every vector in that layer.
4. Add only nonzero vectors that increase the current basis rank.
5. Stop when the queue is empty, the basis reaches dimension n, or the round limit is reached.

If `max_rounds` is omitted, the implemented limit is

$$L = n \max(1, m) + 2,$$

where m is the number of operators. Since every accepted vector increases a rank bounded by n, this is a conservative finite guard. A caller-supplied round limit is a truncation of the orbit search, not a proof that the omitted orbit contains nothing new.

The related methods are

```
hull_vectors(self, *, max_rounds: int | None = None) -> tuple[Any, ...]
hull_basis(self, *, max_rounds: int | None = None) -> Any
hull_dimension(self, *, max_rounds: int | None = None) -> int
is_generating(self) -> bool
generation_certificate(self) -> Certificate
orbit_layers(self, *, max_rounds: int | None = None) -> tuple[tuple[Any, ...], ...]
```

`hull_basis()` stacks accepted vectors as columns. If none survive, it returns a backend zero matrix of shape `(dimension, 0)`. `orbit_layers()` repeats the same rank-increment principle but groups vectors by the round in which they first appear. `is_generating()` and `generation_certificate()` always use the default full closure. They do not inherit a previous truncated `max_rounds` call.

Executed example: one seed for a cyclic shift

```
import numpy as np

from komorebi_math import SeedSystem, cyclic_span

def cyclic_shift(size: int) -> np.ndarray:
    shift = np.zeros((size, size))
    for column in range(size):
        shift[(column + 1) % size, column] = 1.0
    return shift

shift = cyclic_shift(5)
seed = np.eye(5)[:, 0]
system = SeedSystem({"S": shift}, [seed])
result = cyclic_span({"S": shift}, [seed])

print("layers:", [len(layer) for layer in system.orbit_layers()])
print("hull shape:", result.value.shape)
print("valid:", result.certificate.valid)
print("exactness:", result.certificate.exactness.value)
print("diagnostics:", result.certificate.diagnostics)
print("zero rounds:", system.hull_dimension(max_rounds=0))
```

Output:

```
layers: [1, 1, 1, 1, 1]
hull shape: (5, 5)
valid: True
exactness: numerical
diagnostics: {'ambient_dimension': 5, 'hull_dimension': 5, 'operator_count': 1, 'seed_count': 1, 'backend':
    ↪ 'numpy'}
zero rounds: 1
```

The layers are e_1, e_2, e_3, e_4, e_5. The last line is intentionally different: at zero expansion rounds, only the independent starting seed has been admitted.

The convenience wrapper has the exact signature

```
cyclic_span(
    operators: Mapping[str, Any] | Sequence[Any],
    seeds: Sequence[Any],
    *,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float | None = None,
) -> ComputationResult[Any]
```

It constructs a `SeedSystem`, places `hull_basis()` in `result.value`, and places `generation_certificate()` in `result.certificate`. A proper hull is therefore a normal returned computation with an invalid certificate, not an exception. Use `result.require()` when a generating hull is a precondition for the next step.

Proper hull

If

$$D = \operatorname{diag}(1, 2, 3), \qquad s = e_1,$$

then $D^k s = e_1$ for every k. The executed result is

```
hull_dimension = 1
certificate.valid = False
```

The computation is still well-defined. What fails is the claim that the chosen seeds generate the full ambient space.

Evaluation presentations

Given a supplied algebra basis or spanning family $B = (B_1, \dots, B_q)$ and seeds $S = (s_1, \dots, s_r)$, the evaluation map is

$$\operatorname{ev}_{B,S} : K^{qr} \longrightarrow K^n, \qquad (c_{ja}) \longmapsto \sum_{j=1}^{r} \sum_{a=1}^{q} c_{ja} B_a s_j.$$

The columns are ordered seed first, then algebra matrix:

$$B_1 s_1, \dots, B_q s_1, B_1 s_2, \dots, B_q s_2, \dots .$$

The method

```
presentation(self, algebra_basis: Sequence[Any]) -> FreePresentation
```

returns the record

Field	Meaning
`evaluation_matrix`	The $n \times qr$ matrix of evaluated seed images
`kernel_basis`	Backend nullspace vectors for the evaluation map
`rank`	Rank of the evaluation matrix
`domain_dimension`	Number qr of evaluation columns
`codomain_dimension`	Ambient dimension n
`backend`	Backend name
`nullity`	Property `domain_dimension - rank`

The caller, not the method, is responsible for supplying an algebra basis or a spanning family. `presentation()` checks only that the sequence is nonempty and that every matrix has the correct shape. It does not check linear independence or multiplicative closure.

For the flip matrix T and seed e_1, the family (I, T) evaluates to (e_1, e_2):

```
flip = np.array([[0.0, 1.0], [1.0, 0.0]])
presentation = SeedSystem(
    [flip], [np.array([1.0, 0.0])]
).presentation([np.eye(2), flip])

print(np.real_if_close(presentation.evaluation_matrix).astype(int).tolist())
print(presentation.rank, presentation.nullity)
print(presentation.domain_dimension, presentation.codomain_dimension)
```

Output:

```
[[1, 0], [0, 1]]
2 0
2 2
```

Smallest standard-basis diagnostic

```
minimum_standard_basis_seeds(
    self,
    *,
    max_dimension: int = 12,
    force: bool = False,
) -> StandardSeedSearchResult
```

This method examines subsets of the ambient standard basis $\{e_1, \dots, e_n\}$ in increasing cardinality and lexicographic combination order. The first generating subset produces

Field	Meaning
`count`	Cardinality of the first generating standard-basis subset
`indices`	Zero-based standard-basis indices
`certificate`	Generation certificate for that subset

It does **not** compute the unrestricted seed rank. For example, a diagonal matrix with three distinct eigenvalues is cyclic: the single vector $(1, 1, 1)^T$ generates under its powers. No single standard basis vector does.

```
diagonal = np.diag([1.0, 2.0, 3.0])
system = SeedSystem([diagonal], [np.ones(3)])
search = system.minimum_standard_basis_seeds()

print("original generating:", system.is_generating())
print("standard subset:", search.count, search.indices, search.certificate.valid)
```

Output:

```
original generating: True
standard subset: 3 (0, 1, 2) True
```

This distinction is essential: `count == 3` describes the restricted standard-coordinate search, while the displayed system already proves that an unrestricted one-vector generating family exists.

10.3 Semisimple, single-operator, direct-sum, and tensor seed ranks

Komorebi Math also exposes finite formulas and bounds that do not require an orbit search. They answer different structural questions and should not be interchanged.

Semisimple seed rank

Suppose a semisimple Artinian algebra acts on a module whose simple block types have dimensions $d_i > 0$ and multiplicities $m_i \geq 0$. The implemented formula is

$$r_{\mathrm{ss}} = \max_i \left\lceil \frac{m_i}{d_i} \right\rceil .$$

```
semisimple_seed_rank(
    block_dimensions: Sequence[int],
    multiplicities: Sequence[int],
) -> int
```

The two sequences must be nonempty and have equal length. Dimensions must be positive and multiplicities nonnegative. The provenance record is `PSC-I-T10`, “Semisimple seed rank formula,” with the assumption of a semisimple Artinian acting algebra.

Executed example:

```
semisimple_seed_rank([2, 4], [5, 9])
```

returns `3`, because

$$\max\{\lceil 5/2\rceil, \lceil 9/4\rceil\} = 3.$$

This function accepts the structural dimensions and multiplicities as data. It does not inspect a matrix representation to prove semisimplicity or infer those values.

Exact seed rank for one rational operator

For one rational matrix $T \in M_n(\mathbb{Q})$, regard $\mathbb{Q}^n$ as a $\mathbb{Q}[t]$-module with $t \cdot v = Tv$. Factor the characteristic polynomial over $\mathbb{Q}$:

$$\chi_T(t) = \prod_p p(t)^{e_p},$$

where the p are distinct monic irreducibles. The number of primary cyclic blocks belonging to p is

$$b_p = \frac{\operatorname{nullity} p(T)}{\deg p},$$

and the implemented seed rank is

$$r_T = \max_p b_p.$$

```
single_operator_seed_rank(operator: Any) -> int
```

The current executable path is exact and rational only. It converts the input to `sympy.Matrix`, requires a square matrix with entries in `sympy.QQ`, factors the characteristic polynomial over $\mathbb{Q}$, evaluates each irreducible factor at T by Horner’s rule, and computes exact ranks. The provenance record is `PSC-I-T13`, “Single operator primary seed rank formula.”

```
import sympy as sp

from komorebi_math import single_operator_seed_rank

jordan2 = sp.Matrix([[4, 1], [0, 4]])
jordan1 = sp.Matrix([[4]])
rotation = sp.Matrix([[0, -1], [1, 0]])

print(single_operator_seed_rank(sp.diag(jordan2, jordan1)))
print(single_operator_seed_rank(sp.diag(rotation, rotation)))
```

Output:

```
2
2
```

In the first case $p(t) = t - 4$, and $T - 4I$ has nullity 2. In the second, $p(t) = t^2 + 1$. Two repeated rational irreducible blocks give nullity $p(T)/2 = 4/2 = 2$.

An empty 0×0 square matrix returns `0`. Missing SymPy support raises `BackendUnavailableError`. Irrational or otherwise nonrational entries raise `ValidationError` rather than silently changing the coefficient field.

Direct-sum and tensor helpers

The remaining helpers are pure integer constructions:

```
shared_direct_sum_seed_bounds(seed_ranks: Sequence[int]) -> tuple[int, int]
independent_direct_sum_seed_rank(seed_ranks: Sequence[int]) -> int
tensor_seed_rank_upper_bound(left_rank: int, right_rank: int) -> int
```

For component ranks $r_1, \dots, r_k$, the declared shared-action bounds are

$$\max_i r_i \le r_{\text{shared}} \le \sum_i r_i.$$

For the library's independent direct-sum construction, the returned rank is

$$r_{\text{independent}} = \sum_i r_i.$$

For tensor products, the function supplies only the product upper bound

$$r_{\otimes} \le r_L r_R.$$

Executed values are:

```
shared_direct_sum_seed_bounds([2, 5, 3])       # (5, 10)
independent_direct_sum_seed_rank([2, 5, 3])    # 10
tensor_seed_rank_upper_bound(3, 4)             # 12
```

These functions do not receive operators, modules, or certificates. Their outputs are valid only after the caller has matched the mathematical situation to the named construction. In particular, the tensor result is an upper bound, not a claim of equality.

10.4 Algebra and seed certificates

The certificate interfaces follow Chapter 5. They record the finite computation that was actually performed, including its exactness boundary.

Algebra certificate

`OperatorAlgebra.certificate()` checks every product of returned basis matrices, all original generators, and, when requested, the identity. Its validity law is

$$\text{valid} = \text{closed} \wedge \text{contains_generators} \wedge \text{contains_required_identity}.$$

The returned fields are populated as follows:

Certificate component	Value
`exactness`	`EXACT` for an exact backend, otherwise `NUMERICAL`
`tolerance`	`None` for exact arithmetic, otherwise the algebra tolerance
`residuals`	Empty mapping in the current implementation
`assumptions_checked`	generator dimensions, linear independence, multiplicative closure
`diagnostics`	degree, algebra dimension, maximum dimension, backend
`theorem_id`	`PSC-I-D05`
success message	`valid generated operator algebra`
failure message	`operator algebra closure failed`

`PSC-I-D05` is a provenance definition, "Realized operator algebra," under the assumption of finite matrix generators.

Seed generation certificate

`SeedSystem.generation_certificate()` certifies only the equality between the computed full hull dimension and the ambient dimension:

$$\text{valid} \iff \dim \mathcal{H}_{\mathcal{T}}(S) = \dim V.$$

Its populated fields are:

Certificate component	Value
`exactness`	`EXACT` for an exact backend, otherwise `NUMERICAL`
`tolerance`	`None` for exact arithmetic, otherwise the seed-system tolerance
`residuals`	Empty mapping in the current implementation
`assumptions_checked`	operator dimensions, seed dimensions, finite orbit closure
`diagnostics`	ambient dimension, hull dimension, operator count, seed count, backend
`theorem_id`	`PSC-I-T02`
success message	`the seeds generate the ambient space`
failure message	`the seed hull is proper`

The provenance theorem `PSC-I-T02`, "Finite seed hull generation," assumes a finite-dimensional realized operator family and explicitly records that numerical rank depends on the declared tolerance.

Neither certificate stores the basis itself. The algebra basis comes from `algebra.basis()`, while the orbit basis comes from `system.hull_basis()` or the value inside `cyclic_span(...)`.

Result records and their exact fields

Three related records appear here:

```
@dataclass(frozen=True, slots=True)
class AlgebraBasisResult:
    basis: tuple[Any, ...]
    dimension: int
    certificate: Certificate

@dataclass(frozen=True, slots=True)
class FreePresentation:
    evaluation_matrix: Any
    kernel_basis: tuple[Any, ...]
    rank: int
    domain_dimension: int
    codomain_dimension: int
    backend: str

    @property
    def nullity(self) -> int: ...

@dataclass(frozen=True, slots=True)
class StandardSeedSearchResult:
    count: int
    indices: tuple[int, ...]
    certificate: Certificate
```

`FreePresentation` and `StandardSeedSearchResult` are returned by the methods documented above and are exported from `komorebi_math.core`. `AlgebraBasisResult` is also exported, including at package top level, but the current `OperatorAlgebra.basis()` method returns `tuple[Any, ...]` directly. The guide therefore does not imply a currently nonexistent `AlgebraBasisResult` return path.

`SeedSystem` is part of the frozen stable namespace. `OperatorAlgebra` and the rank/construction helpers are available from the broader top-level research namespace. Code that requires only the stable contract should import `SeedSystem` from `komorebi_math.stable`.

Failure and caution table

Operation	Boundary	Behavior
`OperatorAlgebra([])`	No generator supplied	`ValidationError`
algebra construction	First generator nonsquare	`DimensionError`
algebra construction	Generator sizes differ	`DimensionError`
`contains(X)`	X has the wrong square size	Returns `False`
`matrix_units(size)`	`size < 1`	`ValueError`
`SeedSystem(..., seeds=[])`	No seed supplied	`ValidationError`
seed construction	Seed dimensions differ	`DimensionError`
seed construction	Operator is not $n \times n$	`DimensionError`
`presentation([])`	No supplied algebra matrix	`ValidationError`
`presentation(B)`	A matrix has the wrong size	`DimensionError`
standard-basis search	$n >$ `max_dimension` and not forced	`ValidationError`
semisimple formula	Empty/mismatched data or invalid dimensions	`ValidationError`
direct-sum helpers	Empty or negative rank data	`ValidationError`
tensor bound	Negative rank	`ValidationError`
single-operator formula	SymPy absent	`BackendUnavailableError`
single-operator formula	Nonsquare matrix	`DimensionError`
single-operator formula	Entry outside $\mathbb{Q}$	`ValidationError`

Operation	Boundary	Behavior
single-operator formula	Primary nullity not divisible by factor degree	`ArithmeticError`

Additional practical boundaries matter:

- `max_rounds=0` intentionally returns only the independent seeds. Negative round values are not rejected by the constructor and also prevent expansion. Callers should use nonnegative values.
- The constructors convert an explicit tolerance with `float(tolerance)` but do not separately validate that it is nonnegative. A negative rank threshold has no useful mathematical interpretation and must not be supplied.
- Numerical closure can merge nearly dependent matrices or vectors, or separate perturbations that should be identified in an ideal exact model. Record the tolerance whenever a dimension claim is reported.
- The SymPy backend makes the rank decisions exact, but exact characteristic polynomial factorization and exact nullspaces can grow expensive as matrix size and coefficient height increase.
- `minimum_standard_basis_seeds(force=True)` removes only the dimension guard. It does not change the exponential search.
- The algebra basis is cached. The exposed generator dictionary and backend matrices should be treated as construction-time data rather than mutated after a basis has been computed.

Complexity and resource profile

Let n be the matrix degree, m the number of operators, $d_A \leq n^2$ the generated-algebra dimension, $d_H \leq n$ the orbit-hull dimension, q the length of a supplied algebra spanning family, and r the seed count.

Computation	Finite scale	Dominant work
Algebra closure	At most $d_A \leq n^2$ accepted matrices	Repeated $n \times n$ products and ranks of flattened $n^2 \times k$ matrices
Algebra storage	d_A matrices	$O(d_A n^2)$, at most $O(n^4)$ scalar entries
Seed hull	At most $d_H \leq n$ accepted vectors	Up to m matrix-vector applications per expanded independent vector, plus repeated ranks
Seed storage	d_H vectors	$O(d_H n)$, at most $O(n^2)$ scalar entries
Presentation	qr evaluated columns	Matrix-vector products followed by rank and nullspace of an $n \times qr$ matrix
Standard-basis search	Up to $2^n - 1$ nonempty subsets	A fresh finite hull computation for each tested subset
Single-operator rank	One exact $n \times n$ rational matrix	Characteristic polynomial, factorization over $\mathbb{Q}$, polynomial evaluation, exact ranks

The algebra and hull searches are bounded by finite-dimensional rank, but that does not make every instance cheap. The explicit `max_dimension=12` guard marks the library's clearest combinatorial boundary in this chapter.

What the shipped tests establish

The focused algebra, seed, and packet-operator replay executed 24 tests with 24 passes. Seventeen directly exercise the algebra and seed layer. The remaining seven confirm the adjacent packet-operator bridge. The Chapter 10 portion establishes at least these finite cases:

- Matrix units generate the full 2×2 algebra.
- A 3×3 Jordan block generates a three-dimensional polynomial algebra.
- A nilpotent generator produces an exact two-dimensional SymPy algebra.
- Algebra generators induce the expected reachable packet transfer graph.
- One seed generates a five-state cyclic shift, layer by layer.
- A coordinate-axis seed for a diagonal matrix has a proper one-dimensional hull.
- An evaluation presentation can have rank two and nullity zero.
- The standard-basis search returns all three coordinate vectors for a three-dimensional diagonal action.
- The dimension guard rejects the default search in dimension 13.
- The semisimple formula matches three supplied block profiles.
- The rational single-operator formula handles repeated linear and irreducible quadratic primary blocks.
- The rational path rejects an irrational SymPy entry.
- The direct-sum and tensor helpers return their declared values.

These tests validate implemented finite contracts and representative examples. They do not prove that a numerical tolerance is appropriate for arbitrary data, infer semisimplicity from a representation, turn the standard-basis diagnostic into an unrestricted seed-rank algorithm, or remove the exact-factorization cost boundary.

> **Chapter 10 summary.** `OperatorAlgebra` closes finite realized generators under multiplication and rank-increasing span. `SeedSystem` closes finite seeds under an acting family. Their certificates report whether those finite closures satisfy the requested algebra or generation condition at the backend's exactness level. Structural rank helpers add exact formulas and named bounds, but only under their stated semisimple, rational single-operator, direct-sum, or tensor assumptions.

11. Packet systems and transfer blocks

First route. Start with analysis and synthesis in Section 11.1.2, then use Section 11.2 to represent an operator between packets. Section 11.3 is the next step when you need reachability or paths. Before interpreting a returned array, identify whether it is an ambient vector, an embedded operator block, or a Boolean adjacency matrix. Their shapes and row conventions differ.

A packet system resolves one finite vector space into labeled pieces. A packet operator then resolves a linear map into every target-by-source transfer block, and a transfer graph forgets the coefficients while retaining which packet transfers are structurally active. These three levels answer different questions:

Level	Stored object	Question answered
packet geometry	projectors P_i	Which component of a vector lies in packet i?
packet operator	blocks $T_{ji} = Q_j T P_i$	How does the operator move source packet i into target packet j?
transfer graph	Boolean edges $i \to j$	Which packet-to-packet transfers are nonzero at the active tolerance?

The implementation is finite dimensional. With the optional SymPy backend it checks matrix equalities exactly. With the default NumPy backend it checks residual norms against a declared tolerance. The graph layer is combinatorial, but a graph extracted from a numerical operator inherits the support decisions made by the numerical zero test.

The main imports are:

```
from komorebi_math import (
    OperatorMorphism,
    PacketCoordinates,
    PacketMorphism,
    PacketOperator,
    PacketSystem,
    SeedMorphism,
    SupportPreorder,
    TransferGraph,
    block_from_paths,
    path_contributions,
)
```

`PacketSystem`, `PacketCoordinates`, `PacketOperator`, `TransferGraph`, `TransferPath`, `block_from_paths`, and `path_contributions` are also members of the frozen `komorebi_math.stable` namespace. `TransferPath` is not exported by the top-level research namespace, although it is the concrete type returned by `path_contributions`. Import that name from `komorebi_math.stable` or `komorebi_math.core` when a direct type reference is needed. `SupportPreorder` is available from the package root and `komorebi_math.core`, but not the stable namespace. The three morphism classes remain research-namespace APIs in `1.0.0b4`.

11.1 `PacketSystem` and `PacketCoordinates`

Let V be an n-dimensional space. A packet system is a nonempty labeled family of endomorphisms

$$P_i : V \to V, \qquad i = 0, \dots, r-1,$$

such that

$$P_i^2 = P_i, \qquad P_i P_j = 0 \quad (i \neq j), \qquad \sum_{i=0}^{r-1} P_i = I_V.$$

These are algebraic projectors. Self-adjointness is not part of the defining packet contract. Consequently, a valid packet decomposition can be oblique.

The constructor is:

```
PacketSystem(
    projectors: Sequence[Any],
    *,
    names: Sequence[str] | None = None,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float | None = None,
    validate: bool | None = None,
) -> None
```

The family must be nonempty. Every converted projector must be a square matrix, and all projectors must have one common shape. Omitted names become `P0`, `P1`, and so on. Supplied names are converted to strings, must have the same count as the projectors, and must be unique. An individual packet is allowed to have rank zero. Completeness concerns the family as a whole.

When `tolerance` is omitted, the active setting is copied into the object. When `validate` is omitted, the active `validate_on_construction` setting decides whether `certificate().require()` runs during construction. Its default is `True`. Passing `validate=False` allows an invalid family to exist for diagnostic inspection. It does not make that family valid.

11.1.1 Algebraic and Hilbert certificates

`PacketSystem.certificate()` computes three residuals:

$$\delta_{\mathrm{id}} = \max_i \|P_i^2 - P_i\|,$$
$$\delta_{\mathrm{ann}} = \max_{i \neq j} \|P_i P_j\|,$$
$$\delta_{\mathrm{sum}} = \left\| \sum_i P_i - I \right\|.$$

The returned `Certificate` uses theorem identifier `PSC-I-T20`. Under an exact backend it is valid exactly when all three residuals are zero. Under a numerical backend it is valid when all three are no larger than the packet tolerance. Its diagnostics record the backend name, ambient dimension, and packet count.

`hilbert_certificate()` is a separate check:

$$\delta_* = \max_i \|P_i - P_i^*\|.$$

It returns a valid certificate only when every packet is self-adjoint, exactly or within tolerance. It assumes the algebraic packet axioms. It does not rerun or combine the algebraic certificate. A caller needing orthogonal Hilbert packets should require both records:

```
packets.certificate().require()
packets.hilbert_certificate().require()
```

The distinction is substantive. Pairwise annihilation and completeness do not force self-adjointness.

11.1.2 Analysis, embedded coordinates, and synthesis

Analysis sends a vector to its packet projections:

$$\mathcal{A}_P : V \to V^r, \qquad \mathcal{A}_P(x) = (P_0 x, \dots, P_{r-1} x).$$

Synthesis adds the embedded components:

$$\mathcal{S}_P(c_0, \dots, c_{r-1}) = \sum_i c_i.$$

Completeness gives

$$\mathcal{S}_P \mathcal{A}_P(x) = \sum_i P_i x = x.$$

This API uses **embedded coordinates**: every `PacketCoordinates.values[i]` is still an ambient n-vector. It is not a compressed vector of length `rank(P_i)`. This choice makes reconstruction, block application, and transfer products uniform, but it means storing all packet values can use rn scalars even when the packets are low rank.

```
PacketCoordinates(
    system: PacketSystem,
    values: tuple[Any, ...],
) -> None

PacketSystem.analyze(vector: Any) -> PacketCoordinates
PacketSystem.synthesize(
    coordinates: PacketCoordinates | Sequence[Any] | Mapping[str, Any],
) -> Any
PacketSystem.support(vector: Any, *, tolerance: float | None = None) -> tuple[str, ...]

PacketCoordinates.reconstruct() -> Any
PacketCoordinates.support(*, tolerance: float | None = None) -> tuple[str, ...]
PacketCoordinates.__getitem__(key: int | str) -> Any
PacketCoordinates.as_dict() -> dict[str, Any]
```

`analyze` converts the input through the packet backend and requires ambient dimension n. `synthesize` accepts a coordinate object, a positional sequence, or a mapping whose keys match the packet names exactly. Every value must convert to an ambient n-vector. Coordinates produced by a different system are accepted only when that system is `equivalent` to the receiver.

The `PacketCoordinates` dataclass constructor itself is intentionally shallow: it stores the supplied tuple without checking its count, dimensions, or packet support. `PacketSystem.analyze` is the canonical producer. If coordinates are assembled directly, `reconstruct()` and `synthesize()` check the count and ambient vector dimensions, but they do not check $P_i c_i = c_i$. Only analysis guarantees packet-supported components. Direct callers must establish that stronger invariant themselves.

In practice, begin by obtaining coordinates from `analyze`, and use the same packet system for synthesis. If you later construct components manually, check their packet support as well as their lengths. Correctly sized ambient vectors can still assign a contribution to the wrong packet.

Integer indexing follows ordinary tuple indexing. String indexing resolves a packet name and raises `KeyError` when the name is absent. `support` reports the names whose embedded values are not zero under the selected tolerance. It is a support decision, not a rank or energy threshold.

This example was executed against the delivered source:

```
import numpy as np
from komorebi_math import PacketSystem

packets = PacketSystem(
    [np.diag([1, 0, 0]), np.diag([0, 1, 0]), np.diag([0, 0, 1])],
    names=("a", "b", "c"),
)
x = np.array([2.0, 0.0, -3.0])
coordinates = packets.analyze(x)

print(coordinates.support())
print({name: np.real_if_close(value).tolist()
       for name, value in coordinates.as_dict().items()})
print(np.real_if_close(coordinates.reconstruct()).tolist())
print(packets.packet_dimensions())

coarse = packets.aggregate({"ab": ("a", "b"), "c": ("c",)})
print(coarse.names)
print(coarse.packet_dimensions())
print(coarse.certificate().exactness.value)

A = np.arange(9.0).reshape(3, 3)
print(np.real_if_close(packets.block_diagonal_projection(A)).tolist())
```

Output:

```
('a', 'c')
{'a': [2.0, 0.0, 0.0], 'b': [0.0, 0.0, 0.0], 'c': [0.0, 0.0, -3.0]}
[2.0, 0.0, -3.0]
{'a': 1, 'b': 1, 'c': 1}
('ab', 'c')
{'ab': 2, 'c': 1}
numerical
[[0.0, 0.0, 0.0], [0.0, 4.0, 0.0], [0.0, 0.0, 8.0]]
```

The numerical label is correct even though the matrices contain exact-looking zeros and ones: this execution used the NumPy backend.

11.1.3 Structural operations on packet systems

The remaining packet methods transform or inspect the decomposition.

Method	Implemented map	Main precondition
`index(name)`	packet name to integer index	name must exist
`packet_dimensions()`	`name -> rank(P_i)`	rank follows backend semantics
`aggregate(groups)`	$\widetilde{P}_a = \sum_{i \in G_a} P_i$	groups partition every packet index exactly once
`tensor(other)`	$P_i \otimes Q_j$	both systems use the same backend name
`dual()`	$P_i \mapsto P_i^T$	no additional precondition
`equivalent(other)`	compare backend, dimensions, names, and projectors	numerical comparison uses a tolerance
`transport(C)`	$P_i \mapsto C P_i C^{-1}$	C is an invertible $n \times n$ matrix
`restrict(J,R)`	$P_i \mapsto R P_i J$	$RJ = I$ and $P_i J = J(R P_i J)$
`quotient(Q,S)`	$P_i \mapsto Q P_i S$	$QS = I$ and $Q P_i = (Q P_i S) Q$
`block_diagonal_projection(T)`	$T \mapsto \sum_i P_i T P_i$	T is an $n \times n$ operator

`aggregate` accepts packet names or indices. The values of the mapping must partition the integer index set exactly once: omissions, duplicates, and empty groups fail. Mapping insertion order determines the new packet order and names.

`tensor` produces names such as `left⊗right` in nested left-then-right order. The new tolerance is the maximum of the two input tolerances. Backend identity is checked by backend name.

`dual()` uses **transpose**, not conjugate transpose, despite the generated `name*` labels. It is the algebraic dual packet system. The Hilbert adjoint is used by `hilbert_certificate()` and by `PacketOperator.adjoint()`. For complex objects, do not substitute one operation for the other.

`transport` delegates invertibility to the backend inverse operation. With NumPy, a singular map therefore raises `numpy.linalg.LinAlgError`. It is not wrapped as a package validation exception. Restriction and quotient use declared splitting maps and explicitly verify both the split identity and packet invariance. They retain all packet labels, so a packet can descend to a zero-rank projector.

For example, restricting three coordinate packets to the first two coordinates and quotienting onto the last coordinate preserve all three names:

```
import numpy as np
from komorebi_math import PacketSystem

packets = PacketSystem(
    [np.diag([1, 0, 0]), np.diag([0, 1, 0]), np.diag([0, 0, 1])],
    names=("a", "b", "c"),
)

J = np.array([[1.0, 0.0], [0.0, 1.0], [0.0, 0.0]])
restricted = packets.restrict(J, J.T)

Q = np.array([[0.0, 0.0, 1.0]])
quotient = packets.quotient(Q, Q.T)

print(restricted.packet_dimensions(), restricted.certificate().valid)
print(quotient.packet_dimensions(), quotient.certificate().valid)
```

Output:

```
{'a': 1, 'b': 1, 'c': 0} True
{'a': 0, 'b': 0, 'c': 1} True
```

Finally, `block_diagonal_projection` means diagonal relative to the algebraic packet decomposition. For oblique packets it should not be described as an orthogonal projection in a Hilbert-space norm.

11.1.4 Exact oblique example

This optional-SymPy example separates the algebraic and Hilbert contracts:

```
import sympy as sp
from komorebi_math import PacketSystem

P0 = sp.Matrix([[1, 1], [0, 0]])
P1 = sp.eye(2) - P0
packets = PacketSystem((P0, P1), names=("u", "v"), backend="sympy")
coordinates = packets.analyze(sp.Matrix([2, 3]))
algebraic = packets.certificate()
hilbert = packets.hilbert_certificate()

print(tuple(tuple(value) for value in coordinates.values))
print(tuple(coordinates.reconstruct()))
print(algebraic.valid, algebraic.exactness.value, algebraic.residuals)
```

```
print(hilbert.valid, hilbert.residuals)
print(packets.dual().certificate().valid)
```

Output:

```
((5, 0), (-3, 3))
(2, 3)
True exact {'idempotence': 0.0, 'annihilation': 0.0, 'completeness': 0.0}
False {'self_adjointness': 1.4142135623730951}
True
```

The decomposition and reconstruction are exact. The failed Hilbert certificate does not invalidate the algebraic decomposition. It rejects the stronger claim that the packets are orthogonal.

11.2 `PacketOperator`

Let $P_i : V \to V$ be source packets and $Q_j : W \to W$ target packets. For a linear map $T : V \to W$, define the embedded block

$$T_{ji} = Q_j T P_i : V \to W.$$

Completeness on both sides gives

$$T = \left(\sum_j Q_j\right) T \left(\sum_i P_i\right) = \sum_{j,i} T_{ji}.$$

`PacketOperator` stores blocks as `blocks[target_index][source_index]`:

```
PacketOperator(
    source: PacketSystem,
    target: PacketSystem,
    blocks: tuple[tuple[Any, ...], ...],
) -> None

PacketOperator.from_operator(
    operator: Any,
    source: PacketSystem,
    target: PacketSystem | None = None,
) -> PacketOperator
```

When `target` is omitted, `from_operator` constructs an endomorphism over the source packet system. Source and target must use the same backend name. A rectangular ambient operator is allowed when it has shape `(target.dimension, source.dimension)`. Every stored block nevertheless has that full embedded shape. Blocks are not compressed rank-by-rank matrices.

The direct dataclass constructor verifies the block grid and matrix shapes, but it does not coerce blocks and does not automatically require the block-support certificate. `from_operator` is the canonical constructor for an ordinary ambient matrix. A caller constructing blocks directly should explicitly use

```
packet_operator.certificate().require()
```

before relying on packet support.

11.2.1 Reconstruction and action

The primary methods are:

```
reconstruct() -> Any
certificate() -> Certificate
apply(vector: Any) -> Any
apply_coordinates(coordinates: PacketCoordinates) -> PacketCoordinates
```

`reconstruct()` adds every block. `apply(vector)` reconstructs the ambient matrix and multiplies it by the source vector. `apply_coordinates()` instead performs block matrix multiplication in embedded coordinates:

$$d_j = \sum_i T_{ji} c_i.$$

It requires the coordinate system to be equivalent to the source system and returns a `PacketCoordinates` object tied to the target system.

`certificate()` reconstructs T, reprojects it through `from_operator(T, source, target)`, and checks

$$\delta_{\mathrm{block}} = \max_{j,i} \|B_{ji} - Q_j T P_i\|.$$

The theorem identifier is `PSC-I-T27`. The certificate is exact or numerical according to the backend and uses the maximum of the source and target packet tolerances. This check is especially important for directly supplied blocks.

11.2.2 Composition, adjoints, tensors, and powers

If $T : U \to V$ and $S : V \to W$, then packet composition is ordinary block matrix multiplication:

$$(S \circ T)_{ki} = \sum_j S_{kj} T_{ji}.$$

The method call is intentionally ordered as

```
left.compose(right)   # left after right
```

and requires `right.target.equivalent(left.source)`.

The remaining algebraic methods are:

```
adjoint() -> PacketOperator
tensor(other: PacketOperator) -> PacketOperator
is_endomorphism() -> bool
power(exponent: int) -> PacketOperator
block_norms() -> tuple[tuple[float, ...], ...]
is_block_diagonal(*, tolerance: float | None = None) -> bool
support_mask(*, tolerance: float | None = None) -> tuple[tuple[bool, ...], ...]
```

`adjoint()` conjugate-transposes every block, transposes the block grid, and swaps source with target. For self-adjoint packet systems this is the familiar Hilbert packet adjoint. For oblique packets, the returned direct block object is not automatically reprojected against algebraic dual packet systems. Require its certificate before asserting packet support.

`tensor` forms the Kronecker product of block pairs and uses tensor packet systems on both sides. `power` is defined only for packet endomorphisms and accepts nonnegative exponents. Exponent zero returns the packet-resolved ambient identity. Negative powers raise `ValueError`. Inverse packet powers are not implemented. Positive powers use repeated composition rather than binary exponentiation.

`block_norms` returns backend diagnostic norms as Python floats. Both `is_block_diagonal` and `support_mask` use the selected zero tolerance. `support_mask` retains the storage orientation: rows are targets and columns are sources.

This compact execution exercises the ambient and coordinate actions as well as the composition order:

```
import numpy as np
from komorebi_math import PacketOperator, PacketSystem

packets = PacketSystem(
    (np.diag([1, 0]), np.diag([0, 1])),
    names=("x", "y"),
)
T = np.array([[1.0, 2.0], [3.0, 4.0]])
S = np.array([[0.0, 1.0], [1.0, 0.0]])
t = PacketOperator.from_operator(T, packets)
s = PacketOperator.from_operator(S, packets)
v = np.array([1.0, 2.0])

print(np.real_if_close(t.reconstruct()).tolist())
print(np.real_if_close(t.apply(v)).tolist())
print(np.real_if_close(t.apply_coordinates(packets.analyze(v)).reconstruct()).tolist())
print(t.block_norms())
print(t.support_mask(), t.is_block_diagonal())
print(np.real_if_close(s.compose(t).reconstruct()).tolist())
print(np.real_if_close(t.adjoint().reconstruct()).tolist())
print(np.real_if_close(t.power(0).reconstruct()).tolist())
print(t.certificate().valid, t.certificate().exactness.value)
```

Output:

```
[[1.0, 2.0], [3.0, 4.0]]
[5.0, 11.0]
[5.0, 11.0]
((1.0, 2.0), (3.0, 4.0))
((True, True), (True, True)) False
[[3.0, 4.0], [1.0, 2.0]]
[[1.0, 3.0], [2.0, 4.0]]
[[1.0, 0.0], [0.0, 1.0]]
True numerical
```

11.3 `TransferGraph`, paths, and `TransferPath`

A `TransferGraph` is a finite directed graph. Its adjacency matrix uses the opposite indexing convention from the packet block grid:

$$\texttt{adjacency}[\texttt{source}][\texttt{target}] = \text{edge } source \to target.$$

For a packet endomorphism,

$$i \to j \quad \iff \quad T_{ji} \neq 0$$

under the active exact or tolerance-aware zero test. Thus

```
graph.adjacency[source][target]
    == operator.support_mask()[target][source]
```

The constructors are:

```
TransferGraph(
    adjacency: Sequence[Sequence[bool | int]],
    *,
    names: Sequence[str] | None = None,
) -> None

TransferGraph.from_packet_operator(
    operator: PacketOperator,
    *,
    tolerance: float | None = None,
) -> TransferGraph

TransferGraph.from_operator_family(
    operators: Iterable[PacketOperator],
    *,
    tolerance: float | None = None,
) -> TransferGraph
```

Direct adjacency entries are converted to Boolean values. The matrix must be nonempty and square. Names must be unique and match its order. Extraction from one operator requires a packet endomorphism. Extraction from a family requires a nonempty family using one equivalent packet system and takes the union of the individual support edges.

The graph query API is:

```
successors(vertex) -> tuple[int, ...]
predecessors(vertex) -> tuple[int, ...]
reachable(starts) -> frozenset[int]
paths(source, target, *, length) -> tuple[tuple[int, ...], ...]
strongly_connected_components() -> tuple[tuple[int, ...], ...]
condensation() -> tuple[TransferGraph, tuple[tuple[int, ...], ...]]
source_components() -> tuple[tuple[int, ...], ...]
is_acyclic() -> bool
topological_order() -> tuple[int, ...]
longest_path_vertices() -> int
source_component_certificate() -> ConditionalResult[int]
edges() -> Iterator[tuple[int, int]]
```

`reachable` includes every supplied start vertex. `paths` enumerates walks of **exactly** the requested edge length. Repeated vertices are allowed. At length zero it returns `(source,)` only when source equals target. A negative length raises `ValueError`. Enumeration materializes every matching path, so its time and memory can grow exponentially with length. There is no path-count resource guard in this API.

Strongly connected components are returned as sorted tuples in component order. `condensation()` removes within-component loops and returns the acyclic component graph together with the component membership. A self-loop makes a singleton component cyclic. `topological_order()` rejects every cyclic graph. `longest_path_vertices()` counts vertices rather than edges, so a one-vertex acyclic graph has value one.

`source_component_certificate()` deserves special care. It returns the number of source strongly connected components as a `ConditionalResult[int]` with theorem identifier `PSC-I-T44`. The certificate is intentionally conditional and leaves two assumptions unchecked:

- edge maps are surjective on the declared packet spaces
- each source component is generated by one packet-pure seed

The graph count is therefore not an unconditional seed-rank theorem.

11.3.1 `SupportPreorder`

`SupportPreorder` records a reflexive, transitive Boolean relation on packet labels. It is exported from the package root and `komorebi_math.core`, but not from the frozen stable namespace.

```
SupportPreorder(
    relation: Sequence[Sequence[bool | int]],
) -> None
```

The relation must be nonempty and square. Construction converts each entry to `bool`, then rejects a relation that is not reflexive or transitive. Its public queries are:

```
order -> int
is_reflexive() -> bool
is_transitive() -> bool
equivalence_classes() -> tuple[tuple[int, ...], ...]
strict_class_graph() -> TransferGraph
strict_ideal_nilpotency_bound() -> int
```

Mutual comparability defines the equivalence classes. Collapsing those classes and retaining only strict relations produces an acyclic transfer graph. If its longest class chain contains c vertices, then

$$I^c = 0$$

is the bound returned for the strict transfer ideal. For example, the preorder

$$\begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 \\ 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

has equivalence classes `((0, 1), (2,), (3,))` and nilpotency bound `3`. A merely reflexive but nontransitive matrix is rejected with `ValidationError`. The constructor does not silently take a transitive closure.

`TransferPath` is a frozen record:

```
TransferPath(vertices: tuple[int, ...], product: Any)
```

Its `length` property is `len(vertices) - 1`. The `product` is the full embedded matrix contribution attached to that path. Direct construction does not verify vertex incidence or consistency between the vertices and product. Normally consume these records from `path_contributions()`.

11.4 `block_from_paths` and `path_contributions`

For a packet endomorphism T, source packet a, target packet b, and nonnegative integer ℓ, the transfer-path identity is

$$(T^\ell)_{ba} = \sum_{\pi : a \to b,\ |\pi| = \ell} T_\pi,$$

where a path

$$\pi = (v_0 = a, v_1, \dots, v_\ell = b)$$

has ordered product

$$T_\pi = T_{v_\ell v_{\ell-1}} \cdots T_{v_2 v_1} T_{v_1 v_0}.$$

The two functions separate enumeration from certified summation:

```
path_contributions(
    operator: PacketOperator,
    *,
    source: int,
    target: int,
    length: int,
    tolerance: float | None = None,
) -> tuple[TransferPath, ...]

block_from_paths(
    operator: PacketOperator,
    *,
    source: int,
    target: int,
    length: int,
    tolerance: float | None = None,
) -> ComputationResult[Any]
```

Both require a packet endomorphism. `path_contributions` first extracts a transfer graph at the selected tolerance and returns one record for every structurally active path. At length zero, the only nonempty case is `source == target`, and its product is the source packet projector P_a. Neither function automatically requires `operator.certificate()`. Require that certificate first when the operator was assembled through the direct block constructor rather than `from_operator`.

`block_from_paths` sums the contributions, independently computes `operator.power(length).blocks[target][source]`, and certifies their difference:

$$\delta_{\mathrm{path}} = \left\| \sum_{\pi} T_{\pi} - (T^{\ell})_{ba} \right\|.$$

The resulting `ComputationResult` carries theorem identifier `PSC-I-T29` and records `path_count` and `length` in its diagnostics. Under an exact backend, validity requires zero residual. Under a numerical backend, it requires the residual to be at most the selected tolerance, defaulting to the source packet tolerance.

This certificate matters because the graph extraction can prune a small but nonzero numerical block. The path sum then represents the thresholded support graph, while the comparison target remains the full operator power. A valid certificate says the omitted contribution is within the same declared tolerance. It does not say that the omitted block was algebraically zero.

11.4.1 Diamond transfer example

This endomorphism has two length-two paths from packet zero to packet three:

$$0 \xrightarrow{2} 1 \xrightarrow{5} 3, \qquad 0 \xrightarrow{3} 2 \xrightarrow{7} 3.$$

Their contributions are 10 and 21, so the corresponding block of T^2 is 31.

```
import numpy as np
from komorebi_math import (
    PacketOperator, PacketSystem, TransferGraph,
    block_from_paths, path_contributions,
)

packets = PacketSystem(
    [np.diag([1 if i == j else 0 for i in range(4)]) for j in range(4)],
    names=("s", "u", "v", "t"),
)
T = np.array([
```

```
    [0, 0, 0, 0],
    [2, 0, 0, 0],
    [3, 0, 0, 0],
    [0, 5, 7, 0],
], dtype=float)
operator = PacketOperator.from_operator(T, packets)
graph = TransferGraph.from_packet_operator(operator)

print(operator.support_mask())
print(graph.adjacency)
print(tuple(graph.edges()))
print(graph.paths(0, 3, length=2))

parts = path_contributions(operator, source=0, target=3, length=2)
print([(path.vertices, path.length,
        np.real_if_close(path.product[3, 0]).item()) for path in parts])

result = block_from_paths(operator, source=0, target=3, length=2)
print(np.real_if_close(result.value[3, 0]).item())
print(result.valid, result.certificate.exactness.value,
      result.certificate.diagnostics)
print(np.real_if_close(operator.power(2).reconstruct()[3, 0]).item())
```

Output:

```
((False, False, False, False), (True, False, False, False), (True, False, False, False), (False, True, True, False))
((False, True, True, False), (False, False, False, True), (False, False, False, True), (False, False, False, False))
((0, 1), (0, 2), (1, 3), (2, 3))
((0, 1, 3), (0, 2, 3))
[((0, 1, 3), 2, 10.0), ((0, 2, 3), 2, 21.0)]
31.0
True numerical {'path_count': 2, 'length': 2}
31.0
```

The first two Boolean matrices visibly demonstrate the orientation reversal: the operator mask is target-by-source, while graph adjacency is source-by-target.

11.5 Operator, packet, and seed morphisms

Morphism certificates make declared compatibility equations executable. They do not infer the declaration. The caller supplies the operator-name map, packet-image map, and optional seed images to be checked.

11.5.1 `OperatorMorphism`

For source operators $A_a : V \to V$, target operators $B_b : W \to W$, a linear map $\Phi : V \to W$, and a declared name map $f : a \mapsto b$, the checked equation is

$$\Phi A_a = B_{f(a)} \Phi.$$

Construction should normally use:

```
OperatorMorphism.create(
    source_operators: Mapping[str, Any],
    target_operators: Mapping[str, Any],
    linear_map: Any,
    operator_map: Mapping[str, str] | None = None,
    *,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float = 1e-10,
) -> OperatorMorphism
```

The public record can also be instantiated directly with the manifested dataclass signature:

```
OperatorMorphism(
    source_operators,
    target_operators,
    linear_map,
    operator_map,
    backend,
    tolerance,
) -> None
```

That direct path performs no matrix conversion or shape validation. Use `create()` for the validated construction route.

When `operator_map` is omitted, it maps names in the intersection identically. Every explicitly mapped name must exist. The certificate stores one residual `source_name->target_name`, uses theorem identifier `PSC-I-T50`, and is exact or numerical according to the selected backend.

The mapping is allowed to be partial. Passing `{}` does not force an empty map: because `create()` uses the explicit mapping or the shared-name fallback, an empty dictionary still maps shared names identically. The factory produces an empty map only when the operator families have no shared names and no nonempty map is supplied. In that case the certificate has no residuals, and the universal check over the empty set is valid. The per-pair shape check is also vacuous. Therefore a meaningful morphism contract should provide a nonempty map covering every generator whose naturality is being claimed. `create()` converts matrices but does not perform a complete independent audit that every supplied operator is square.

11.5.2 `PacketMorphism`

A packet morphism supplies source packets P_i, target packets Q_j, a linear map Φ, and for every source name a tuple $F(i)$ of admissible target names. The certificate checks image containment:

$$\Phi P_i = \left(\sum_{j \in F(i)} Q_j \right) \Phi P_i.$$

Its constructor is the dataclass signature:

```
PacketMorphism(
    source: PacketSystem,
    target: PacketSystem,
    linear_map: Any,
    packet_map: Mapping[str, tuple[str, ...]],
) -> None
```

Source and target must use one backend. The map Φ must have shape `(target.dimension, source.dimension)`. `packet_map` must name every source packet exactly as a key, and every listed target name must exist. The certificate uses theorem identifier `PSC-I-T52`.

This is containment, not equality of packet ranges and not a claim that Φ is injective, surjective, or invertible. Empty target tuples are allowed and certify a source packet only when its image under Φ is zero. Target packets need not be used exactly once. Repeated names inside one tuple are not rejected structurally, but their projectors are added repeatedly and will normally cause a failed residual. Use duplicate-free tuples.

11.5.3 `SeedMorphism`

`SeedMorphism` combines operator intertwining with optional declared images of the source seeds:

```
SeedMorphism(
    source: SeedSystem,
    target: SeedSystem,
    linear_map: Any,
    operator_map: Mapping[str, str],
    seed_images: Sequence[Any] | None = None,
) -> None
```

It first applies the `OperatorMorphism` equation to the source and target seed systems. If expected seed images are provided, it additionally checks

$$\Phi s_i = \hat{s}_i$$

for every source seed. Its certificate uses theorem identifier `PSC-I-T50`. The expected vectors are caller declarations. The implementation does not independently require each $\hat{s}_i$ to equal a listed seed of the target system. When `seed_images=None`, no seed-vector residual is checked. A complete application-level claim should therefore declare and audit the intended target seed images explicitly.

11.5.4 Executed morphism example

```
import numpy as np
from komorebi_math import OperatorMorphism, PacketMorphism, PacketSystem

operator_morphism = OperatorMorphism.create(
    {"T": np.diag([1.0, 2.0])},
    {"S": np.diag([1.0, 2.0, 3.0])},
    np.array([[1.0, 0.0], [0.0, 1.0], [0.0, 0.0]]),
    {"T": "S"},
)
print(operator_morphism.certificate().valid)
print(operator_morphism.certificate().residuals)

fine = PacketSystem(
    [np.diag([1, 0, 0]), np.diag([0, 1, 0]), np.diag([0, 0, 1])],
    names=("a", "b", "c"),
)
coarse = fine.aggregate({"ab": ("a", "b"), "c": ("c",)})
packet_morphism = PacketMorphism(
    fine,
    coarse,
    np.eye(3),
    {"a": ("ab",), "b": ("ab",), "c": ("c",)},
)
print(packet_morphism.certificate().valid)
print(packet_morphism.certificate().residuals)
```

Output:

```
True
{'T->S': 0.0}
True
{'a': 0.0, 'b': 0.0, 'c': 0.0}
```

The first map embeds the two-dimensional source into the first two target coordinates, preserving its one-dimensional eigenspaces for eigenvalues one and two. The second map certifies that the fine packets `a` and `b` land inside the aggregate packet `ab`, while `c` remains in `c`.

11.5.5 Exactness, tolerances, and failure boundaries

The execution boundary can be summarized as follows.

Operation	Exact backend	NumPy backend	Conditional branch
packet axioms	exact matrix equalities	norm residuals at packet tolerance	none
Hilbert packet check	exact self-adjointness	adjoint residual at packet tolerance	none
packet-operator support	exact reprojection equality	maximum block residual at max source/target tolerance	none
path block identity	exact path sum	path residual at selected tolerance	none
graph support	exact structural zero	tolerance-aware structural zero	none
morphism equations	exact intertwining or containment	residual at morphism/packet tolerance	none
source-component count as seed rank	graph count is finite	graph count is finite	explicitly conditional on propagation assumptions

Exact backends still expose residuals as floating diagnostic values because the backend norm interface returns `float`. The exactness label comes from the backend's declared exact arithmetic and the equality branch used by the producer, not from the Python type of the residual field.

The important failure cases are:

Boundary	Failure behavior
empty packet family. Nonsquare or mixed-size projectors	`ValidationError` or `DimensionError` during construction
invalid packet axioms with ordinary validation enabled	invalid `PSC-I-T20` certificate is required and raises `ValidationError`
invalid packet axioms with `validate=False`	object is returned. `certificate().valid` is `False`
duplicate or wrong-count names	`ValidationError`
wrong analysis vector or synthesis coordinate dimensions	`DimensionError`
coordinate mapping missing or adding packet names	`ValidationError`
coordinates from a nonequivalent packet system	`ValidationError`
aggregate groups omit or repeat a packet	`ValidationError`
singular transport matrix	backend inverse exception, such as `numpy.linalg.LinAlgError`
invalid restriction split or noninvariant subspace	`ValidationError`
invalid quotient split or noninvariant kernel	`ValidationError`
direct packet blocks with wrong grid or embedded shape	`DimensionError`
direct packet blocks with correct shapes but wrong packet support	object exists. `PSC-I-T27` certificate is invalid
composition across nonequivalent intermediate packets	`ValidationError`
negative packet-operator power	`ValueError`
power, graph extraction, or path expansion for a nonendomorphism	`ValidationError`
empty operator family for a graph	`ValidationError`
out-of-range graph vertex	`IndexError`
negative path length	`ValueError`
topological order on a cyclic graph	`ValidationError`
malformed morphism maps or dimensions	`ValidationError` or `DimensionError`
well-shaped but false morphism equation	returned certificate has `valid=False`

A controlled packet failure demonstrates the difference between construction validation and diagnostic construction:

```
import numpy as np
from komorebi_math import PacketSystem
from komorebi_math.exceptions import ValidationError

projectors = (np.diag([1.0, 0.0]), np.diag([1.0, 0.0]))

try:
    PacketSystem(projectors)
except ValidationError as error:
    print(f"{type(error).__name__}: {error}")

diagnostic = PacketSystem(projectors, validate=False)
print(diagnostic.certificate().valid)
print(diagnostic.certificate().residuals)
```

Output:

```
ValidationError: projectors do not form a complete packet system
False
{'idempotence': 0.0, 'annihilation': 1.0, 'completeness': 1.4142135623730951}
```

`validate=False` is appropriate for inspecting why a proposed family failed. It should not appear as a way to suppress a failed mathematical premise in production code.

11.5.6 What the shipped tests establish

The focused packet, operator, transfer, graph, morphism, and quotient tests were executed together while preparing this chapter:

```
34 passed in 1.58s
```

Those tests establish these implemented finite contracts:

- packet analysis reconstructs the input and support names follow projected zero tests
- packet ranks, aggregation, tensors, algebraic duals, oblique-versus-Hilbert certification, and block-diagonal projection behave as declared
- coordinate transport, invariant restriction, and quotient descent produce valid packet systems in the tested cases
- packet operators reconstruct, apply in ambient and packet coordinates, compose in the stated order, take adjoints and tensors, and detect block diagonal structure
- positive powers agree with ambient matrix powers. Zero-length path blocks are packet identities
- fixed-length transfer paths reconstruct the tested operator-power block
- graph reachability, path enumeration, strongly connected components, condensation, topological rejection, and conditional source-component evidence follow the source-by-target convention
- valid and invalid operator intertwiners are distinguished, aggregate packet morphisms certify, and declared seed morphisms certify in the tested cases

These are finite source-level checks. They do not establish that a thresholded numerical edge is algebraically zero, that an arbitrary packet morphism is an isomorphism, that source-component count is an unconditional seed rank, or that enumerating long path families is computationally feasible.

Chapter 11 summary. A `PacketSystem` is an algebraic direct-sum decomposition represented by complete pairwise-annihilating idempotents. Orthogonality is a separate Hilbert certificate. `PacketCoordinates` retain ambient embedded vectors. A `PacketOperator` stores $T_{ji} = Q_j T P_i$ target-by-source and reconstructs by summation. A `TransferGraph` transposes that support mask into source-by-target adjacency. Fixed-length path products reconstruct blocks of operator powers, with `PSC-I-T29` recording the exact or tolerance-aware comparison. Morphism certificates check only the declared intertwining, image-containment, and seed-image equations. They do not infer missing declarations or promote conditional graph evidence into an unconditional theorem.

Chapter 12 refines these finite packet systems across multiple resolutions and adds explicit parent maps, compatibility certificates, common refinements, and weighted transfer structure.

12. Refinement towers

First route. Build and inspect one adjacent refinement in Section 12.1 before constructing a tower. Write down the parent of each fine packet and check a coarse-to-fine-to-coarse coordinate roundtrip. Section 12.2 then adds several levels. Weighted inverses and linear defects in Sections 12.3 to 12.4 are separate operator workflows and can be read when those tasks arise.

A packet system describes one decomposition of an ambient finite-dimensional space. A refinement records how a second packet system resolves every coarse packet into smaller packets without changing that ambient space. A refinement tower then chains several such resolutions.

This is not interpolation, resampling, or a change in vector dimension. If $P = (P_a)_{a \in A}$ is coarse and $Q = (Q_b)_{b \in B}$ is fine, both families act on the same vectors. The parent map

$$p : B \longrightarrow A$$

must satisfy

$$P_a = \sum_{b : p(b) = a} Q_b.$$

The library uses that identity in three related ways:

1. `PacketRefinement` moves packet coordinates and packet operators between two adjacent resolutions.
2. `RefinementTower` composes adjacent refinements, while `common_refinement()` constructs a shared fine level for two commuting packet systems.
3. `WeightedTransferGraph` and `LinearRefinementDefect` describe how operators move across packets or fail to intertwine across levels.

`PacketRefinement`, `RefinementTower`, and `common_refinement` are in the frozen stable namespace. Weighted transfer and defect propagation remain research APIs. Their evidence classes still use the certificate rules from Chapter 5.

12.1 `PacketRefinement`, parent maps, and compatibility

The stable constructor is

```
PacketRefinement(
    coarse: PacketSystem,
    fine: PacketSystem,
    parent_of_fine: tuple[int, ...],
) -> None
```

`parent_of_fine[b]` is the coarse index $p(b)$ assigned to fine packet Q_b. The direction matters: there is one tuple entry per fine packet, not one tuple entry per coarse packet.

Construction enforces these conditions.

Condition	Implemented check
Common scalar implementation	`coarse.backend.name == fine.backend.name`
Common ambient space	`coarse.dimension == fine.dimension`
Total parent map	`len(parent_of_fine) == len(fine)`
Valid parent indices	Every entry lies in `range(len(coarse))`
No empty coarse parent	Every coarse index occurs at least once
Projector reconstruction	$P_a = \sum_{p(b)=a} Q_b$ for every a

Condition	Implemented check

The last condition is checked by `certificate()` and required during `__post_init__`. Under an exact backend, every residual must be exactly zero. Under a numerical backend, each residual must be at most

$$\tau = \max(\tau_P, \tau_Q).$$

The returned certificate has theorem identifier `PSC-II-T03`. Its residual dictionary is keyed by coarse packet name, its checked assumptions are `"packet axioms"`, `"one parent per fine packet"`, and `"coarse projector equals child sum"`, and its exactness is inherited from the backend. A successful NumPy construction is therefore numerical even when every displayed residual is `0.0`.

The frozen record exposes `coarse`, `fine`, and `parent_of_fine` unchanged. Its read-only `backend` property is the coarse system's backend, which is also the fine system's backend after construction succeeds.

Ordinary `PacketSystem` construction validates the packet axioms before a refinement is made. If a caller created either endpoint with `validate=False`, the caller should require those packet certificates separately. `PacketRefinement.certificate()` verifies the parent-sum identity. It does not independently re-run both full packet-system certificates.

Parent and child queries

The address queries are

```
refinement.children(coarse_index: int | str) -> tuple[int, ...]
refinement.parent(fine_index: int | str) -> int
```

A string is resolved through the corresponding packet system's name table. The result of `children()` is an ordered tuple of fine indices in their original packet order. `parent()` always returns the integer coarse index, even when its input is a fine packet name.

Use valid integer indices. String lookups raise `KeyError` for unknown names, but the two methods do not impose a separate uniform integer-range guard: `children()` can return an empty tuple for an out-of-range integer, and normal Python tuple indexing governs integer input to `parent()`.

Coordinate refinement and coarsening

For an ambient vector x, write

$$c_a = P_a x, \qquad f_b = Q_b x.$$

Since each packet system is complete,

$$x = \sum_a c_a = \sum_b f_b.$$

The parent identity gives the exact coordinate law

$$c_a = P_a x = \sum_{b:p(b)=a} Q_b x = \sum_{b:p(b)=a} f_b.$$

The two methods implement that law in opposite directions:

```
refinement.coarsen(coordinates: PacketCoordinates) -> PacketCoordinates
refinement.refine(coordinates: PacketCoordinates) -> PacketCoordinates
```

`coarsen()` requires coordinates belonging to the fine system and explicitly sums the embedded fine coordinate vectors under each parent. `refine()` requires coordinates belonging to the coarse system, reconstructs their ambient vector, and analyzes that vector with the fine packet system:

$$(c_a)_a \xrightarrow{\sum_a} x \xrightarrow{(Q_b x)_b} (f_b)_b.$$

Thus refinement is defined by the projectors, not by arbitrarily dividing a coarse coordinate among its children. Both membership checks use `PacketSystem.equivalent()`. Equivalence includes the backend name, ambient dimension, packet count, packet names, and projector equality at the systems' tolerance. Two mathematically similar systems with different names are not interchangeable coordinate owners.

The coordinate-change claim is documented as `PSC-II-T04`. The methods return `PacketCoordinates` directly because construction already required the refinement certificate. They do not wrap each coordinate conversion in a new `ComputationResult`.

Operator resolution and support reflection

An ambient operator can be represented at either packet resolution:

```
refinement.refine_operator(operator: PacketOperator | Any) -> PacketOperator
refinement.coarsen_operator(operator: PacketOperator | Any) -> PacketOperator
```

If the input is a `PacketOperator`, the method first reconstructs its ambient matrix. Otherwise it treats the input itself as the ambient matrix. It then calls `PacketOperator.from_operator()` with the requested packet system. These methods therefore preserve the reconstructed operator, while the number and arrangement of stored blocks change with the packet resolution.

Support reflection has signature

```
refinement.support_reflection(
    coordinates: PacketCoordinates,
) -> dict[str, tuple[str, ...]]
```

Fine coordinates are used directly. Coarse coordinates are first refined. For each coarse packet with at least one active child, the result maps its name to the ordered names of its nonzero fine children. Zero tests use the fine system's tolerance. Coarse packets with no active fine child are omitted from the dictionary.

Worked example: one valid structural refinement on NumPy

This example was executed against the recorded reference source. Its packet identities have zero observed residual, but NumPy correctly produces a numerical certificate.

```
import numpy as np

from komorebi_math import PacketRefinement, PacketSystem

coarse = PacketSystem(
    [
        np.diag([1, 1, 0, 0]),
        np.diag([0, 0, 1, 1]),
    ],
    names=["left", "right"],
)
fine = PacketSystem(
```

```
    [
        np.diag([1, 0, 0, 0]),
        np.diag([0, 1, 0, 0]),
        np.diag([0, 0, 1, 0]),
        np.diag([0, 0, 0, 1]),
    ],
    names=["x0", "x1", "x2", "x3"],
)

step = PacketRefinement(coarse, fine, (0, 0, 1, 1))
x = np.array([0.0, 2.0, 0.0, 4.0])
fine_coordinates = step.refine(coarse.analyze(x))
back = step.coarsen(fine_coordinates)
certificate = step.certificate()

print("children(left):", step.children("left"))
print("parent(x3):", step.parent("x3"))
print("roundtrip:", np.real_if_close(back.reconstruct()).tolist())
print("support:", step.support_reflection(coarse.analyze(x)))
print(
    "certificate:",
    certificate.valid,
    certificate.exactness.value,
    certificate.residuals,
    certificate.theorem_id,
)
```

Output:

```
children(left): (0, 1)
parent(x3): 1
roundtrip: [0.0, 2.0, 0.0, 4.0]
support: {'left': ('x1',), 'right': ('x3',)}
certificate: True numerical {'left': 0.0, 'right': 0.0} PSC-II-T03
```

12.2 `RefinementTower` and `common_refinement`

Finite towers

`RefinementTower` accepts an ordered nonempty sequence:

```
RefinementTower(
    refinements: tuple[PacketRefinement, ...] | list[PacketRefinement],
) -> None
```

If the tuple is $(R_0, \dots, R_{L-1})$, its levels are

$$\mathcal{P}^{(0)}, \mathcal{P}^{(1)}, \dots, \mathcal{P}^{(L)},$$

where R_ℓ refines $\mathcal{P}^{(\ell)}$ into $\mathcal{P}^{(\ell+1)}$. The public `levels` property returns those $L+1$ packet systems. Construction requires the fine endpoint of every step to be equivalent to the coarse endpoint of the next step. As above, endpoint equivalence includes packet names and order, not merely an isomorphism between decompositions. The normalized tuple of adjacent steps remains available as `tower.refinements`.

The multilevel coordinate operations are

```
tower.refine(
    coordinates,
    *,
    source_level: int,
    target_level: int,
) -> PacketCoordinates

tower.coarsen(
    coordinates,
    *,
    source_level: int,
    target_level: int,
) -> PacketCoordinates
```

Both level indices must lie in `range(len(tower.levels))`. Refinement requires `target_level >= source_level`. Coarsening requires the opposite inequality. The coordinate owner must be equivalent to the declared source level. Equal source and target levels are legal identity operations and return the current coordinate object after the ownership check.

For addresses rather than coordinate values,

```
tower.descendant_address(
    coarse_index: int,
    fine_index: int,
    *,
    coarse_level: int,
    fine_level: int,
) -> bool
```

walks the fine index backward through the adjacent parent maps and reports whether it lands at the requested coarse index. It requires `fine_level > coarse_level`. This is a Boolean ancestry query. It does not return the intervening address tuple.

`tower.certificate()` combines every adjacent `PSC-II-T03` certificate into a `PSC-II-T05` certificate. Residual keys have the form `level_ell:coarse_name`. The tower is exact only when every local certificate is exact. Otherwise its combined exactness is numerical. This certificate establishes finite adjacent coherence. It does not claim that unrelated operators commute with the coordinate maps.

Worked example: a three-level tower

```
import numpy as np

from komorebi_math import PacketRefinement, PacketSystem, RefinementTower

coarsest = PacketSystem([np.eye(4)], names=["all"])
middle = PacketSystem(
    [
        np.diag([1, 1, 0, 0]),
        np.diag([0, 0, 1, 1]),
    ],
    names=["left", "right"],
)
finest = PacketSystem(
    [
        np.diag([1, 0, 0, 0]),
        np.diag([0, 1, 0, 0]),
        np.diag([0, 0, 1, 0]),
        np.diag([0, 0, 0, 1]),
    ],
    names=["x0", "x1", "x2", "x3"],
)

tower = RefinementTower(
    [
        PacketRefinement(coarsest, middle, (0, 0)),
        PacketRefinement(middle, finest, (0, 0, 1, 1)),
    ]
)
x = np.array([5.0, 6.0, 7.0, 8.0])
fine = tower.refine(
    coarsest.analyze(x), source_level=0, target_level=2
)
back = tower.coarsen(fine, source_level=2, target_level=0)

print("packet counts:", [len(level) for level in tower.levels])
print("fine reconstruction:", np.real_if_close(fine.reconstruct()).tolist())
print("coarse reconstruction:", np.real_if_close(back.reconstruct()).tolist())
print(
    "x3 descends from all:",
    tower.descendant_address(0, 3, coarse_level=0, fine_level=2),
)
certificate = tower.certificate()
print("certificate:", certificate.valid, certificate.exactness.value, certificate.theorem_id)
```

Output:

```
packet counts: [1, 2, 4]
fine reconstruction: [5.0, 6.0, 7.0, 8.0]
coarse reconstruction: [5.0, 6.0, 7.0, 8.0]
x3 descends from all: True
certificate: True numerical PSC-II-T05
```

Common refinements of commuting packet systems

Two packet systems on the same ambient space need not be ordered by refinement. When all of their projectors commute, their nonzero pairwise products form a common fine system. The stable function is

```
common_refinement(
    left: PacketSystem,
    right: PacketSystem,
    *,
    names: tuple[str, ...] | None = None,
) -> tuple[PacketSystem, PacketRefinement, PacketRefinement]
```

For left packets P_a and right packets Q_b, define

$$R_{ab} = P_a Q_b.$$

If $P_a Q_b = Q_b P_a$ for every pair, then

$$R_{ab}^2 = P_a^2 Q_b^2 = R_{ab}.$$

Distinct nonzero products annihilate because at least one of their left or right packet factors annihilates. Completeness follows from

$$\sum_{a,b} R_{ab} = \left(\sum_a P_a\right)\left(\sum_b Q_b\right) = I.$$

Finally,

$$\sum_b R_{ab} = P_a, \qquad \sum_a R_{ab} = Q_b,$$

so the result refines both inputs.

The implementation requires one backend name and one ambient dimension. It checks every commutator at the maximum input tolerance, generates products in left-major then right-minor order, and omits zero products. Default names are `"left_name & right_name"`. A supplied `names` tuple must match the number of retained nonzero packets, not the full Cartesian product size.

The return order is

```
(common_system, refinement_from_left, refinement_from_right)
```

The two refinement objects point from the respective input systems to the common system. Zero products do not appear in either parent tuple.

```
import numpy as np

from komorebi_math import PacketSystem, common_refinement

rows = PacketSystem(
    [
        np.diag([1, 1, 0, 0]),
        np.diag([0, 0, 1, 1]),
    ],
    names=["top", "bottom"],
)
columns = PacketSystem(
    [
        np.diag([1, 0, 1, 0]),
        np.diag([0, 1, 0, 1]),
```

```
    ],
    names=["even", "odd"],
)

common, to_rows, to_columns = common_refinement(rows, columns)

print("common names:", common.names)
print("row parents:", to_rows.parent_of_fine)
print("column parents:", to_columns.parent_of_fine)
print("packet count:", len(common))
```

Output:

```
common names: ('top & even', 'top & odd', 'bottom & even', 'bottom & odd')
row parents: (0, 0, 1, 1)
column parents: (0, 1, 0, 1)
packet count: 4
```

12.3 Weighted transfer graphs

A `WeightedTransferGraph` decomposes an ambient operator into a packet-diagonal part and supported directed transfers:

$$T = D + \sum_{e \in E} E_e.$$

For an edge $e : s(e) \to t(e)$, support means

$$E_e = P_{t(e)} E_e P_{s(e)}.$$

Every edge also has a positive integer weight $w(e)$. Path weights add:

$$w(e_k \cdots e_1) = \sum_{j=1}^{k} w(e_j).$$

The weights can be purely declared filtration data. With an exact SymPy backend and a prime p, they can instead be checked as lower bounds on the p-adic valuations of all edge entries.

Data records and constructor

The research interfaces are

```
WeightedTransferEdge(
    source: int,
    target: int,
    weight: int,
    operator: Any,
    name: str = "",
) -> None

WeightedPath(
    vertices: tuple[int, ...],
    edges: tuple[int, ...],
    weight: int,
) -> None

WeightedTransferGraph(
    packet_system: PacketSystem,
    diagonal: Any,
```

```
    edges: tuple[WeightedTransferEdge, ...] | list[WeightedTransferEdge],
    *,
    backend: str | LinearAlgebraBackend | None = None,
    prime: int | None = None,
    validate_weights: bool = True,
) -> None
```

`WeightedPath.edges` contains indices into `graph.edges`. `vertices` records the corresponding directed vertex sequence. Its `.length` property is `len(edges)`. Callers should normally use graph-generated paths rather than constructing inconsistent records manually, since `WeightedPath` itself is a plain frozen data record and does not validate incidence.

Graph construction enforces these structural rules.

Object	Required condition
Backend	Graph and packet system use the same backend name.
D	Ambient square shape, invertible, and packet diagonal, checked exactly on exact backends and at packet tolerance on numerical backends.
Edge address	Source and target are valid packet indices.
Edge matrix	Ambient operator shape and declared packet support, checked exactly on exact backends and at packet tolerance on numerical backends.
Weight	Declared as `int` and required at runtime to satisfy `weight > 0`.
Prime	`None` or a genuine prime.

Here “packet diagonal” means

$$D = \sum_a P_a D P_a.$$

It does not mean that D must be diagonal in the current coordinate basis. The constructor computes D^{-1} immediately. A singular diagonal part therefore fails with the selected backend’s inversion error before an inverse expansion can be requested.

When `prime=p`, `backend="sympy"`, and weight validation is enabled, the constructor additionally requires

$$\min_{i,j} v_p((E_e)_{ij}) \geq w(e)$$

for every edge. It also requires all entries of D and D^{-1} to have nonnegative p-adic valuation, placing both in filtration level zero. Zeros have infinite valuation. The declared weight is a lower bound, so it need not equal the minimum valuation.

The type annotation declares integer weights, but the edge data class does not perform a separate `isinstance(weight, int)` check. Supplying another positive numeric type can pass the positivity guard and then enter path arithmetic. Treat `int` as part of the public contract rather than relying on that runtime gap.

`validate_weights=False` bypasses those up-front valuation declarations, not the matrix-shape, packet-diagonal, or edge-support checks. It is an advanced escape hatch and should not be used to turn an unverified weight assignment into a claimed filtration.

The ambient dimension, reconstructed operator, and a copy of the diagonal inverse are available as properties:

```
graph.dimension
graph.operator
graph.diagonal_inverse
```

`dimension` is the ambient vector-space dimension, not the number of packet vertices.

Paths and minimum weights

`graph.adjacency()` returns one row per source packet. Each row consists of `(target, edge_index)` pairs in the original edge order. Parallel edges and self-loops are permitted.

All nonempty paths with total weight strictly below a threshold are enumerated by

```
graph.paths_below_weight(
    precision: int,
    *,
    source: int | None = None,
    target: int | None = None,
    max_paths: int | None = 1_000_000,
) -> tuple[WeightedPath, ...]
```

The strict inequality is important:

$$\mathcal{P}_{<q} = \{\pi : w(\pi) < q\}.$$

`precision <= 0` returns the empty tuple. Optional source and target filters restrict the returned paths, while the path-count guard limits generated search states. Positive weights make the set below a finite threshold finite, even when the graph has cycles, but its size can still grow rapidly. Results are sorted by weight, then length, vertices, and edge indices.

The least transfer weight is computed with a positive-weight shortest-path search:

```
graph.minimum_path_weight(source: int, target: int) -> int | float
```

It returns `0` when source equals target and `math.inf` when no directed path exists.

Filtered inverse expansion

Set

$$A_e = D^{-1}E_e.$$

Since

$$T = D\left(I + \sum_e A_e\right),$$

the formal inverse expansion is

$$T^{-1} = \sum_{k\geq 0}(-1)^k \left(\sum_e A_e\right)^k D^{-1}.$$

For a path $\pi = (e_1, \dots, e_k)$ in traversal order, the implemented path operator is

$$A_\pi D^{-1} = A_{e_k} \cdots A_{e_1} D^{-1}.$$

`graph.path_operator(path)` returns that matrix. The filtered truncation is

$$S_{<q} = D^{-1} + \sum_{\substack{\pi \neq \emptyset \\ w(\pi) < q}} (-1)^{|\pi|} A_\pi D^{-1}.$$

It is returned by

```
graph.truncated_inverse(
    precision: int,
    *,
    max_paths: int | None = 1_000_000,
) -> FilteredInverseExpansion
```

where `precision` must be positive. The output record contains

```
FilteredInverseExpansion(
    value,
    precision,
    included_paths,
    omitted_minimum_weight,
    certificate,
)
```

`omitted_minimum_weight` is the declared lower bound `precision`. It is not an independent search for the first omitted path. `.require()` requires the certificate and returns `value`.

There are two evidence paths.

Execution path	Certificate behavior
Exact backend plus prime	Computes the ordinary inverse, measures the minimum p-adic valuation of $T^{-1} - S_{<q}$, and requires it to be at least q. Exactness is `EXACT`.
Any other backend profile	Returns a valid `CONDITIONAL` certificate under the unchecked assumption that declared weights realize a complete multiplicative filtration.

The conditional path tries to compute the ordinary matrix inverse for a useful diagnostic. When available, it stores `ordinary_matrix_residual`. When the evaluated operator is singular, it sets `ordinary_inverse_available=False` and still returns the formal conditional truncation. This behavior is deliberate: the filtered word expression may be meaningful under the declared formal assumptions even when one numerical evaluation of T is singular. It must not be reported as an unconditional matrix inverse.

The truncation certificate uses theorem identifier `PSC-II-T10`. Its checked assumptions are packet support, positive path weights, and invertibility of the packet diagonal. In the conditional path it retains `"declared edge weights realize a complete multiplicative filtration"` as an unchecked assumption.

Exact inverse on an acyclic graph

If the directed packet graph is acyclic, no path has more than $N - 1$ edges, where N is the number of packets. The word expansion is then finite. The methods are

```
graph.is_acyclic() -> bool
graph.exact_inverse_if_acyclic(
    *, max_paths: int | None = 1_000_000
) -> ComputationResult[Any]
```

The second method rejects a cyclic graph, enumerates every possible acyclic path, compares the path sum to the backend's ordinary inverse, and returns a `PSC-II-C11` certificate. Exact backends produce exact evidence. Numerical

backends accept an inverse residual at the packet system's tolerance. This method does not require a prime because acyclicity terminates the expansion as an ordinary finite matrix identity.

Scalar transfer-series matrices

The graph also exposes a combinatorial generating matrix:

```
graph.weighted_adjacency(variable)
graph.transfer_series_matrix(variable)
```

Its target-row, source-column entry is

$$\mathcal{A}(z)_{t,s} = \sum_{e:s(e)=s,\ t(e)=t} z^{w(e)},$$

and the transfer series is

$$(I - \mathcal{A}(z))^{-1}.$$

This scalar matrix records graph incidence and weights. It does not contain the ambient edge operators E_e, their numerical coefficients, or the packet-diagonal operator D.

Worked example: an exact 2-adic weighted chain

This exact SymPy example has edge valuations at least their declared weights. All nonempty paths have weight below 4, so the depth-four truncation is the ordinary inverse.

```
import sympy as sp

from komorebi_math import (
    PacketSystem,
    WeightedTransferEdge,
    WeightedTransferGraph,
)

packets = PacketSystem(
    [sp.diag(1, 0, 0), sp.diag(0, 1, 0), sp.diag(0, 0, 1)],
    names=["a", "b", "c"],
    backend="sympy",
)
edges = [
    WeightedTransferEdge(
        0,
        1,
        1,
        sp.Matrix([[0, 0, 0], [2, 0, 0], [0, 0, 0]]),
        name="a_to_b",
    ),
    WeightedTransferEdge(
        1,
        2,
        2,
        sp.Matrix([[0, 0, 0], [0, 0, 0], [0, 4, 0]]),
        name="b_to_c",
    ),
]
graph = WeightedTransferGraph(packets, sp.eye(3), edges, prime=2)
paths = graph.paths_below_weight(4)
expansion = graph.truncated_inverse(4)
z = sp.symbols("z")
```

```
print("paths:", [(path.vertices, path.weight) for path in paths])
print("minimum 0->2:", graph.minimum_path_weight(0, 2))
print("operator:")
print(graph.operator)
print("truncated inverse:")
print(expansion.value)
print(
    "certificate:",
    expansion.certificate.valid,
    expansion.certificate.exactness.value,
)
print("series:")
print(graph.transfer_series_matrix(z))
```

Output:

```
paths: [((0, 1), 1), ((1, 2), 2), ((0, 1, 2), 3)]
minimum 0->2: 3
operator:
Matrix([[1, 0, 0], [2, 1, 0], [0, 4, 1]])
truncated inverse:
Matrix([[1, 0, 0], [-2, 1, 0], [8, -4, 1]])
certificate: True exact
series:
Matrix([[1, 0, 0], [z, 1, 0], [z**3, z**2, 1]])
```

Worked example: a conditional NumPy truncation

Here the only edge has declared weight 2, so no nonempty path is included at depth 2. With no exact prime-valuation profile, the identity matrix is a conditional filtered approximation rather than a certified ordinary inverse.

```
import numpy as np

from komorebi_math import (
    PacketSystem,
    WeightedTransferEdge,
    WeightedTransferGraph,
)

packets = PacketSystem(
    [np.diag([1, 0]), np.diag([0, 1])],
    names=["u", "v"],
)
edge = WeightedTransferEdge(
    0,
    1,
    2,
    np.array([[0.0, 0.0], [0.25, 0.0]]),
    name="u_to_v",
)
graph = WeightedTransferGraph(packets, np.eye(2), [edge])
expansion = graph.truncated_inverse(2)

print("value:", np.real_if_close(expansion.value).tolist())
print("paths:", len(expansion.included_paths))
print("exactness:", expansion.certificate.exactness.value)
print("unchecked:", expansion.certificate.assumptions_unchecked)
print(
    "ordinary residual:",
    expansion.certificate.residuals["ordinary_matrix_residual"],
)
```

Output:

```
value: [[1.0, 0.0], [0.0, 1.0]]
paths: 0
exactness: conditional
unchecked: ('declared edge weights realize a complete multiplicative filtration',)
ordinary residual: 0.25
```

The nonzero ordinary residual does not invalidate the conditional statement. It shows precisely why the result must not be relabeled as an exact or numerical ordinary inverse at this depth.

12.4 Linear refinement defects

A coordinate coarsening map need not intertwine a fine operator with a coarse operator. `LinearRefinementDefect` makes the failure explicit.

Let

$$C : V_f \longrightarrow V_c, \qquad T_f : V_f \longrightarrow V_f, \qquad T_c : V_c \longrightarrow V_c.$$

The defect is

$$\Delta = CT_f - T_cC.$$

Zero defect means that this diagram commutes. It does not mean that the two spaces, operators, or packet systems are equal.

The research constructor is

```
LinearRefinementDefect(
    coarsen: Any,
    fine_operator: Any,
    coarse_operator: Any,
    backend: str | LinearAlgebraBackend | None = None,
) -> None
```

If C has shape $m \times n$, the fine operator must be $n \times n$ and the coarse operator must be $m \times m$. Shape failures raise `DimensionError`. The `.matrix` property computes Δ, and

```
defect.is_exact(*, tolerance: float | None = None) -> bool
```

asks the backend whether that matrix is zero. Despite its name, the method uses the selected backend's zero test. Under a numerical backend the optional tolerance controls numerical zero. It returns only a Boolean, not a certificate.

Propagated identities

The remaining methods return `ComputationResult` objects and independently verify a finite matrix identity.

For a positive integer n, the power defect is

$$CT_f^n - T_c^nC = \sum_{k=0}^{n-1} T_c^{n-1-k}\Delta T_f^k.$$

It is implemented by

```
defect.power(exponent: int) -> ComputationResult[Any]
```

with theorem identifier `PSC-II-T20`. The exponent must be at least one.

If

$$f(z) = \sum_{k=0}^{d} a_k z^k,$$

then

$$Cf(T_f) - f(T_c)C = \sum_{k=1}^{d} a_k \sum_{j=0}^{k-1} T_c^{k-1-j} \Delta T_f^j.$$

The call

```
defect.polynomial(coefficients) -> ComputationResult[Any]
```

interprets `coefficients[k]` as a_k, so coefficients are in ascending power order. The constant term cancels and makes no defect contribution. Each nonzero positive-degree term is assembled through `power(k)`. The resulting certificate is `PSC-II-C21`.

For any z in both resolvent sets, define

$$R_f(z) = (zI_f - T_f)^{-1}, \qquad R_c(z) = (zI_c - T_c)^{-1}.$$

Then

$$CR_f(z) - R_c(z)C = R_c(z)\Delta R_f(z).$$

`defect.resolvent(z)` computes the right side, compares it with the direct difference, and returns a `PSC-II-T22` result. A singular requested resolvent fails through the backend's inversion error. No conditional resolvent is returned.

The exponential identity is the Duhamel formula

$$Ce^{tT_f} - e^{tT_c}C = \int_0^t e^{(t-s)T_c} \Delta e^{sT_f}\, ds.$$

`defect.exponential(t)` obtains the integral as the upper-right block of

$$\exp\left(t \begin{bmatrix} T_c & \Delta \\ 0 & T_f \end{bmatrix} \right)$$

and compares it with the direct exponential difference. The result carries theorem identifier `PSC-II-T24`. SymPy uses its exact matrix exponential. Numerical backends require SciPy's `scipy.linalg.expm`. If SciPy is unavailable, the method raises `BackendUnavailableError` and identifies the `scientific` extra.

The numerical residual bounds are method-specific:

Method	Residual name	Numerical acceptance bound
`power()`	`power_identity`	10^{-10}
`polynomial()`	`polynomial_identity`	10^{-10}
`resolvent()`	`resolvent_identity`	10^{-9}
`exponential()`	`exponential_identity`	10^{-8}

Exact backends require zero residual and store no tolerance. These residuals certify agreement between two finite evaluations of each identity. They do not bound modeling error between a chosen fine model and the phenomenon it is intended to represent.

Multilevel telescoping

For levels $V_0, \dots, V_L$, let

$$C_i : V_{i+1} \to V_i, \qquad T_i : V_i \to V_i, \qquad \Delta_i = C_i T_{i+1} - T_i C_i.$$

With

$$C_{[a,b)} = C_a C_{a+1} \cdots C_{b-1}, \qquad C_{[a,a)} = I,$$

the total defect telescopes as

$$C_{[0,L)} T_L - T_0 C_{[0,L)} = \sum_{i=0}^{L-1} C_{[0,i)} \Delta_i C_{[i+1,L)}.$$

The module-level research function is

```
multilevel_defect(
    coarsenings: Iterable[Any],
    operators: Iterable[Any],
    *,
    backend: str | LinearAlgebraBackend | None = None,
) -> ComputationResult[Any]
```

A chain with L coarsening maps requires exactly $L + 1$ operators. The result uses theorem identifier `PSC-II-T25`. NumPy accepts the telescoping residual at 10^{-9}, while an exact backend requires zero.

Worked example: exact propagation of a nonzero defect

This SymPy run chooses a nonintertwining coarsening map.

```
import sympy as sp

from komorebi_math import LinearRefinementDefect

C = sp.Matrix([[1, 0]])
T_f = sp.Matrix([[1, 2], [3, 4]])
T_c = sp.Matrix([[1]])
defect = LinearRefinementDefect(C, T_f, T_c, backend="sympy")

power_two = defect.power(2)
polynomial = defect.polynomial([3, 2, 1])  # 3 + 2z + z^2
resolvent = defect.resolvent(10)

print("delta:", defect.matrix)
print(
    "power two:",
    power_two.value,
    power_two.certificate.valid,
    power_two.certificate.exactness.value,
)
print("direct power two:", C * T_f**2 - T_c**2 * C)
print("polynomial:", polynomial.value)
print("resolvent:", resolvent.value)
```

Output:

```
delta: Matrix([[0, 2]])
power two: Matrix([[6, 10]]) True exact
direct power two: Matrix([[6, 10]])
polynomial: Matrix([[6, 14]])
resolvent: Matrix([[1/72, 1/24]])
```

The nonzero Δ is not a failed certificate. It is the mathematical quantity being propagated. The certificates validate the power, polynomial, and resolvent identities that express its consequences.

12.4.1 Exactness, result types, and API placement

The chapter's operations use several evidence patterns. Keep them distinct.

Operation	Return form	Possible exactness
`PacketRefinement.certificate()`	`Certificate`	Exact or numerical by backend
`RefinementTower.certificate()`	`Certificate`	Exact if all levels are exact, otherwise numerical
Coordinate and operator conversions	Raw typed value	Rely on the required construction certificate
`WeightedTransferGraph.truncated_inverse()`	`FilteredInverseExpansion`	Exact only for exact backend plus prime. Otherwise conditional
`exact_inverse_if_acyclic()`	`ComputationResult`	Exact or numerical by backend
Defect propagation methods	`ComputationResult`	Exact or numerical by backend

A particularly important boundary is

$$\text{exact matrix backend} \not\Rightarrow \text{exact filtered inverse certificate}.$$

The filtered inverse also needs an exact prime-valuation profile. SymPy without `prime=` takes the conditional path because no executed valuation check binds the declared weights to a complete filtration.

The imports are divided as follows.

Name	`komorebi_math` root	`komorebi_math.stable`	`komorebi_math.refinement`
`PacketRefinement`	Yes	Yes	Yes
`RefinementTower`	Yes	Yes	Yes
`common_refinement`	Yes	Yes	Yes
`WeightedTransferEdge`	Yes	No	Yes
`WeightedTransferGraph`	Yes	No	Yes
`LinearRefinementDefect`	Yes	No	Yes
`WeightedPath`	No	No	Yes
`FilteredInverseExpansion`	No	No	Yes
`multilevel_defect`	No	No	Yes

For a long-lived application that only needs packet refinement and common refinement, import the three stable names from `komorebi_math.stable`. Code using weighted transfer or defect propagation should pin the package version and treat those interfaces as research-tier APIs.

12.4.2 Failure contracts and edge cases

The principal controlled failures are summarized below.

Situation	Failure behavior
Coarse and fine backends differ	`ValidationError`
Ambient dimensions differ	`DimensionError`
Parent tuple has the wrong length	`DimensionError`
Parent is outside the coarse range	`ValueError`
A coarse packet has no child	`ValidationError`
Child sums do not reconstruct a coarse projector	Invalid `PSC-II-T03` certificate is required, raising `ValidationError`
Coordinates belong to the wrong endpoint	`ValidationError`
Empty tower	`ValueError`
Adjacent tower endpoints are not equivalent	`ValidationError`
Refinement requested toward a coarser level, or coarsening toward a finer level	`ValueError`
`refine()` or `coarsen()` level lies outside the tower	`IndexError`
Common-refinement inputs differ in backend or dimension	`ValidationError`
Common-refinement projectors do not commute	`ValidationError`
Weighted edge has negative index or nonpositive weight	`ValueError`
Weighted edge references an unknown packet	`ValueError`
Diagonal or edge has the wrong ambient shape	`DimensionError`
Declared diagonal is not packet diagonal	`ValidationError`
Edge is not supported on its declared source and target	`ValidationError`
Exact p-adic edge valuation falls below its declared weight	`ValidationError`
Composite `prime`	`ValidationError`
Nonpositive truncation precision	`ValueError`
Generated weighted paths exceed `max_paths`	`ValueError`
Exact finite inverse requested on a cyclic graph	`ValidationError`
Defect matrices have incompatible dimensions	`DimensionError`
Power defect exponent is below one	`ValueError`
A requested resolvent is singular	Backend inversion error
Numerical exponential requested without SciPy	`BackendUnavailableError`
L coarsenings are not paired with $L + 1$ operators	`DimensionError`

Four representative messages were reproduced from the delivered source:

```
ValidationError: every coarse packet must have at least one fine child
ValidationError: common refinement requires commuting packet systems
ValidationError: the packet transfer graph contains a directed cycle
ValueError: power defect exponent must be positive
```

Three subtleties deserve explicit treatment.

First, `descendant_address()` requires `fine_level > coarse_level`, but it does not perform the same explicit level and address range checks as `refine()` and `coarsen()`. Python negative indexing, an incidental `IndexError`, or a simple `False` result can therefore occur for malformed indices. Treat valid levels and packet addresses as caller preconditions for that query.

Second, `common_refinement()` omits zero product packets. Its generated names and parent tuples therefore need not have the full Cartesian length `len(left) * len(right)`.

Third, `paths_below_weight()` can safely traverse cycles only because weights are positive and the threshold is strict. The search remains combinatorial. Keep the default `max_paths` guard or choose a smaller task-specific bound when the graph is dense. Setting it to `None` removes the resource guard. It does not improve the mathematical guarantee.

12.4.3 Shipped pipeline and verification boundary

The repository includes `examples/refinement_pipeline.py`. It builds one two-level packet refinement, performs a roundtrip, constructs residue and CRT data used in Chapter 13, and computes an exact finite inverse for an acyclic weighted chain. Executed from the recorded reference repository, it prints

```
refinement levels: 2
CRT address: 29
minimum transfer weight 0 to 2: 3
```

The focused source replay for this chapter ran

```
tests/test_refinement_towers.py
tests/test_weighted_transfer.py
tests/test_linear_defects.py
```

and produced

```
21 passed
```

Those tests cover coordinate and operator roundtrips, support reflection, three-level coherence, commuting and non-commuting common refinements, exact acyclic inverses, weighted path ordering, conditional and exact p-adic truncations, valuation rejection, scalar transfer series, a singular conditional evaluation, path-count guards, composite-prime rejection, and all implemented linear defect identities.

Across Chapters 9 through 12, the combined focused replay contains **71 unique tests** and all 71 pass. The chapter-local replay counts above intentionally overlap where one module exercises both packet and algebra, or packet and transfer, contracts. They must not be added as if they were disjoint test sets.

> **Chapter 12 summary.** A refinement is a certified parent-sum law on packet projectors sharing one ambient space. Towers compose those laws. Commuting products build common fine packets. Weighted transfer expansions are exact only when their executed valuation or acyclicity checks justify that claim, and linear defects quantify rather than conceal a failure of operator intertwining.

13. Residue, CRT, lattice, and Smith coordinates

Choose by the question. Use residue analysis to split a finite list by index. Use nested addresses to describe a second split within each channel. Use CRT to satisfy simultaneous congruences with coprime moduli. Use the lattice and Smith sections when the input is an exact matrix or rational projector. The examples in Sections 13.2 to 13.3 deliberately use the same small numbers to show why nested addressing and CRT return different answers.

Integer addresses support four related but distinct finite coordinate systems. Residue coordinates split a sequence into congruence channels. Nested residue maps refine one such split by positional digits. Chinese-remainder maps identify one address from compatible residues modulo coprime factors. Lattice and Smith coordinates move exact rational packet data and prime-power congruences into bases where denominators and obstructions are visible.

These constructions share arithmetic notation, but they must not be conflated. The nested address $r + Ms$ works for every pair of positive moduli. CRT requires coprime factors and generally produces a different representative. The lattice and Smith paths require the optional SymPy exact dependency. There is no NumPy approximation of Smith reduction or lattice separation in this release.

The broad implementation surface lives in `komorebi_math.refinement`:

```
from komorebi_math.refinement import (
    LatticePacketData,
    SmithCongruenceProblem,
    crt_pair,
    nested_residue_address,
    residue_analyze,
)
```

`residue_analyze` and `crt_pair` are also convenient root exports. The frozen `stable`, `v1`, and `api.v1` namespaces include the residue-coordinate data path, but not the full CRT, lattice, and Smith research surface. Importing from the defining domain makes that boundary explicit.

13.1 Residue analysis and synthesis

$$x_r[k] = x[r + Mk].$$

For a positive modulus M, the channel with residue r contains the entries whose original indices are congruent to r:

$$x_r[k] = x[r + Mk], \qquad x[n] = x_{n \bmod M}\left[\left\lfloor \frac{n}{M} \right\rfloor\right].$$

The public record and functions are

```
ResidueCoordinates(
    modulus: int,
    channels: tuple[np.ndarray, ...],
    length: int,
)

residue_analyze(values: Any, modulus: int) -> ResidueCoordinates

residue_synthesize(
    channels: ResidueCoordinates | tuple[Any, ...],
```

```
    *,
    length: int | None = None,
) -> np.ndarray
```

`ResidueCoordinates.reconstruct()` is the canonical inverse. Its `refine(fine_modulus, copy=True)` and `coarsen(coarse_modulus, copy=True)` methods delegate to the finite polyphase refinement law developed in Chapter 14. `nested(inner_modulus)` instead returns one residue record for every outer channel.

Channel lengths may differ by one. If $L = qM + t$, with $0 \leq t < M$, the first t channels have $q + 1$ entries and the remaining channels have q. The constructor checks a positive modulus, the channel count, and a nonnegative declared length. Reconstruction performs the decisive ragged-length check. A manually assembled record with the wrong shape can therefore exist until it is reconstructed.

When `residue_synthesize` receives raw channels, it infers the output length from their total sizes unless `length=` is supplied. When it receives an existing `ResidueCoordinates`, the record's own length is authoritative.

Executed ragged-channel example

```
import numpy as np
from komorebi_math.refinement import residue_analyze, residue_synthesize

values = np.arange(17)
coordinates = residue_analyze(values, 5)

print(tuple(channel.tolist() for channel in coordinates.channels))
print(tuple(len(channel) for channel in coordinates.channels))
print(residue_synthesize(coordinates).tolist())
```

The audited output is

```
([0, 5, 10, 15], [1, 6, 11, 16], [2, 7, 12],
 [3, 8, 13], [4, 9, 14])
(4, 4, 3, 3, 3)
[0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16]
```

Residues also have an exact packet-system realization:

```
residue_packet_system(
    length: int,
    modulus: int,
    *,
    backend: str | LinearAlgebraBackend | None = None,
    names: tuple[str, ...] | None = None,
) -> PacketSystem

packet_coordinates_from_residues(
    values: Any,
    modulus: int,
    *,
    backend: str | LinearAlgebraBackend | None = None,
) -> PacketCoordinates
```

For ambient length L, the residue projector keeps standard coordinates with indices $n \equiv r \pmod{M}$. The packet certificate verifies idempotence, pairwise annihilation, and completeness on that finite ambient space. It does not turn an arbitrary infinite sequence into a finite object.

13.2 Nested residue addresses

Let r select a class modulo M, then let s select a class modulo K inside that outer channel. The flattened address is

$$a = r + Ms, \qquad 0 \le r < M, \quad 0 \le s < K.$$

The implementation is

```
nested_residue_address(
    outer_residue: int,
    outer_modulus: int,
    inner_residue: int,
    inner_modulus: int,
) -> int

nested_residue_analysis(
    values: Any,
    outer_modulus: int,
    inner_modulus: int,
) -> ResidueCoordinates
```

The returned flattened record has modulus MK. Its channel at $a = r + Ms$ equals the inner-s channel of the outer-r channel, so nested analysis is exactly direct residue analysis modulo MK. No coprimality condition is needed because this is positional refinement, not simultaneous congruence solving.

For example,

```
assert nested_residue_address(1, 4, 2, 3) == 9
```

The address 9 records outer digit 1 and inner digit 2. In the next section, the CRT solution for the congruences $x \equiv 1 \pmod 4$ and $x \equiv 2 \pmod 3$ is 5, not 9. That contrast is the simplest way to remember which map is being used.

13.3 Chinese remainder maps

$$x \equiv r_i \pmod{m_i}.$$

For positive pairwise-coprime moduli m_i, the Chinese remainder theorem provides one normalized address

$$0 \le x < \prod_i m_i, \qquad x \equiv r_i \pmod{m_i}.$$

The immutable result record is

```
CRTAddress(
    residue: int,
    modulus: int,
    residues: tuple[int, ...],
    moduli: tuple[int, ...],
)
```

Use the checked factories rather than constructing that record directly:

```
crt_pair(
    a: int,
    modulus_a: int,
    b: int,
    modulus_b: int,
) -> CRTAddress

crt_many(
```

```
    residues: Iterable[int],
    moduli: Iterable[int],
) -> CRTAddress

factor_residue(
    residue: int,
    moduli: Iterable[int],
) -> CRTAddress

dyadic_odd_factor(
    residue: int,
    dyadic_power: int,
    odd_modulus: int,
) -> CRTAddress
```

`crt_pair` and `crt_many` validate pairwise coprimality and normalize both the component residues and the combined residue. `factor_residue` starts from an integer, normalizes it modulo the product, and reports its residues. `dyadic_odd_factor(x, a, m)` is the specialized factorization modulo $2^a m$, with $a \geq 0$ and m positive and odd.

```python
from komorebi_math.refinement import crt_many, crt_pair, factor_residue

pair = crt_pair(1, 4, 2, 3)
assert pair.residue == 5
assert pair.modulus == 12
assert pair.residues == (1, 2)

many = crt_many((2, 3, 1), (3, 5, 7))
assert tuple(many.residue % m for m in many.moduli) == many.residues

assert factor_residue(53, (8, 5)).residues == (5, 3)
```

A direct `CRTAddress(...)` checks only the record's local consistency. It does not independently establish that its moduli are coprime. The factory functions are the public theorem-bearing path. Noncoprime moduli are rejected rather than silently changed into a generalized CRT problem.

13.4 Lattice packet data and exact separation

$$w_\alpha = \max\left(0, -\min_{i,j} v_p((B^{-1}P_\alpha B)_{ij})\right).$$

Residue channels organize addresses. `LatticePacketData` instead measures how an exact rational packet decomposition interacts with a chosen integer lattice. It is a SymPy-exact construction:

```
LatticePacketData(
    lattice_basis: Any,
    projectors: Any,
    *,
    prime: int,
    split_basis: Any | None = None,
)
```

If the columns of B are a lattice basis and P_α is a packet projector, then

$$\widetilde{P}_\alpha = B^{-1}P_\alpha B$$

is the projector in lattice coordinates. For prime p, zeros are assigned $v_p(0) = \infty$, and the denominator weight is

$$w_\alpha = \max\left(0, -\min_{i,j} v_p((\widetilde{P}_\alpha)_{ij})\right).$$

The finite packet hypotheses are checked exactly:

$$P_\alpha^2 = P_\alpha, \qquad P_\alpha P_\beta = 0 \quad (\alpha \neq \beta), \qquad \sum_\alpha P_\alpha = I.$$

Self-adjointness is not required. Oblique rational projectors are permitted. The main interface is

Member	Meaning
`dimension`	ambient lattice dimension
`certificate()`	exact packet/lattice construction certificate
`projector_in_lattice_basis(i)`	$B^{-1}P_iB$
`projector_weights()`	all w_i
`separation_weight`	$\max_i w_i$
`precision_delays()`	one `PrecisionDelay` per projector
`inclusion_matrix()`	$B^{-1}S$ for a supplied split basis S
`gluing_module()`	Smith invariants of the integral inclusion
`gluing_weight_certificate()`	exact comparison of gluing and separation weights

The valuation helpers are

```
padic_valuation(value: int, prime: int) -> int | float
rational_padic_valuation(value: Any, prime: int) -> int | float
```

Import these from `komorebi_math.refinement`. The root package has a different arithmetic `padic_valuation` export, so a domain-qualified import avoids a name collision.

Executed denominator example

```
import sympy as sp
from komorebi_math.refinement import (
    LatticePacketData,
    rational_padic_valuation,
)

p0 = sp.Matrix([[1, sp.Rational(1, 8)], [0, 0]])
p1 = sp.eye(2) - p0
data = LatticePacketData(sp.eye(2), [p0, p1], prime=2)

print(rational_padic_valuation(sp.Rational(3, 8), 2))
print(data.projector_weights())
print(data.separation_weight)
print(data.precision_delays()[0].input_depth(10))
```

The audited values are

```
-3
(3, 3)
3
13
```

The code assumes rational exact entries when weights are requested. Packet axioms alone do not exclude an algebraic irrational such as `sqrt(2)`. Such an entry can survive construction and then fail valuation conversion. Rationality is therefore a caller-visible hypothesis, not an inferred theorem.

13.5 Smith congruence problems

Smith coordinates diagonalize an integer matrix up to unimodular changes of basis. The shipped decomposition has

```
SmithDecomposition(
    matrix,
    diagonal,
    left,
    right,
    invariant_factors,
)

smith_decomposition(matrix: Any) -> SmithDecomposition
```

and satisfies

$$LAR = D.$$

`rank` is the number of nonzero Smith factors. `certificate()` directly checks the displayed matrix identity. The underlying SymPy algorithm supplies the unimodularity and invariant-factor divisibility properties. The certificate's assumption text names them, but this release does not independently recompute both properties inside the certificate.

Prime-power systems use

```
SmithCongruenceProblem(
    matrix: Any,
    rhs: Any,
    *,
    prime: int,
```

```
    depth: int,
)

solve() -> SmithCongruenceSolution
enumerate_solutions(*, limit: int = 100000) -> tuple[tuple[int, ...], ...]
```

For

$$Ax \equiv b \pmod{p^k}, \qquad b' = Lb,$$

let r be the Smith rank and

$$e_i = \min(v_p(d_i), k).$$

The transformed divisibility conditions are

$$b'_i \equiv 0 \pmod{p^{e_i}} \quad (i < r),$$

and every transformed zero row must vanish modulo p^k. With n unknowns, the exact solution count is

$$p^{(n-r)k+\sum_{i<r} e_i}.$$

The result record exposes all evidence needed to audit that conclusion:

```
solvable                prime
depth                   modulus
rank                    smith_factors
smith_exponents         transformed_rhs
obstruction_rows        solution_count
particular_solution     kernel_generators
certificate
```

An obstructed problem returns a valid exact certificate: the certificate establishes the obstruction. `result.require()` first requires that certificate and then raises because there is no solution.

Executed prime-power example

```
from komorebi_math.refinement import SmithCongruenceProblem

problem = SmithCongruenceProblem(
    [[2, 0, 0], [0, 4, 0], [0, 0, 0]],
    [2, 4, 0],
    prime=2,
    depth=3,
)
solution = problem.solve().require()

print(solution.smith_factors)
print(solution.smith_exponents)
print(solution.solution_count)
print(solution.particular_solution)
print(solution.kernel_generators)
```

Output:

```
(2, 4)
(1, 2)
64
(1, 1, 0)
((4, 0, 0), (0, 2, 0), (0, 0, 1))
```

Signed diagonal entries matter when the particular solution is reconstructed. The regression contract is

$$-2x \equiv 2 \pmod 8 \quad \Longrightarrow \quad x \in \{3, 7\}.$$

`enumerate_solutions` first rejects a known solution count above `limit`. For some dependent generator configurations its fallback can still inspect a much larger ambient modular space. The limit is a solution-count guard, not a strict bound on every internal loop.

13.6 Gluing modules, precision delays, and refinement-weight monotonicity

When a split basis S is supplied, `LatticePacketData` forms the inclusion matrix

$$C = B^{-1}S.$$

It must be integral and nonsingular. If the nonzero Smith factors are d_i, the `GluingModule(invariant_factors, prime)` record reports

$$|G| = \prod_i d_i, \qquad \text{length}_p(G) = \sum_i v_p(d_i), \qquad w_G = \max_i v_p(d_i).$$

Its public properties are `prime_exponents`, `separation_weight`, `length`, and `order`. This is not an arbitrary lattice-intersection algorithm: the caller provides the split basis, and the implementation checks the resulting integral containment and Smith data.

`PrecisionDelay(weight, prime, projector_index=None)` translates a requested output precision into the required input depth:

$$L_{\text{input}} = L_{\text{output}} + w.$$

The gluing example shipped in `examples/exact_lattice_separation.py` uses

$$P_0 = \begin{pmatrix} 1 & 1/4 \\ 0 & 0 \end{pmatrix}, \qquad P_1 = I - P_0, \qquad S = \begin{pmatrix} 1 & -1 \\ 0 & 4 \end{pmatrix},$$

and prints

```
projector weights: (2, 2)
gluing factors: (1, 4)
congruence solutions: 64
```

For a genuine fine decomposition of a coarse one, `refinement_weight_monotonicity(coarse, fine)` first finds the unique parent of every nonzero fine projector using two-sided containment,

$$P_\alpha Q_\beta = Q_\beta P_\alpha = Q_\beta,$$

then verifies that each coarse projector is exactly reconstructed by its children. Only after those checks does it certify

$$w_{\text{coarse}} \leq w_{\text{fine}}.$$

An unrelated decomposition cannot pass merely because its denominator weights happen to be larger. Zero fine projectors receive parent diagnostic `-1` and do not falsify the reconstruction law.

13.7 Exact, numerical, and failure examples

Residue analysis accepts NumPy data and can therefore carry integers, floats, or complex values. Its reconstruction is a finite reindexing, so it introduces no arithmetic error by itself. Packet certificates still follow the backend rules of Chapter 11. CRT, lattice valuation, gluing, and Smith congruence records are integer or rational constructions. The lattice and Smith branches require SymPy.

The main controlled failures are:

Condition	Public outcome
nonpositive residue modulus	validation failure
wrong residue channel count or ragged length	construction or reconstruction failure
noncoprime CRT moduli	checked factory raises
negative dyadic exponent or nonpositive/even odd factor	checked factory raises
singular lattice basis	validation failure
composite value supplied as `prime`	validation failure
nonprojector, overlapping, or incomplete packet family	exact packet validation failure
nonintegral or singular split inclusion	gluing validation failure
nonrational lattice entry during valuation	exact conversion failure
inconsistent Smith congruence	solvable is false. Obstruction is certified
exact solution count above enumeration limit	guarded enumeration failure
unrelated coarse and fine packet decompositions	refinement-parent validation failure

Python integers and SymPy rationals are unbounded. There is no explicit denominator-overflow exception or precision budget in this subsystem. Very large exact matrices can instead incur large time and memory costs. Callers that need a resource envelope should impose one before decomposition or enumeration.

The installed provenance identifiers used here are:

Identifier	Executed contract
`PSC-II-T06`	exact residue analysis/synthesis
`PSC-II-T07`	nested residue address
`PSC-II-T08`	two-modulus CRT
`PSC-II-C09`	many-modulus CRT
`PSC-II-D12`	lattice packet definition
`PSC-II-T13`	denominator/gluing weight facets
`PSC-II-T15`	refinement-weight monotonicity
`PSC-II-SNF`	integer Smith decomposition provenance
`PSC-II-T18`	prime-power Smith solve

`PSC-II-T13` labels two related provenance records. Read them as denominator and gluing facets of the same finite separation result, not as two unrelated theorems.

13.8 Strict portable refinement records and schema rejection

Only `ResidueCoordinates` among the Chapter 13 result types has a registered portable codec. There are no portable codecs in this release for `CRTAddress`, `LatticePacketData`, `GluingModule`, `PrecisionDelay`, `SmithDecomposition`, or `SmithCongruenceSolution`. Serialize those only through an application-defined format that records its own schema.

The Chapter 14 refinement plan objects have strict local dictionaries. For example,

```
PolyphaseRefinement(4, 12).to_dict()
```

returns

```
{
  "schema": "komorebi-math.polyphase-refinement",
  "schema_version": 1,
  "coarse_order": 4,
  "fine_order": 12
}
```

The three local schema names are

```
komorebi-math.polyphase-refinement
komorebi-math.polyphase-refinement-tower
komorebi-math.lattice-polyphase-refinement
```

Local parsers reject missing or extra fields, unknown schema names, and unsupported versions. Only `PolyphaseRefinement` supplies local `to_json`/`from_json`. The tower and lattice plans supply `to_dict`/`from_dict`.

Portable persistence uses the separate digest-checked envelope from Chapter 61. Its outer fields are exactly

```
schema  schema_version  producer_version  payload_sha256  payload
```

with schema `komorebi-math.portable` and version 1. The relevant codec tags are

Codec tag	Payload fields
`refinement.residue_coordinates`	`modulus`, `channels`, `length`
`refinement.polyphase`	`coarse_order`, `fine_order`
`refinement.polyphase_tower`	`orders`
`refinement.lattice_polyphase`	`coarse_strides`, `fine_strides`
`signals.polyphase_coordinates`	`channels`, `order`, `axis`, `original_shape`
`signals.lattice_polyphase_coordinates`	`channels`, `strides`, `original_shape`
`arithmetic.polyphase_coordinates`	`modulus`, `channels`, `length`

The loader rejects a malformed field set, unknown codec, unsupported version, duplicate JSON keys, and a payload digest mismatch before reconstructing the object. “Strict” here principally means field-strict. Some scalar values are coerced by local plan constructors, and `producer_version` is not part of the payload digest. Applications should not treat the envelope as a digital signature or an authorization mechanism.

The focused Chapter 13 replay covers six residue/CRT tests and ten lattice/Smith tests. The larger shipped deep audit executed 11,716 checks in the residue/CRT and Smith-congruence groups with zero failures. The test record supports the implemented finite contracts. It does not establish asymptotic performance or a numerical lattice backend.

> **Chapter 13 summary.** Residue coordinates split and exactly reassemble finite arrays. Nested digits and CRT solve different address problems. Rational packet projectors expose prime-adic denominator delays, while Smith coordinates turn a prime-power linear congruence into explicit obstruction, count, particular-solution, and kernel data. Portable coverage is intentionally narrower than the complete research surface.

14. Polyphase systems and refinement

Before the first refinement. Identify the record type in Section 14.1 and retain its original length or shape. For a one-dimensional plan, check that the fine order is divisible by the coarse order. For a lattice plan, check divisibility along every axis. Work through the address table in Section 14.2 before changing channel data, then compare refinement with direct fine analysis using the certificate described in Section 14.5.

Polyphase coordinates are residue coordinates with an explicit signal, arithmetic, or lattice realization. A refinement plan changes the channel order without first rebuilding the ambient object. Every implementation in this chapter is finite: it proves array reindexing and finite tower coherence, not convergence of an infinite refinement limit or existence of a continuum wavelet.

The complete surface is split across three domain namespaces:

```
import komorebi_math.signals as signals
import komorebi_math.arithmetic as arithmetic
import komorebi_math.refinement as refinement
```

The frozen `stable`, `v1`, and `api.v1` namespaces re-export the supported records and plan objects. The package root exposes only `PolyphaseSystem` and the signal `polyphase_analyze` from this family, so examples that need a refinement plan should import from `komorebi_math.refinement` or a versioned namespace.

14.1 Signal and arithmetic polyphase coordinates

There are four coordinate records, three one-dimensional and one lattice:

Record	Payload	Reconstruction target
`PolyphaseCoordinates`	NumPy channels, order, axis, original shape	NumPy array
`ResidueCoordinates`	NumPy channels, modulus, length	one-dimensional NumPy array
`ArithmeticPolyphase`	exact/general-number tuple channels, modulus, length	Python tuple
`LatticePolyphaseCoordinates`	address-to-array map, strides, original shape	NumPy array

The one-dimensional refinement union is exactly

```
PolyphaseCoordinateRecord = (
    PolyphaseCoordinates | ResidueCoordinates | ArithmeticPolyphase
)
```

It does not include `LatticePolyphaseCoordinates`. Lattice refinement has a separate class because its addresses are tuples.

Signal analysis and synthesis are

```
polyphase_analyze(
    signal: Any,
    order: int,
    *,
    axis: int = -1,
    copy: bool = True,
) -> PolyphaseCoordinates
```

```
polyphase_synthesize(
    coordinates: PolyphaseCoordinates,
) -> np.ndarray

PolyphaseSystem(order: int, axis: int = -1)
```

`PolyphaseSystem.analyze` and `.synthesize` bind the order and axis. A record exposes `reconstruct()`, `channel_lengths()`, `refine()`, `coarsen()`, `certificate(original, tolerance=...)`, and `dtype`. The analyzed axis can be any valid NumPy axis. The other dimensions remain attached to each channel.

The exact arithmetic path is

```
ArithmeticPolyphase(
    modulus: int,
    channels: tuple[tuple[Number, ...], ...],
    length: int,
)

arithmetic.polyphase_analyze(
    values: Iterable[Number],
    modulus: int,
) -> ArithmeticPolyphase

arithmetic.polyphase_synthesize(
    channels: Iterable[Iterable[Number]],
    length: int | None = None,
) -> tuple[Number, ...]
```

`ArithmeticPolyphase.reconstruct`, `.nested`, `.refine`, and `.coarsen` preserve the Python scalar values. Construct it through the analyzer when possible: the dataclass constructor does not have a post-initialization validator, whereas the analyzer enforces the public modulus/channel conventions.

For an M-channel record, signal and arithmetic channels obey the same law:

$$x_r[k] = x[r + Mk], \qquad 0 \le r < M.$$

With `copy=False`, signal refinement may retain NumPy slices where the layout permits. Coarsening necessarily allocates interleaved outputs in many cases. The flag is not a general promise of view semantics.

14.2 `PolyphaseRefinement` and `PolyphaseRefinementTower`

$$m_c \mid m_f, \qquad r_f = r_c + m_c q.$$

The canonical finite plan is

```
PolyphaseRefinement(
    coarse_order: int,
    fine_order: int,
)
```

Both orders must be positive non-Boolean integers and the coarse order must divide the fine order. Write $M = m_c$, $N = m_f$, and $K = N/M$. A fine address is split uniquely as

$$a = r + Ms, \qquad r = a \bmod M, \qquad s = \left\lfloor \frac{a}{M} \right\rfloor, \qquad 0 \le s < K.$$

At the level of channels,

$$\left(x_r^{(M)}\right)_s^{(K)} = x_{r+Ms}^{(N)}.$$

The implementation slices the parent channel `r` by `s::K`. It does not need to reconstruct and reanalyze the full signal. Coarsening performs the inverse interleaving. In projector notation the same law is

$$P_r^{(M)} = \sum_{s=0}^{K-1} P_{r+Ms}^{(N)}.$$

The address and execution surface is

Member	Result
`ratio`	$K = N/M$
`address(r, s)`	$r + Ms$
`split_address(a)`	`(r, s)`
`parent(a)`	coarse residue r
`child_digit(a)`	digit s
`children(r)`	all fine addresses over r
`parent_map`	parent of every fine residue
`refine(record, copy=True)`	fine coordinate record of the same concrete type
`coarsen(record, copy=True)`	coarse coordinate record
`certified_refine(...)`	fine record plus `KM-B15-T01` certificate
`certificate(...)`	refinement/roundtrip evidence
`compose(next_refinement)`	direct endpoint plan

Address-table example

```python
from komorebi_math.refinement import PolyphaseRefinement

plan = PolyphaseRefinement(2, 8)

print(plan.ratio)
print(plan.address(1, 3))
print(plan.split_address(7))
print(plan.children(1))
print(plan.parent_map)
```

Output:

```
4
7
(1, 3)
(1, 3, 5, 7)
(0, 1, 0, 1, 0, 1, 0, 1)
```

Exact residue refinement

```python
import numpy as np
from komorebi_math.refinement import (
    PolyphaseRefinement,
    residue_analyze,
)

values = np.arange(31)
```

```
coarse = residue_analyze(values, 4)
plan = PolyphaseRefinement(4, 12)
fine = plan.refine(coarse)
direct = residue_analyze(values, 12)

assert plan.coarsen(fine).reconstruct().tolist() == values.tolist()
assert all(
    np.array_equal(left, right)
    for left, right in zip(fine.channels, direct.channels, strict=True)
)
plan.certificate(coarse).require()
```

The coarse lengths are `(8, 8, 8, 7)`. The twelve fine channels are

```
(0,12,24), (1,13,25), (2,14,26), (3,15,27),
(4,16,28), (5,17,29), (6,18,30), (7,19),
(8,20), (9,21), (10,22), (11,23)
```

and the certificate is exact and valid.

Finite chains use

```
PolyphaseRefinementTower(
    orders: tuple[int, ...],
)
```

There must be at least two distinct orders and every order must divide the next. The public methods resolve a level, construct a direct refinement between two listed orders, refine or coarsen to a target order, enumerate descendants, evaluate a path address, and produce a coherence certificate.

For

$$M_0 \mid M_1 \mid \cdots \mid M_L,$$

the terminal address is

$$a_L = r + \sum_{j=0}^{L-1} M_j s_j, \qquad 0 \le s_j < M_{j+1}/M_j.$$

```
from komorebi_math.refinement import PolyphaseRefinementTower, residue_analyze

tower = PolyphaseRefinementTower((2, 6, 24))
coarse = residue_analyze(range(31), 2)

print(tower.descendants(1, 2, 24))
print(tower.path_address(1, (2, 3)))
tower.coherence_certificate(coarse).require()
```

The descendants are all odd addresses from 1 through 23, the path address is 23, and the exact sequential-versus-direct residual is zero. `KM-B15-T02` checks that coherence comparison. It does not itself check tower coarsening. Coarsening is exercised separately by the methods and tests.

14.3 Lattice polyphase refinement

For an array with one stride per dimension,

```
lattice_polyphase_analyze(
    signal: Any,
    strides: Iterable[int],
    *,
    copy: bool = True,
) -> LatticePolyphaseCoordinates

lattice_polyphase_synthesize(
    coordinates: LatticePolyphaseCoordinates,
) -> np.ndarray
```

creates one channel for each address tuple. A lattice record exposes `reconstruct`, `refine`, `coarsen`, `certificate`, and `dtype`.

The plan

```
LatticePolyphaseRefinement(
    coarse_strides: tuple[int, ...],
    fine_strides: tuple[int, ...],
)
```

requires equal positive dimension and componentwise divisibility. If $K_j = N_j/M_j$, then addresses split componentwise:

$$\mathbf{a} = \mathbf{r} + \mathbf{M} \odot \mathbf{s}, \qquad 0 \le s_j < K_j.$$

Each coarse address has $\prod_j K_j$ children. The coarse and fine channel counts are $\prod_j M_j$ and $\prod_j N_j$. Methods mirror the one-dimensional plan: `address`, `split_address`, `parent`, `children`, `refine`, `coarsen`, `certificate`, `compose`, `to_dict`, and `from_dict`.

For an array of shape `(6, 9)` and strides `(2, 3) -> (4, 9)`, the executed facts are

```
ratios               = (2, 3)
coarse channel count = 6
fine channel count   = 36
children of (1,2)    = ((1,2),(1,5),(1,8),(3,2),(3,5),(3,8))
roundtrip             = True
KM-B15-T03            = exact and valid
```

There is no lattice refinement tower class in this release. Compose compatible lattice plans explicitly when more than one level is needed.

14.4 Mixed-radix addresses

$$a = d_0 + r_0(d_1 + r_1(\cdots)).$$

Mixed-radix encoding generalizes the nested residue address. Digits are stored least-significant first:

$$a = \sum_{j=0}^{L-1} d_j \prod_{i<j} r_i, \qquad 0 \le d_j < r_j.$$

The signal helpers are

```
signals.mixed_radix_address(digits, radices) -> int
signals.split_mixed_radix_address(address, radices) -> tuple[int, ...]
```

and the arithmetic helpers are

```
arithmetic.mixed_radix_address(digits, radices) -> int
arithmetic.mixed_radix_digits(address, radices) -> tuple[int, ...]
```

The frozen namespace exports the latter pair as `arithmetic_mixed_radix_address` and `arithmetic_mixed_radix_digits`. The signal pair remains a domain/research API.

```
assert signals.mixed_radix_address((1, 2, 3), (2, 3, 5)) == 23
assert arithmetic.mixed_radix_address((2, 1, 3), (4, 3, 5)) == 42
```

Digit and radix counts must agree, every radix must be positive, and each digit must lie in its own half-open range. Decoding rejects an address outside the finite range represented by the declared radices. A scalar has no polyphase or lattice packet decomposition, so zero-dimensional shape shortcuts are not silently introduced.

14.5 Roundtrip and refinement certificates

The certificate family distinguishes basic signal reconstruction from refinement coherence:

Identifier	Checked equality	Evidence class
`PSC-V-T02`	signal analyze then reconstruct	numerical
`PSC-V-T04`	lattice analyze then reconstruct	numerical
`KM-B15-T01`	coarsen-after-refine and refined-vs-direct fine analysis	exact or numerical
`KM-B15-T02`	sequential tower refinement versus direct refinement	exact or numerical
`KM-B15-T03`	lattice coarsen-after-refine and refined-vs-direct analysis	exact or numerical

`KM-B15-T01` and `KM-B15-T03` record residual keys `coarsen_after_refine` and `direct_fine_analysis`. `KM-B15-T02` records `sequential_vs_direct_refinement` only. Arithmetic records and NumPy channels whose dtype is neither floating nor complex can produce `Exactness.EXACT` with zero residual and `tolerance=None`. Floating and complex paths use a norm-scaled tolerance and produce numerical evidence.

The basic `PolyphaseCoordinates.certificate` and `LatticePolyphaseCoordinates.certificate` remain numerical even for integer arrays. This is an API classification decision, not evidence that reindexing changed an integer value.

Only the `KM-B15-T01` implementation explicitly rejects negative, infinite, or NaN tolerance at this release. Callers should still pass a positive finite tolerance to every numerical certificate. The absence of validation in another entry point is not permission to use a nonsensical threshold.

Convenience functions construct the canonical plans:

```
refine_polyphase(coordinates, fine_order, *, copy=True)
coarsen_polyphase(coordinates, coarse_order, *, copy=True)
polyphase_refinement_certificate(coordinates, fine_order, *, tolerance=1e-12)
refine_lattice_polyphase(coordinates, fine_strides, *, copy=True)
coarsen_lattice_polyphase(coordinates, coarse_strides, *, copy=True)
```

The stable aliases `polyphase_refine`, `polyphase_coarsen`, `lattice_polyphase_refine`, and `lattice_polyphase_coarsen` are object-identical to those canonical functions.

Persistence and controlled failures

`PolyphaseRefinement` supports `to_dict`, `from_dict`, `to_json`, and `from_json`. Towers and lattice plans support the first two only. All three also have registered version-1 portable codecs in the digest-checked envelope described in Section 13.8.

Construction and execution reject nonpositive or Boolean orders, nondivisible endpoints, malformed addresses or child digits, wrong coordinate order, inconsistent child shapes, incompatible composition endpoints, duplicate or nondivisible tower orders, dimension/stride mismatch, and missing or extra schema fields. `copy=False` does not weaken any shape or address invariant.

The shipped `examples/block15_polyphase_refinement.py` executes all three plan families and prints

```
Block 15 polyphase refinement verified
```

The recorded polyphase-refinement tests contain 44 parameter-expanded refinement cases, 8 persistence cases, and 9 stable API/codec cases. The independent shipped audit records 39,070 comparisons with zero failures. Those checks establish finite addressing, roundtrip, coherence, and schema behavior. They do not claim an infinite inverse limit, regularity of a limit function, or wavelet convergence.

Chapter 14 summary. A polyphase record is a finite residue split with a concrete scalar and shape convention. A refinement plan factors a fine address into a coarse address and child digit, refines channels without an ambient reconstruction, and certifies equality with direct fine analysis. Towers and lattice plans extend that law finitely and componentwise.

Part IV. Coordinate calculus and analysis-synthesis systems

Reading route. Begin with the object you want to represent. Chapters 15 and 16 establish the common input, matrix-direction, and composition rules. The later chapters apply those rules to particular kinds of data.

Task	First destination	Useful next destination
Express a vector in a finite basis	Section 15.2	Section 15.3 for several named coordinate systems
Change basis or compose coordinate maps	Sections 16.1 to 16.3	Section 19.4 for transporting an operator
Change a polynomial's coefficient family	Section 17.5	Section 16.6 for differentiation and multiplication
Separate a sequence into initial values and recurrence defects	Section 18.3	Section 18.4 for state-space coordinates
Inspect a small spectral matrix or reorder indices	Sections 19.1 to 19.2	Chapter 32 for signal-analysis workflows
Represent a vector with redundant coefficients	Sections 20.1 to 20.2	Section 20.5 for maps and coefficient blocks

Most exact examples need only integer inputs and Python's `Fraction` type. The numerical spectral and frame examples use NumPy. Read the constructor's scalar contract before moving data between these layers. Also distinguish *degree* from *length*: a polynomial through degree four has five coefficient slots. The direction of a coordinate map tells you what its input tuple means, so retain source and target names beside any matrix saved or passed to another routine.

15. Coordinate objects

First route. Normalize exact input as described in Section 15.1, then follow the square-basis example in Section 15.2. If your vectors span only a subspace, use the rectangular example next. An atlas becomes useful when you have several named bases to connect. Affine and barycentric coordinates in Section 15.6 add an origin or simplex and can be read independently of atlas routing.

The coordinate package begins with a small exact algebra: dense, immutable tuples of rational numbers. On top of it, `FiniteBasis` represents a finite independent family, `CoordinateAtlas` routes exact changes of basis, and affine and barycentric objects add origins and simplex coordinates. These are finite computational objects, not symbolic manifold charts or sparse large-scale solvers.

The frozen basis surface is available from `komorebi_math.stable`, `komorebi_math.v1`, and `komorebi_math.api.v1`:

```
import komorebi_math.stable as km

standard = km.standard_basis(2, name="standard")
shear = km.basis_from_matrix("shear", ((1, 1), (0, 1)))
change = standard.connection_to(shear)
```

The complete object, exact-linear-algebra, atlas, budget, affine, and barycentric surface lives in `komorebi_math.coordinates`. `CoordinateSystem`, `CoordinateBudget`, the affine types, and several basis combinators are research APIs even though `FiniteBasis`, `CoordinateAtlas`, `standard_basis`, and `basis_from_matrix` are frozen.

15.1 Scalar, vector, matrix, and polynomial conventions

The exact aliases are

```
Scalar = int | Fraction
Vector = tuple[Fraction, ...]
Matrix = tuple[tuple[Fraction, ...], ...]
Polynomial = tuple[Fraction, ...]
```

A polynomial tuple uses ascending powers:

$$(a_0, a_1, \dots, a_n) \longleftrightarrow a_0 + a_1 x + \cdots + a_n x^n.$$

Polynomial helpers trim trailing zeros and use `(Fraction(0),)` as the canonical zero polynomial. Polynomial families are developed in Chapter 17, and polynomial operators in Section 16.6. Only the scalar and storage conventions are fixed here.

Normalize user inputs at the boundary:

```
from komorebi_math.coordinates import as_matrix, as_vector

v = as_vector((3, -2, 5))
A = as_matrix(((3, 1), (1, 2)))
```

`as_vector` and `as_matrix` reject Boolean coefficients and return immutable `Fraction` tuples. Integers and explicit `Fraction` values are the intended inputs. Although `Fraction(value)` accepts certain other Python values, a float such as `0.1` encodes its exact binary floating value, not the decimal rational $1/10$. Use `Fraction(1, 10)` when that rational is intended.

Low-level elimination functions are typed to an already normalized `Matrix`. Passing raw integer rows straight to such a helper can permit Python `/` to create floating intermediates. High-level constructors normalize automatically, but direct calls to `rref`, `determinant`, `inverse_matrix`, and related helpers should receive the output of `as_matrix`.

The dense exact primitives are

```
matrix_shape(matrix)
zero_matrix(rows, columns)
identity_matrix(size)
transpose(matrix)
matrix_add(left, right)
matrix_subtract(left, right)
matrix_multiply(left, right)
matrix_vector_multiply(matrix, vector)
matrix_power(matrix, exponent)
matrix_from_columns(columns)
```

The deep exact module also exposes `columns(matrix)` and `kronecker(left, right)`. Matrix shape, inner dimension, squareness, and nonnegative-exponent conditions are checked exactly. Some low-level operations admit mathematically meaningful empty matrices. Finite bases and coordinate transforms impose their own nonempty requirements. Avoid a blanket rule that every empty matrix is invalid.

15.2 `FiniteBasis`, standard bases, and basis matrices

```
FiniteBasis(
    name: str,
    vectors: tuple[Vector, ...],
    labels: tuple[str, ...] = (),
    description: str = "",
)
```

The `vectors` argument contains basis vectors. If $B = [b_0 \ \cdots \ b_{d-1}]$, then

$$x = Bc$$

is synthesis and exact analysis solves $Bc = x$. Vectors must be nonempty, share an ambient dimension, and be linearly independent. Missing labels become `b0`, `b1`, and so on. Properties report `dimension`, `ambient_dimension`, `matrix`, and whether the basis is `square`.

The principal methods are

```
synthesize(coordinates) -> Vector
analyze(vector) -> Vector
contains(vector) -> bool
connection_to(target, *, theorem="CC.B1", budget=DEFAULT_COORDINATE_BUDGET)
dual_rows() -> Matrix
gram_matrix() -> Matrix
orthogonal_projector() -> Matrix
certificate() -> Certificate
```

Rectangular bases represent exact subspaces. `analyze` rejects a vector outside the span, while `contains` turns scalar, shape, or span failure into `False`. For a square basis, the dual rows are B^{-1}. For any full-column-rank basis,

$$G = B^{\mathsf{T}}B, \qquad P = B(B^{\mathsf{T}}B)^{-1}B^{\mathsf{T}}.$$

The inner product here is ordinary rational Euclidean transpose, not a complex Hermitian or weighted product.

If square source and target bases have synthesis matrices B_s and B_t, then

$$C_{t \leftarrow s} = B_t^{-1} B_s.$$

For rectangular bases, `connection_to` additionally requires equal ambient dimension, equal basis dimension, and equal exact span. The result is the `CoordinateTransform` of Chapter 16.

Basis constructors

```
standard_basis(dimension: int, *, name: str = "standard")

basis_from_matrix(
    name: str,
    matrix: Iterable[Iterable[Scalar]],
    *,
    labels: Sequence[str] = (),
    description: str = "",
)

direct_sum_basis(left, right, *, name=None)
tensor_product_basis(left, right, *, name=None)
permutation_transform(permutation, *, source=..., target=...)
scaling_transform(scales, *, source=..., target=...)
```

`basis_from_matrix` receives a row-major matrix whose **columns** are the basis vectors. This differs from direct `FiniteBasis(...)`, which receives the vectors themselves.

When adapting input from another program, inspect one basis vector before construction. A list of vectors and a matrix with those vectors as columns have different outer layouts. For a square array, both layouts have the same shape, so a shape check alone will not reveal an accidental transpose.

Standard labels are zero-based `e0`, `e1`, and so forth. Direct-sum labels use `L:` and `R:`. Tensor order is left-outer lexicographic and labels use `⊗`. A permutation has semantics

```
target[i] = source[permutation[i]]
```

and a scaling transform is diagonal with all scale factors nonzero.

Executed square-basis contract

```
standard = standard_basis(2, name="standard")
shear = basis_from_matrix("shear", ((1, 1), (0, 1)))
change = standard.connection_to(shear)

assert change.matrix == ((1, -1), (0, 1))
assert change.apply((3, 5)) == (-2, 5)
change.certificate().require()
assert change.roundtrip_valid()
```

This behavior is frozen in the stable semantic fixture.

Rectangular plane example

```
from fractions import Fraction as Q
from komorebi_math.coordinates import basis_from_matrix

plane = basis_from_matrix(
    "plane",
    ((1, 0), (0, 1), (1, 1)),
    labels=("u", "v"),
```

```
)

print(plane.gram_matrix())
print(plane.orthogonal_projector())
print(plane.analyze((2, 3, 5)))
print(plane.contains((2, 3, 4)))
```

The exact results are

$$G = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}, \qquad P = \begin{pmatrix} 2/3 & -1/3 & 1/3 \\ -1/3 & 2/3 & 1/3 \\ 1/3 & 1/3 & 2/3 \end{pmatrix}.$$

Analysis returns `(2, 3)`, the second membership check is false, and `dual_rows()` raises because the ambient basis is not square. The projector satisfies $P^2 = P$ exactly.

15.3 `CoordinateAtlas`

An atlas is a finite directed graph whose vertices name coordinate systems and whose edges are exact transforms.

```
CoordinateSystem(
    name: str,
    dimension: int,
    kind: str = "exact",
    description: str = "",
)

CoordinateAtlas(name: str = "coordinate atlas")
```

System names must be nonempty, and dimensions are positive non-Boolean integers. `register_basis(basis)` adds a system with kind `finite_basis`. `register_system(system)` adds metadata directly.

```
atlas.register_transform(
    transform,
    *,
    include_inverse: bool = False,
    replace: bool = False,
)

atlas.direct_transform(source, target)
atlas.resolve(source, target) -> AtlasPath
atlas.compose_path(systems) -> AtlasPath
atlas.compare_paths(left, right) -> CommutingDiagramCheck
```

Transforms require registered endpoints with matching dimensions. Repeating identical metadata is idempotent. Conflicting metadata or an existing different edge is rejected unless replacement was requested. `include_inverse=True` requires a square nonsingular transform. One implementation caveat is that the forward edge is stored before inverse construction. If inversion fails, the forward edge can remain registered.

`resolve` uses deterministic breadth-first search: minimum edge count, with neighbors considered in lexical order. It returns

```
AtlasPath(
    systems: tuple[str, ...],
    transform: CoordinateTransform,
)
```

where `length` is the number of edges. Resolving a system to itself returns an identity path with theorem identifier `CC.A0`. `compose_path` follows only the edges explicitly named by the caller. It does not search for missing links.

Two paths with common named endpoints commute exactly when their composed matrices agree. `CommutingDiagramCheck` stores the left and right paths, Boolean `valid`, and the exact matrix `difference`. Its certificate records both routes rather than reducing the comparison to a bare Boolean.

```
from komorebi_math.coordinates import (
    CoordinateAtlas,
    CoordinateSystem,
    CoordinateTransform,
)

atlas = CoordinateAtlas("example")
for name in ("A", "B", "C"):
    atlas.register_system(CoordinateSystem(name, 2))

T_ab = CoordinateTransform("A", "B", ((1, 1), (0, 1)), "demo")
T_bc = CoordinateTransform("B", "C", ((1, 0), (1, 1)), "demo")
T_ac = T_ab.then(T_bc)

atlas.register_transform(T_ab)
atlas.register_transform(T_bc)
atlas.register_transform(T_ac)

check = atlas.compare_paths(("A", "B", "C"), ("A", "C"))
print(check.valid)
print(check.difference)
```

If the direct edge is perturbed in its lower-right entry, a representative diagnostic is

```
valid      = False
difference = ((0, 0), (0, 1))
```

The shipped `examples/general_coordinate_atlas.py` exercises deterministic route resolution and prints

```
path: ('standard', 'scaled')
scaled coordinates: (Fraction(7, 2), Fraction(-1, 1), Fraction(11, 5))
```

15.4 Coordinate budgets and resource guards

Chapter 6 introduced the failure semantics of

```
CoordinateBudget(
    maximum_matrix_dimension: int = 512,
    maximum_polynomial_degree: int = 512,
    maximum_horizon: int = 4096,
    maximum_exact_entries: int = 1_000_000,
)
```

Its methods are

```
require_matrix(rows, columns, *, operation)
require_degree(degree, *, operation)
require_horizon(horizon, *, operation)
```

Constructor limits are positive non-Boolean integers. Degree and horizon requests are nonnegative integers. A malformed request raises `ValidationError`, while a valid request beyond the declared limit raises `ResourceLimitError`.

The budget is explicit rather than ambient. `FiniteBasis.connection_to` checks the dimension-by-dimension output against its supplied budget, and several higher-level polynomial/formal constructors do likewise. Basis construction, analysis, RREF, inversion, projector construction, and the other low-level exact helpers do **not** automatically consult a global budget. A caller building large exact matrices should run the appropriate `require_*` method before invoking them.

This design keeps low-level functions deterministic and context-free, but it also means that importing or configuring a budget does not by itself constrain all exact work.

15.5 Exact finite linear algebra: solve, rank, nullspace, and RREF

The elimination surface is

```
rref(matrix: Matrix) -> tuple[Matrix, tuple[int, ...]]
matrix_rank(matrix: Matrix) -> int
determinant(matrix: Matrix) -> Fraction
inverse_matrix(matrix: Matrix) -> Matrix
solve_linear_system(
    matrix: Matrix,
    right_hand_side: Sequence[Scalar],
) -> ExactLinearSystem
nullspace(matrix: Matrix) -> tuple[Vector, ...]
```

`rref` chooses leftmost pivots. `nullspace` means the right nullspace, with basis vectors ordered by ascending free column. `solve_linear_system` returns

```
consistent
rank
solution
nullspace_basis
pivot_columns
residual
```

Free variables in the chosen particular solution are zero. A consistent system has exact zero residual. For an inconsistent system, `solution` is `None` and `residual` stores the original right-hand side. It is not a least-squares or minimum-norm residual.

Underdetermined worked example

```
from komorebi_math.coordinates import as_matrix, rref, solve_linear_system

A = as_matrix(((1, 1, 0), (0, 1, 1)))
result = solve_linear_system(A, (3, 5))

print(result.consistent)
print(result.rank)
print(result.solution)
print(result.nullspace_basis)
print(result.pivot_columns)
print(result.residual)
print(rref(A))
```

The exact record is

```
consistent      = True
rank            = 2
solution        = (-2, 5, 0)
nullspace_basis = ((1, -1, 1),)
pivot_columns   = (0, 1)
residual        = (0, 0)
```

The corresponding row-reduced matrix is

$$\operatorname{rref}(A) = \begin{pmatrix} 1 & 0 & -1 \\ 0 & 1 & 1 \end{pmatrix}.$$

Thus every solution is

$$x = (-2, 5, 0) + t(1, -1, 1).$$

For $A = ((1,), (1,))$ and $b = (1, 2)$, the result is inconsistent, has rank one, `solution=None`, and `residual=(1, 2)`.

There is no tolerance, pseudoinverse, sparse representation, matrix right-hand side, or backend choice in this exact layer. Those are separate numerical or specialized APIs.

15.6 Affine, local, and barycentric coordinates

An affine coordinate transform is

```
AffineCoordinateTransform(
    source: str,
    target: str,
    matrix: Matrix,
    offset: Vector,
    theorem: str = "CC.F1",
    description: str = "",
)
```

The transform acts by

$$y = Ax + b.$$

The linear matrix must be nonempty, square, and invertible at construction, and the offset must have matching dimension. The inverse is

$$(A, b)^{-1} = (A^{-1}, -A^{-1}b),$$

compatible affine maps compose by

$$(B, c) \circ (A, b) = (BA, Bb + c),$$

and the homogeneous representation is

$$H(A, b) = \begin{pmatrix} A & b \\ 0 & 1 \end{pmatrix}.$$

Methods apply, invert, compose, form the homogeneous matrix, and emit an exact certificate.

There is no separate generic `LocalCoordinateSystem` class. A square local chart is constructed by

```
affine_basis_transform(
    origin,
    basis_vectors,
    *,
    local_name="local affine coordinates",
    ambient_name="ambient Cartesian coordinates",
) -> AffineCoordinateTransform
```

A pure translation is constructed by

```
translation_transform(
    offset,
    *,
    source="original affine coordinates",
    target="translated affine coordinates",
) -> AffineCoordinateTransform
```

For origin `(3, -2)` and basis vectors `((1, 1), (1, -1))`, local coordinates `(5/2, -3/2)` map to Cartesian `(4, 2)`. The homogeneous matrix is

$$\begin{pmatrix} 1 & 1 & 3 \\ 1 & -1 & -2 \\ 0 & 0 & 1 \end{pmatrix},$$

and the inverse roundtrip is exact.

Full simplices use

```
BarycentricCoordinateSystem(
    name: str,
    vertices: tuple[Vector, ...],
)
```

A d-dimensional system requires exactly $d+1$ affinely independent vertices. The methods convert in both directions and certify the finite simplex:

$$x = \sum_i \lambda_i v_i, \qquad \sum_i \lambda_i = 1.$$

`to_cartesian(weights, require_affine=True)` checks the affine sum by default. It does not require $\lambda_i \geq 0$. Negative weights are valid affine coordinates, so this object does not test convex-simplex membership.

For vertices `((0, 0), (2, 0), (0, 3))`, weights `(1/6, 1/3, 1/2)` map to `(2/3, 3/2)` and roundtrip exactly. The weights `(2, -1, 0)` also satisfy the affine-sum rule and map to `(-2, 0)`, outside the triangle.

Evidence, persistence, and failure boundary

The principal exact theorem identifiers are

Identifier	Producer
`CC.B0`	`FiniteBasis.certificate()`
`CC.B1`	default basis connection
`CC.B2`	permutation transform
`CC.B3`	scaling transform
`CC.A0`	atlas identity path
`CC.A1`	composed atlas path
`CC.A2`	commuting-diagram check
`CC.F1`	direct affine transform
`CC.F2`	affine basis transform
`CC.F3`	barycentric system
`CC.F4`	translation transform

These labels identify implementation contracts. They are not links to a separate theorem registry. Exact solve, RREF, nullspace, and budget calls return data or raise. They do not emit certificates.

Portable version-1 codecs exist for budgets, systems, atlases, finite bases, affine transforms, and barycentric systems. Raw matrices and vectors, `ExactLinearSystem`, `AtlasPath`, and `CommutingDiagramCheck` have no standalone coordinate codec.

Controlled failures include ragged matrices, shape disagreement, singular inverse, inconsistent basis spans, a vector outside a rectangular span, duplicate incompatible atlas nodes or edges, a disconnected route, a singular affine matrix, degenerate simplex vertices, and barycentric weights that do not sum to one. Low-level exact operations remain dense and can become expensive. Apply an explicit budget before large work.

The focused source replay covers exact elimination, square and rectangular bases, projectors, atlas routing and commutation, affine and barycentric roundtrips, and portable reconstruction. The guide's perturbed noncommuting atlas path is a derived executable example. It is not separately shipped as an example file.

> **Chapter 15 summary.** Exact coordinate objects use immutable rational tuples. A finite basis synthesizes a vector, analyzes exact span membership, and constructs a change of basis. An atlas composes those changes along a deterministic finite graph. Budgets are explicit, and affine/barycentric objects add origins without claiming convex membership or manifold structure.

16. Exact and numerical coordinate transforms

First route. Choose the exact rational or numerical transform in Sections 16.1 to 16.2, then read the composition convention in Section 16.3 before combining maps. The remaining sections are task references: polynomial rules, normalization, recurrence reconstruction, state recovery, finite fields, and redundant coefficients. If the next operation needs an inverse, check the invertibility contract for your particular transform type.

A coordinate transform records direction, dimensions, coefficients, and provenance. The package has separate exact rational, NumPy numerical, affine, formal, and prime-field realizations. They use compatible composition conventions, but their certificates answer different questions. In particular, an exact transform certificate can validate a singular map as a well-formed linear transformation, while a numerical square-map certificate treats singularity as invalid for its inverse-residual contract.

Use `komorebi_math.coordinates` for the full chapter:

```
from komorebi_math import coordinates
```

`CoordinateTransform`, its true alias `ExactCoordinateTransform`, `NumericCoordinateTransform`, `FormalCoordinateChange`, and the numerical `AnalysisSynthesisSystem` are present on versioned compatibility surfaces as specified below. Several calculus, tensor, state-recovery, and modular helpers remain research APIs.

16.1 `CoordinateTransform` and `ExactCoordinateTransform`

$$[v]_{B_t} = B_t^{-1} B_s [v]_{B_s}.$$

The exact record is

```
CoordinateTransform(
    source: str,
    target: str,
    matrix: Matrix,
    theorem: str,
    description: str = "",
)
```

`ExactCoordinateTransform` is the same class object, not a subclass. It is exported from `komorebi_math.coordinates`, `stable`, `v1`, and `api.v1`, but not from the package root. The matrix is normalized to immutable rational tuples.

The convention is

$$c_t = T c_s, \qquad T \in \mathbb{Q}^{m \times n},$$

so rows count the target dimension and columns count the source dimension. A rectangular map can be applied and composed. Determinant and inverse are square-only.

```
source_dimension
target_dimension
square
determinant
apply(coordinates) -> Vector
inverse(*, theorem=None) -> CoordinateTransform
then(following, *, theorem=None) -> CoordinateTransform
```

```
roundtrip_valid() -> bool
certificate() -> Certificate
```

For synthesis bases B_s and B_t, the change-of-basis formula is the one displayed above. Inputs are intended to be integers or `Fraction` values. A float is converted to its exact binary rational, which is rarely the desired symbolic coefficient.

Exact composition example

```
from fractions import Fraction as Q
from komorebi_math.coordinates import CoordinateTransform

T = CoordinateTransform("A", "B", ((1, 2), (0, 1)), "T")
U = CoordinateTransform("B", "C", ((2, 0), (3, 1)), "U")
x = (Q(3), Q(5))

composed = T.then(U)

print(T.apply(x))
print(composed.matrix)
print(composed.apply(x))
print(composed.inverse().apply(composed.apply(x)))
print(composed.roundtrip_valid())
```

Output:

```
(Fraction(13, 1), Fraction(5, 1))
((Fraction(2, 1), Fraction(4, 1)),
 (Fraction(3, 1), Fraction(7, 1)))
(Fraction(26, 1), Fraction(44, 1))
(Fraction(3, 1), Fraction(5, 1))
True
```

A singular square exact transform is representable. Its certificate remains valid because the record is a valid linear map. Diagnostics report `invertible=False`, `roundtrip_valid()` returns false, and `inverse()` raises. Code that needs an isomorphism must check the diagnostic or roundtrip rather than assuming `certificate().require()` proved invertibility.

16.2 `NumericCoordinateTransform`

```
NumericCoordinateTransform(
    source: str,
    target: str,
    matrix: np.ndarray,
    theorem: str = "CC.NM1",
    description: str = "",
    tolerance: float = 1e-12,
)
```

The constructor copies a finite two-dimensional NumPy matrix, marks it read-only, and requires a positive finite tolerance. `apply`, `inverse`, `then`, `condition_number`, and `certificate` mirror the exact class. Composed maps use the larger of the two tolerances.

For a square nonsingular matrix, the certificate computes

$$r = \max(\|T^{-1}T - I\|_\infty, \|TT^{-1} - I\|_\infty)$$

and accepts the inverse contract when

$$r \le \tau \max(1, \kappa_2(T)).$$

Shape/state	Constructible?	Certificate	Inverse
rectangular finite	yes	valid structural numerical record	dimension failure
square nonsingular	yes	inverse residual and condition diagnostic	numerical inverse
square singular	yes	invalid, with `singular=True`	validation failure
empty, nonmatrix, nonfinite	no	not produced	not available

An ill-conditioned but nonsingular matrix is not rejected solely because of its condition number. Conditioning is recorded so the caller can choose an application threshold.

Do not compare two independent numeric-transform dataclasses with plain `==`: the NumPy array comparison can have an ambiguous truth value. Compare fields and matrices with `np.array_equal` or `np.allclose`.

Spectral constructors

```
discrete_fourier_transform(size, *, unitary=True, inverse=False, tolerance=1e-12)
discrete_cosine_transform(size, *, orthonormal=True, tolerance=1e-12)
walsh_hadamard_transform(size, *, orthonormal=True, tolerance=1e-12)
haar_wavelet_transform(size, *, orthonormal=True, tolerance=1e-12)
modal_coordinate_system(operator, *, state_name=..., modal_name=..., tolerance=1e-10)
```

The unitary DFT uses

$$F_{kn} = N^{-1/2} e^{-2\pi i k n / N},$$

and the orthonormal DCT-II uses

$$C_{kn} = \alpha_k \cos\left(\frac{\pi(n + 1/2)k}{N}\right), \quad \alpha_0 = N^{-1/2}, \quad \alpha_k = (2/N)^{1/2}.$$

Walsh-Hadamard and Haar sizes must be positive powers of two. Modal coordinates require a finite square operator with a complete numerical eigenvector basis. None of these constructors upgrades floating evidence to an exact identity.

16.3 Composition, inversion, and transport

If $T : A \to B$ and $U : B \to C$, then

```
T.then(U)
```

means $U \circ T$ and stores

$$UT,$$

not TU. Labels must agree exactly and the intermediate dimensions must match. Consequently,

$$(UT)^{-1} = T^{-1} U^{-1}.$$

The exact tensor-transport surface includes

```
contragredient_transform(transform)
transport_covector(covector, transform)
transport_operator(operator, transform)
transport_rectangular_operator(operator, domain_transform, codomain_transform)
transport_bilinear_form(form, transform)
tensor_coordinate_transform(transform, variance)
transport_tensor_components(components, transform, variance)
tensor_product_transform(left, right)
direct_sum_transform(left, right)
coordinate_pairing(covector, vector)
pairing_invariant(covector, vector, transform)
```

For $v' = Tv$, the standard laws are

$$\alpha' = T^{-\mathsf{T}}\alpha, \qquad A' = TAT^{-1}, \qquad G' = T^{-\mathsf{T}}GT^{-1}.$$

For a rectangular operator $A : X \to Y$ with separate coordinate changes,

$$A' = T_Y A T_X^{-1}.$$

Each contravariant tensor axis contributes T. Each covariant axis contributes $T^{-\mathsf{T}}$. Ordered Kronecker products act on lexicographically flattened components. The rank-zero variance list produces a 1×1 identity.

```python
from komorebi_math.coordinates import (
    CoordinateTransform,
    coordinate_pairing,
    pairing_invariant,
    transport_bilinear_form,
    transport_covector,
    transport_operator,
)

T = CoordinateTransform("old", "new", ((2, 1), (1, 1)), "T")
v = (3, -2)
alpha = (5, 7)

print(T.apply(v))
print(transport_covector(alpha, T))
print(transport_operator(((1, 2), (3, 4)), T))
print(transport_bilinear_form(((2, 1), (1, 3)), T))
print(coordinate_pairing(alpha, v), pairing_invariant(alpha, v, T))
```

The audited output ends with `1 True`. The transformed vector is `(4, 1)` and the transformed covector is `(-2, 9)`. Covector, operator, form, and positive-rank tensor transport require a square nonsingular exact transform. Even an all-contravariant positive-rank tensor currently computes the inverse during construction, so nonsingularity is an implementation requirement. Parallel NumPy transport helpers are not shipped.

16.4 Affine and formal coordinate changes

The affine class, local-basis helper, translations, and barycentric systems were introduced in Section 15.6. Their composition law remains

$$(B, c) \circ (A, b) = (BA, Bb + c),$$

and an affine map rejects a singular linear part at construction.

Formal changes are finite jets:

```
FormalCoordinateChange(
    name: str,
    coefficients: Vector,
    source: str = "source formal coordinate",
    target: str = "target formal coordinate",
)
```

With ascending coefficients,

$$\phi(z) = a_0 + a_1 z + \cdots + a_N z^N,$$

the constructor enforces

$$a_0 = 0, \qquad a_1 \neq 0, \qquad N \geq 1.$$

The object reports `degree` and `linear_coefficient` and provides

```
truncate(degree)
compose(inner, *, degree=None, name=None)
inverse(*, degree=None, name=None)
pullback_coefficients(coefficients, *, degree=None)
pushforward_coefficients(coefficients, *, degree=None)
substitution_transform(degree=None, *, budget=DEFAULT_COORDINATE_BUDGET)
certificate()
```

`outer.compose(inner)` means

$$\text{outer}(\text{inner}(z)) \pmod{z^{N+1}}.$$

Pullback and pushforward are

$$\phi^* f = f \circ \phi, \qquad \phi_* f = f \circ \phi^{-1}.$$

The substitution-transform columns are the coefficient vectors of $1, \phi, \phi^2, \ldots, \phi^N$. Composition labels must match. A truncation cannot increase stored degree, and requested inversion or substitution degree cannot exceed the available jet. The substitution matrix consults the coordinate budget.

```
compose_ordinary_series(outer, inner, degree)
identity_formal_coordinate(degree, *, name=..., coordinate=...)
formal_coordinate_from_iterable(coefficients, *, name=..., source=..., target=...)
```

are the corresponding helpers. An empty pushforward input returns `()`. A constant-only nonempty input currently requests an impossible degree-zero inverse and raises. Callers should handle constants directly.

The shipped affine/formal example prints

```
Cartesian point: (Fraction(4, 1), Fraction(2, 1))
barycentric point: (Fraction(2, 3), Fraction(3, 2))
formal pullback: (Fraction(3, 1), Fraction(4, 1), Fraction(3, 1), Fraction(-8, 1), Fraction(26, 1))
```

16.5 Portable coordinate records

Coordinate-specific file helpers use path-first argument order:

```
save_transform(path, transform, *, overwrite=False)
load_transform(path) -> CoordinateTransform

save_coordinate_record(path, record, *, overwrite=False)
load_coordinate_record(path) -> RecurrenceCoordinateRecord

save_coordinate_object(path, value, *, overwrite=False)
load_coordinate_object(path) -> Any
```

The generic stable portable helpers use value-first order:

```
dumps_portable(value, *, indent=2, max_depth=128)
loads_portable(text, *, max_depth=128)
save_portable(value, path, *, overwrite=False, indent=2, max_depth=128)
load_portable(path, *, max_depth=128)
portable_digest(value, *, max_depth=128)
```

Every JSON file uses the version-1 envelope

```
{
  "schema": "komorebi-math.portable",
  "schema_version": 1,
  "producer_version": "1.0.0b4",
  "payload_sha256": "...",
  "payload": {}
}
```

Core coordinate codec tags include

Object	Tag
exact transform	`coordinates.transform`
numeric transform	`coordinates.numeric_transform`
affine transform	`coordinates.affine_transform`
formal change	`coordinates.formal_change`
barycentric system	`coordinates.barycentric_system`
recurrence coordinate record	`coordinates.recurrence_record`

Fractions store numerator and denominator. NumPy arrays store dtype, shape, and flattened data. Tagged records and their data dictionaries use exact field sets. The loader rejects unknown tags and versions, duplicate keys, non-finite JSON, invalid array shapes, excess nesting depth, malformed scalar records, and payload-digest mismatch. It reconstructs only registered codecs. A file cannot name an arbitrary Python class for import.

Writes are atomic, parent directories are created, and existing files are refused unless `overwrite=True`. The SHA-256 detects accidental or untrusted payload alteration only when the digest itself has not been rewritten. It is not a signature or message-authentication code.

```
import json
from komorebi_math.coordinates import CoordinateTransform, load_transform, save_transform
from komorebi_math.export import dumps_portable, loads_portable

T = CoordinateTransform("A", "B", ((1, 2), (0, 1)), "CC.X", "shear")
save_transform("transform.km.json", T, overwrite=True)
assert load_transform("transform.km.json") == T
```

```
text = dumps_portable(T)
envelope = json.loads(text)
print(envelope["schema"])
print(envelope["payload"]["__komorebi_type__"])
print(loads_portable(text) == T)
```

Output:

```
komorebi-math.portable
coordinates.transform
True
```

16.6 Polynomial differential and multiplication operators in arbitrary coordinates

`PolynomialCoordinateOperator` compiles a polynomial rule column by column in declared source and target families:

```
PolynomialCoordinateOperator(
    name: str,
    source_family: str,
    target_family: str,
    source_degree: int,
    target_degree: int,
    matrix: Matrix,
    theorem: str = "CC.O1",
)
```

If $P_0, \dots, P_d$ is the source basis, $Q_0, \dots, Q_e$ the target basis, and R the rule, the matrix O is defined by

$$R(P_j) = \sum_{k=0}^{e} O_{kj} Q_k.$$

Equivalently,

$$O = M_Q^{-1} \begin{bmatrix} [R(P_0)]_{\mathrm{mon}} & \cdots & [R(P_d)]_{\mathrm{mon}} \end{bmatrix}.$$

The general compiler and standard constructors are

```
polynomial_operator(source, target, source_degree, target_degree, rule,
                    *, name, theorem="CC.O1", budget=...)
derivative_coordinate_operator(family, degree, *, budget=...)
integral_coordinate_operator(family, degree, *, budget=...)
multiplication_coordinate_operator(family, degree, multiplier, *, budget=...)
affine_substitution_coordinate_operator(family, degree, *, scale=1, shift=0, budget=...)
finite_difference_coordinate_operator(family, degree, *, step=1, budget=...)
transport_polynomial_operator(operator, source_family, target_family, *, budget=...)
operator_commutator(left, right) -> Matrix
```

Derivative maps degree $d \to d$, zero-constant integration maps $d \to d+1$, multiplication by a degree-r polynomial maps $d \to d+r$, and affine substitution and finite difference retain the declared degree. High-degree terms are never silently dropped: if a rule image exceeds `target_degree`, compilation raises.

The object exposes `square`, `apply`, `compose`, and `certificate`. As elsewhere, `operator.compose(following)` stores this matrix after the first:

$$O_{\text{composed}} = O_{\text{following}} O_{\text{self}}.$$

Transport uses domain and codomain connections:

$$O_{\text{target}} = C_{\text{codomain}} O_{\text{source}} C_{\text{domain}}^{-1}.$$

For the Legendre family,

```
from komorebi_math.coordinates import (
    derivative_coordinate_operator,
    multiplication_coordinate_operator,
)
from komorebi_math.coordinates.classical import legendre_polynomial_family

legendre = legendre_polynomial_family()
D = derivative_coordinate_operator(legendre, 3)
X = multiplication_coordinate_operator(legendre, 3, (0, 1))

print(D.apply((0, 0, 0, 1)))
print(X.apply((0, 0, 0, 1)))
```

returns

```
(Fraction(1, 1), Fraction(0, 1), Fraction(5, 1), Fraction(0, 1))
(Fraction(0, 1), Fraction(0, 1), Fraction(3, 7), Fraction(0, 1), Fraction(4, 7))
```

so $P_3' = P_0 + 5P_2$ and $xP_3 = \frac{3}{7}P_2 + \frac{4}{7}P_4$.

Failures include wrong matrix/vector dimensions, an empty name or multiplier, zero finite-difference step, non-composable family labels or degree bounds, a rule image beyond the target, and budget overflow. The certificate validates the exact finite matrix and labels. The original Python callable is not retained or replayed. The version-1 portable tag is `coordinates.polynomial_operator`.

16.7 Normalized coefficient coordinates

`NormalizedBasis` is an alias of `WeightedMonomialBasis`. Such a basis has

$$e_n(z) = \frac{z^n}{\gamma_n}, \qquad \gamma_0 = 1, \qquad \gamma_n \neq 0.$$

If one formal series is written in two normalizations,

$$F(z) = \sum_n a_n \frac{z^n}{\gamma_n} = \sum_n b_n \frac{z^n}{\eta_n},$$

then

$$b_n = \frac{\eta_n}{\gamma_n} a_n.$$

The exact conversion is therefore diagonal:

```
normalization_change_transform(source, target, degree, *, budget=...)
convert_normalized_coefficients(coefficients, source, target, *, budget=...)
apply_lowering_polynomial(coefficients, polynomial)
```

with $T_{nn} = \eta_n/\gamma_n$. Built-in factories exposed from `komorebi_math.coordinates` are

Factory	Weight γ_n
`ordinary_basis()`	1
`exponential_basis()`	$n!$
`fibonacci_factorial_basis()`	$\prod_{j=1}^{n} F_j$

Additional factorial-power, q-factorial, Pochhammer, table, and callback bases live in `komorebi_math.generating`.

```
source = exponential_basis()
target = fibonacci_factorial_basis()
T = normalization_change_transform(source, target, 4)

print(T.apply((1, 0, -1, 0, 5)))
```

The diagonal is `(1, 1, 1/2, 1/3, 1/4)` and the result is

```
(Fraction(1, 1), Fraction(0, 1), Fraction(-1, 2),
 Fraction(0, 1), Fraction(5, 4))
```

The canonical lowering operator satisfies $D_\gamma e_n = e_{n-1}$. For $q(L) = \sum_{j=0}^{r} q_j L^j$,

$$(q(L)a)_n = \sum_{j=0}^{r} q_j a_{n+j}$$

on the available finite interior. Thus

```
apply_lowering_polynomial((1, 2, 3, 4, 5), (-1, 0, 1))
```

returns `(2, 2, 2)`. If the input is no longer than the operator degree, the finite interior is empty and the result is `()`. Callback-defined bases support live finite computation but require a declarative descriptor for persistence. No analytic convergence claim is made.

16.8 Shift-polynomial Bézout identities and defect reconstruction

Shift polynomials store ascending coefficients:

```
ShiftPolynomial(coefficients, name="shift polynomial")
```

They expose `degree`, `apply(values)`, and `multiply(other, name=None)`. The extended Euclidean routine

```
polynomial_extended_gcd(left, right) -> tuple[gcd, u, v]
```

returns a monic polynomial g and multipliers satisfying

$$u(x)q(x) + v(x)r(x) = g(x).$$

When $g = 1$, substitution of the lowering operator gives

$$u(L)q(L)a + v(L)r(L)a = a$$

only on the common finite interior. Each operator composition consumes its degree from the available horizon. This is not a boundary-reconstruction theorem.

```
BezoutDefectIdentity(
    gcd,
    left_multiplier,
    right_multiplier,
    reconstructed,
    expected,
    valid,
)

bezout_defect_identity(values, left, right) -> BezoutDefectIdentity
```

For

$$q = x^2 - x - 1, \qquad r = x^2 - 1,$$

the implementation returns $g = 1$, $u = -x$, and $v = x - 1$. Executing

```
values = (2, 7, -3, 5, 11, 13, 17, 19)
result = bezout_defect_identity(
    values,
    (-1, -1, 1),
    (-1, 0, 1),
)
```

produces

```
reconstructed = (2, 7, -3, 5, 11)
expected      = (2, 7, -3, 5, 11)
valid         = True
```

Only five entries lie in the common interior. Noncoprime shift polynomials are rejected. The input pair must not both be zero: that uncovered edge currently leaks a `ZeroDivisionError` from the polynomial algorithm. A short prefix may yield an empty but formally valid interior. `CC.O2` is used here and also by the derivative-coordinate operator. Theorem identifiers in this area are local implementation labels rather than globally unique keys. Both shift polynomials and defect identities have version-1 portable codecs.

16.9 State recovery, observability, Krylov similarity, and intertwiner spaces

A scalar linear realization is

```
LinearRealization(
    transition: Matrix,
    initial: Vector,
    output: Vector,
    name: str = "linear realization",
)
```

and represents

$$a_n = h^{\mathsf{T}} A^n v.$$

It exposes `dimension`, `state(index)`, `term(index)`, and `prefix(count)`. State recovery uses the exact observability matrix

$$\mathcal{O}_H = \begin{pmatrix} h^{\mathsf{T}} \\ h^{\mathsf{T}}A \\ \vdots \\ h^{\mathsf{T}}A^{H-1} \end{pmatrix}$$

through

```
observability_matrix(transition, output, horizon, *, budget=...)

recover_initial_state(prefix, transition, output, *, budget=...)
    -> StateRecovery
```

`StateRecovery` records `exact`, `unique`, `rank`, `horizon`, `state`, `predicted`, and `residual`. It solves over the rationals. `unique` means full state-column rank. The certificate requires an available state and zero residual but does not require uniqueness. Require $H \geq 1$: a zero-horizon call is an uncovered implementation edge that can return a degenerate empty state marked exact and unique.

For the Fibonacci companion $A = ((0, 1), (1, 1))$ with output `(1, 0)`, the two-row observability matrix is the identity. Fitting eight signed secant-Euler values yields

```
exact     = False
unique    = True
rank      = 2
state     = (1, 0)
predicted = (1, 0, 1, 1, 2, 3, 5, 8)
residual[2] = -2
```

The exact Krylov and intertwiner functions are

```
cyclic_krylov_matrix(transition, vector)
intertwiner_space(source, target) -> IntertwinerSpace
similarity_from_cyclic_vectors(source, target, source_vector, target_vector)
realization_defect(realization, target_coefficients)
```

For a cyclic vector,

$$K_A(v) = [v, Av, \dots, A^{d-1}v].$$

Given cyclic v, w, the similarity is

$$S = K_B(w)K_A(v)^{-1}, \qquad BS = SA,$$

and the identity is checked before return. `intertwiner_space` solves the exact nullspace equations $BS - SA = 0$ and returns source dimension, target dimension, and a matrix basis. Its `contains_invertible_basis_element()` checks only the displayed basis matrices, not arbitrary linear combinations. A span can contain an invertible matrix even when every chosen basis element is singular.

For $S = ((1, 2), (3, 5))$ and $B = SAS^{-1} = ((-1, 1), (-1, 2))$, the shipped routines recover that exact S, report a two-dimensional intertwiner space, and validate the intertwining certificate.

This route is a cyclic-vector similarity method, not a general canonical-form solver. Scalar recovery handles one output covector. The separate `StateSpaceModel`, controllability, block observability, and state-coordinate transform APIs belong to Chapter 18. Those state-space laws are discrete-time:

$$x_{k+1} = Ax_k + Bu_k, \qquad y_k = Cx_k + Du_k.$$

16.10 Exact finite-field coordinate changes and denominator obstructions

Prime-field coordinates use

```
FiniteFieldCoordinateTransform(
    source: str,
    target: str,
    matrix: ModularMatrix,
    prime: int,
    theorem: str = "CC.M1",
    description: str = "",
)
```

with `source_dimension`, `target_dimension`, `square`, `apply`, `inverse`, `then`, and `certificate`. The modulus must be a genuine prime. Matrix and vector entries should be actual integers. Runtime `int(...)` coercion is not a strong validation of noninteger inputs.

Rational reduction is

```
reduce_exact_transform_mod_prime(
    transform: CoordinateTransform,
    prime: int,
) -> FiniteFieldCoordinateTransform
```

For a rational coefficient a/b, reduction sends

$$\frac{a}{b} \longmapsto (a \bmod p)(b \bmod p)^{-1}$$

only when $p \nmid b$. Composition and Gauss-Jordan inversion are exact in $\mathbb{F}_p$.

For

```
R = CoordinateTransform(
    "q",
    "r",
    ((Fraction(1, 2), Fraction(1, 3)),
     (Fraction(2, 3), Fraction(3, 4))),
    "demo",
)
```

reduction modulo five gives

```
matrix          = ((3, 2), (4, 2))
apply((7, -2))  = (2, 4)
certificate     = valid
```

Modulo two, the denominator obstruction raises because 2 is not invertible. A different loss can occur after all denominators reduce: a rational isomorphism whose determinant numerator vanishes modulo p becomes a singular prime-field map. Reduction then succeeds, but the square-map certificate is invalid and inversion fails.

Rectangular maps remain valid maps but are not isomorphisms. Composition requires equal primes, matching labels, and compatible dimensions. This module implements $\mathbb{F}_p$, not extension fields, prime-power rings, or composite-modulus arithmetic. Its portable tag is `coordinates.finite_field_transform`, version 1.

16.11 `komorebi_math.coordinates.analysis_synthesis` canonical implementation page

The stable numerical analysis/synthesis system is

```
AnalysisSynthesisSystem(
    analysis: np.ndarray,
    synthesis: np.ndarray,
    source: str = "source",
    coordinates: str = "coordinates",
    tolerance: float = 1e-12,
    theorem: str = "KM-AS-01",
)
```

It is exported identically from `komorebi_math.coordinates`, `stable`, `v1`, and `api.v1`. Stored arrays are copied and read-only. With

$$A \in \mathbb{F}^{m \times n}, \qquad S \in \mathbb{F}^{n \times m},$$

the defining finite reconstruction law is

$$SA = I_n.$$

Factories are

```
AnalysisSynthesisSystem.from_invertible(
    matrix,
    *,
    source="source",
    coordinates="coordinates",
    tolerance=1e-12,
    theorem="KM-AS-01",
)

AnalysisSynthesisSystem.canonical_dual(
    analysis,
    *,
    source="source",
    coordinates="coordinates",
    tolerance=1e-12,
    theorem="KM-AS-01",
)
```

`canonical_dual` requires full column rank at the declared relative SVD cutoff and computes the Moore-Penrose left inverse. Properties report source and coordinate dimensions, redundancy, and squareness. Methods include

```
frame_operator()
analyze(value)
synthesize(value)
reconstruct(value)
component(indices)
components(groups=None)
operator_blocks(operator, *, groups=None)
certificate()
reconstruction_certificate(value)
```

`projector` and `projectors` remain compatibility aliases for `component` and `components`. The canonical terminology matters: in a redundant system, a singleton component

$$C_I = SE_IA$$

need not be idempotent. For a complete coordinate partition,

$$\sum_I C_I = SA = I.$$

For a source-space operator T, the block identity is

$$T = \sum_{\beta,\alpha} C_\beta T C_\alpha.$$

`AnalysisSynthesisBlocks` stores the system, groups, blocks, and operator and can reconstruct and certify that numerical sum. Construct it through `system.operator_blocks(...)`: direct record construction checks shapes and the summed result, but does not independently prove every supplied block equals $C_\beta T C_\alpha$.

Redundant canonical-dual example

```
import numpy as np
from komorebi_math.coordinates import AnalysisSynthesisSystem

A = np.array([
    [1.0, 0.0],
    [0.0, 1.0],
    [1.0, 1.0],
    [1.0, -1.0],
])
system = AnalysisSynthesisSystem.canonical_dual(A)
x = np.array([3.0, -2.0])

system.certificate().require()
print(system.analyze(x))
print(system.reconstruct(x))
```

The canonical synthesis matrix is

$$S = \begin{pmatrix} 1/3 & 0 & 1/3 & 1/3 \\ 0 & 1/3 & 1/3 & -1/3 \end{pmatrix},$$

and the numerical output is

```
analyze(x)     = [3.0, -2.0, 1.0, 5.0]
reconstruct(x) = [3.0000000000000004, -2.0000000000000004]
```

The four singleton components sum to identity, but each has idempotence residual about `0.22222222`. Calling them projectors would therefore overstate the algebraic property.

The system certificate uses `KM-AS-01`, reports numerical exactness, dimensions, rank, square/redundant state, and the $SA - I$ residual. Operator blocks use `KM-AS-02`. Direct construction does not automatically require $SA = I$, so the documented pattern calls `certificate().require(). from_invertible` also leaves that explicit check to the caller. The portable decoder is stricter: it reconstructs the system and immediately requires the certificate.

Groups must be nonempty, disjoint, and partition every coordinate. Indices must be unique and in range. Source operators must be square. Analysis and synthesis must be finite nonempty matrices with compatible shapes. Names must be nonempty. And tolerance must be positive and finite. `canonical_dual` rejects rank deficiency at the declared cutoff.

This class is NumPy numerical even when input arrays happen to contain integers, and it is not a CUDA/device runtime. The separate `ExactAnalysisSynthesisSystem` in `coordinates.frame_algebra` is a rational exact alternative and is not the stable canonical page documented here. The version-1 portable tag is `coordinates.analysis_synthesis`. Blocks have no independent codec.

The shipped `examples/block16_analysis_synthesis.py` validates a redundant system and operator blocks and reconstructs `[3, -2]`. Across the complete Chapter 16 surface, focused source tests for formal, affine, tensor, modular, calculus, normalization, shift-polynomial, realization, persistence, and analysis/synthesis paths passed in the recorded baseline. The coordinate verifier passed 24/24 checks. The coordinate-calculus verifier passed 168/168 in the baseline profile and 170/170 in the executed SymPy-enabled exact profile. Historical large randomized audit records remain useful provenance but are not relabeled as freshly generated `1.0.0b4` evidence.

> **Chapter 16 summary.** Exact and numerical transform records share a direction and composition convention but have different validity semantics. The same finite language transports tensors, compiles polynomial rules, changes normalization, reconstructs interior shift identities, recovers rational states, detects modular denominator obstructions, and builds redundant numerical analysis/synthesis systems. Each claim stops at its executed finite domain and evidence class.

17. Polynomial and classical coordinate families

First route. Review ascending coefficient order in Section 17.0. For a built-in graded family, choose its catalog name in Section 17.1 and follow the Legendre-to-Chebyshev example in Section 17.5.4. For fixed-degree Bernstein, Newton, or Lagrange coordinates, use the finite-basis route in Section 17.2. Check a small reconstructed polynomial before increasing the degree.

Komorebi Math represents a finite exact polynomial by its coefficients in ascending power order. Thus

$$p(x) = a_0 + a_1 x + \cdots + a_d x^d$$

is stored as

```
(a_0, a_1, ..., a_d)
```

with every entry converted to `fractions.Fraction`. The polynomial layer does not introduce a symbolic variable object. It works with immutable finite coefficient tuples and exact rational matrix operations. This keeps the coordinate convention explicit: a polynomial is the mathematical object, and a family coefficient vector is one representation of that object.

Three related constructions must be kept separate:

1. A `PolynomialFamily`, whose member of index n has exact degree n.
2. A `FiniteBasis`, such as a fixed-degree Bernstein or interpolation basis.
3. A `CoordinateTransform`, which changes coefficient vectors without changing the represented polynomial.

The distinction is operationally important. Graded families can be passed to `connection_transform`. Fixed-degree bases instead use `FiniteBasis.connection_to`. Bell and Touchard polynomial rows are generated in `komorebi_math.generating` and require an explicit finite adapter before they participate in the polynomial-family coordinate calculus.

17.0 Exact polynomial representation

17.0.1 Polynomial storage convention

The complete exact polynomial type is

```
Polynomial = tuple[Fraction, ...]
```

These primitive operations are public from `komorebi_math.coordinates`:

```
polynomial_add(
    left: Sequence[Scalar],
    right: Sequence[Scalar],
) -> Polynomial

polynomial_scale(
    polynomial: Sequence[Scalar],
    scalar: Scalar,
) -> Polynomial

polynomial_shift(
    polynomial: Sequence[Scalar],
```

```
    steps: int = 1,
) -> Polynomial

polynomial_multiply(
    left: Sequence[Scalar],
    right: Sequence[Scalar],
) -> Polynomial

polynomial_evaluate(
    polynomial: Sequence[Scalar],
    value: Scalar,
) -> Fraction

polynomial_derivative(
    polynomial: Sequence[Scalar],
) -> Polynomial

polynomial_subtract(
    left: Sequence[Scalar],
    right: Sequence[Scalar],
) -> Polynomial

constant_polynomial(
    value: Scalar,
) -> Polynomial

affine_polynomial(
    scale: Scalar,
    shift: Scalar,
) -> Polynomial

polynomial_compose_affine(
    polynomial: Sequence[Scalar],
    *,
    scale: Scalar = 1,
    shift: Scalar = 0,
) -> Polynomial
```

`polynomial_shift(p, r)` means multiplication by x^r, not translation of the argument. Translation and scaling of the argument are performed by `polynomial_compose_affine`:

$$p(x) \longmapsto p(\alpha x + \beta).$$

17.0.2 Exact arithmetic example

```
from fractions import Fraction

from komorebi_math.coordinates import (
    polynomial_add,
    polynomial_derivative,
    polynomial_evaluate,
    polynomial_multiply,
)

p = (1, -2, 1)                 # (x - 1)^2
q = (Fraction(1, 2), 3)        # 1/2 + 3x

print(polynomial_add(p, q))
print(polynomial_multiply(p, q))
```

```
print(polynomial_derivative(p))
print(polynomial_evaluate(p, 3))
```

Output:

```
(Fraction(3, 2), Fraction(1, 1), Fraction(1, 1))
(Fraction(1, 2), Fraction(2, 1), Fraction(-11, 2), Fraction(3, 1))
(Fraction(-2, 1), Fraction(2, 1))
4
```

The coefficient order explains the multiplication result:

$$(x-1)^2\left(\frac{1}{2}+3x\right)=\frac{1}{2}+2x-\frac{11}{2}x^2+3x^3.$$

Exact-input practice. Use integers and `Fraction` objects when the intended coefficients are rational. The type contract is `int | Fraction`. Boolean coefficients are rejected. Python does not enforce the scalar type annotation before conversion, so a supplied binary floating-point value can still reach `Fraction` and preserve its exact binary value rather than the short decimal a reader may have intended.

17.1 Family protocol and `get_polynomial_family`

17.1.1 The graded-family invariant

A polynomial family $P=(P_n)_{n\geq 0}$ is admissible when

$$\deg P_n=n, \qquad [x^n]P_n\neq 0.$$

The public record is

```
PolynomialFamily(
    name: str,
    rule: Callable[[int], Polynomial],
) -> None
```

and its public methods are

```
PolynomialFamily.polynomial(
    self,
    degree: int,
) -> Polynomial

PolynomialFamily.coefficient_matrix(
    self,
    degree: int,
) -> Matrix
```

The callback is evaluated lazily. Construction of `PolynomialFamily` alone does not execute or certify the rule. `polynomial(n)` trims trailing zeros and then checks that the result has length $n+1$ with a nonzero final coefficient. Consequently, an invalid callback fails at the first requested degree for which it violates the graded-family invariant.

For a degree bound d, the coefficient matrix is

$$M_P^{(d)} = \begin{bmatrix} | & | & & | \\ [P_0]_{\mathrm{mon}} & [P_1]_{\mathrm{mon}} & \cdots & [P_d]_{\mathrm{mon}} \\ | & | & & | \end{bmatrix}.$$

Rows index monomial power and columns index family degree. Since the column for P_n has no coefficient above degree n, $M_P^{(d)}$ is upper triangular. Its diagonal consists of the nonzero leading coefficients of the family members, so it is invertible over the rationals.

17.1.2 Catalog interface

The catalog record and lookup functions have these exact signatures:

```
PolynomialFamilyCatalog(
    families: tuple[PolynomialFamily, ...],
) -> None

PolynomialFamilyCatalog.names(
    self,
) -> tuple[str, ...]

PolynomialFamilyCatalog.get(
    self,
    name: str,
) -> PolynomialFamily

classical_polynomial_catalog(
) -> PolynomialFamilyCatalog

get_polynomial_family(
    name: str,
) -> PolynomialFamily
```

The built-in catalog contains these 15 graded families.

Short lookup	Canonical family name	Degree-n member
`monomial`	`monomials`	x^n
`euler`	`Euler polynomials`	$E_n(x)$
`fibonacci`	`Fibonacci polynomials`	$F_{n+1}(x)$
`falling`	`falling factorials`	$x^{\underline{n}}$
`rising`	`rising factorials`	$x^{\overline{n}}$
`binomial`	`binomial polynomials`	$\binom{x}{n}$
`bernoulli`	`Bernoulli polynomials`	$B_n(x)$
`lucas`	`Lucas polynomials`	$L_n(x)$
`pell`	`Pell polynomials`	$P_{n+1}(x)$
`chebyshev-t`	`Chebyshev T polynomials`	$T_n(x)$
`chebyshev-u`	`Chebyshev U polynomials`	$U_n(x)$
`legendre`	`Legendre polynomials`	$P_n(x)$
`hermite-probabilists`	`probabilists Hermite polynomials`	$He_n(x)$
`hermite-physicists`	`physicists Hermite polynomials`	$H_n(x)$
`laguerre`	`Laguerre polynomials`	$L_n(x)$

Lookup is case-insensitive and discards nonalphanumeric characters. An exact canonical name also works. For example, each call below returns the same family:

```
from komorebi_math.coordinates import get_polynomial_family

a = get_polynomial_family("chebyshev-t")
b = get_polynomial_family("Chebyshev T")
c = get_polynomial_family("Chebyshev T polynomials")

assert a.name == b.name == c.name == "Chebyshev T polynomials"
```

The catalog does not include aliases for Bernstein, Newton, Lagrange, Bell, or Touchard objects. Their distinct ownership and construction rules are described in Sections 17.2 and 17.4.

17.1.3 Stable and complete import surfaces

The stable family-connection workflow is available from `komorebi_math.stable`:

```
from komorebi_math.stable import (
    connection_transform,
    get_polynomial_family,
)
```

The complete family-construction surface is in `komorebi_math.coordinates`:

```
from komorebi_math.coordinates import (
    PolynomialFamily,
    classical_polynomial_catalog,
    get_polynomial_family,
)
```

`PolynomialFamily` itself is not re-exported by `komorebi_math.stable`. `get_polynomial_family`, `connection_transform`, and their returned `CoordinateTransform` workflow belong to the frozen 1.x stable surface. The additional constructors documented from `komorebi_math.coordinates` are public research-tier APIs: they are covered by the release's public API manifest, but their presence in a public namespace does not give them the same 1.x compatibility promise as `komorebi_math.stable`.

> **Namespace boundary.** The root name `komorebi_math.appell_polynomial` belongs to the analytic Appell subsystem and has a different signature. Use `komorebi_math.coordinates.appell_polynomial` or a namespace-qualified coordinate import for the finite classical-family constructor.

17.1.4 Custom family example

The binomial theorem gives a graded family

$$S_n(x) = (x+1)^n = \sum_{k=0}^{n} \binom{n}{k} x^k.$$

It can be declared directly:

```
from fractions import Fraction
from math import comb

from komorebi_math.coordinates import PolynomialFamily

shifted_monomials = PolynomialFamily(
    "powers of x+1",
    lambda degree: tuple(
```

```
        Fraction(comb(degree, power))
        for power in range(degree + 1)
    ),
)

assert shifted_monomials.polynomial(3) == (1, 3, 3, 1)
assert shifted_monomials.coefficient_matrix(3) == (
    (1, 1, 1, 1),
    (0, 1, 2, 3),
    (0, 0, 1, 3),
    (0, 0, 0, 1),
)
```

The callback is ordinary executable Python. Exactness requires it to be deterministic and to return exact coefficients. The runtime validates the returned polynomial's grade, but it does not attempt to prove purity or inspect the callback's source.

17.1.5 Family construction failures

Condition	Exception	Diagnostic
Negative, Boolean, or noninteger degree	`ValidationError`	`degree must be a nonnegative integer`
Callback result has degree other than n	`ValidationError`	`family polynomials must have exact graded degree`
Callback returns a zero leading coefficient	`ValidationError`	same graded-degree diagnostic
Unknown catalog lookup	`ValidationError`	`unknown polynomial family ...`

For example:

```
from komorebi_math.coordinates import PolynomialFamily

bad = PolynomialFamily("not graded", lambda degree: (1,))

try:
    bad.polynomial(2)
except Exception as error:
    print(type(error).__name__, str(error))
```

Output:

```
ValidationError family polynomials must have exact graded degree
```

17.2 Monomial, falling/rising factorial, Bernstein, Lagrange

17.2.1 Monomial and factorial families

The elementary graded constructors are

```
monomial_polynomial_family(
) -> PolynomialFamily

falling_factorial_polynomial(
    degree: int,
) -> Polynomial

rising_factorial_polynomial(
    degree: int,
) -> Polynomial

binomial_polynomial(
    degree: int,
) -> Polynomial

falling_factorial_polynomial_family(
) -> PolynomialFamily

rising_factorial_polynomial_family(
) -> PolynomialFamily

binomial_polynomial_family(
) -> PolynomialFamily
```

Their defining expressions are

$$m_n(x) = x^n,$$

$$x^{\underline{n}} = \prod_{j=0}^{n-1}(x-j),$$

$$x^{\overline{n}} = \prod_{j=0}^{n-1}(x+j),$$

and

$$\binom{x}{n} = \frac{x^{\underline{n}}}{n!}.$$

The degree-four coefficient tuples make the normalization difference visible.

Family	Degree-four tuple
Monomial	$(0, 0, 0, 0, 1)$
Falling factorial	$(0, -6, 11, -6, 1)$
Rising factorial	$(0, 6, 11, 6, 1)$
Binomial polynomial	$(0, -1/4, 11/24, -1/4, 1/24)$

The falling and rising factorial families are monic. The binomial family has leading coefficient $1/n!$. These leading coefficients determine the diagonal and determinant of every connection involving the family.

17.2.2 Fixed-degree Bernstein coordinates

The Bernstein constructor is

```
bernstein_polynomial(
    degree: int,
    index: int,
) -> Polynomial

bernstein_basis(
    degree: int,
) -> FiniteBasis
```

For fixed degree n,

$$B_{k,n}(x) = \binom{n}{k} x^k (1-x)^{n-k}, \qquad 0 \le k \le n.$$

Every $B_{k,n}$ belongs to the same $(n+1)$-dimensional polynomial space. This is not a graded family indexed by degree, because the family index k does not equal the polynomial degree. `bernstein_basis(n)` therefore returns a `FiniteBasis` whose vectors are coefficient columns in the monomial ambient space.

For $n = 3$:

```
B(3,0) = (1, -3, 3, -1)
B(3,1) = (0, 3, -6, 3)
B(3,2) = (0, 0, 3, -3)
B(3,3) = (0, 0, 0, 1)
```

They satisfy the partition-of-unity identity

$$\sum_{k=0}^{n} B_{k,n}(x) = 1.$$

The implementation-faithful path to monomial coefficients is a finite-basis connection:

```
from komorebi_math.coordinates import bernstein_basis, standard_basis

bernstein = bernstein_basis(3)
monomials = standard_basis(4, name="monomial coefficients")
to_monomials = bernstein.connection_to(monomials)

assert to_monomials.apply((1, 1, 1, 1)) == (1, 0, 0, 0)
assert to_monomials.inverse().apply((1, 0, 0, 0)) == (1, 1, 1, 1)
```

`connection_transform` is not used here because its arguments must both be `PolynomialFamily` objects.

17.2.3 Newton interpolation coordinates

The Newton basis at distinct exact nodes $\xi_0, \dots, \xi_{m-1}$ is

$$N_0(x) = 1, \qquad N_k(x) = \prod_{j=0}^{k-1} (x - \xi_j).$$

Its constructor is

```
newton_interpolation_basis(
    nodes: Sequence[Scalar],
) -> FiniteBasis
```

17.2.4 Lagrange interpolation coordinates

The cardinal basis at the same nodes is

$$L_i(x) = \prod_{\substack{0 \le j < m \\ j \ne i}} \frac{x - \xi_j}{\xi_i - \xi_j},$$

with the exact invariant

$$L_i(\xi_j) = \delta_{ij}.$$

Its constructor is

```
lagrange_interpolation_basis(
    nodes: Sequence[Scalar],
) -> FiniteBasis
```

For the nodes $(-1, 0, 2)$, the two bases are

```
from fractions import Fraction

from komorebi_math.coordinates import (
    lagrange_interpolation_basis,
    newton_interpolation_basis,
)

nodes = (Fraction(-1), Fraction(0), Fraction(2))

print(newton_interpolation_basis(nodes).vectors)
print(lagrange_interpolation_basis(nodes).vectors)
```

Mathematically simplified values:

```
((1, 0, 0), (1, 1, 0), (0, 1, 1))
((0, -2/3, 1/3), (1, 1/2, -1/2), (0, 1/6, 1/6))
```

The coefficient tuples represent

$$N_0 = 1, \qquad N_1 = x + 1, \qquad N_2 = x(x + 1),$$

and

$$L_0 = \frac{x^2 - 2x}{3}, \qquad L_1 = 1 + \frac{x}{2} - \frac{x^2}{2}, \qquad L_2 = \frac{x + x^2}{6}.$$

17.2.5 Evaluation and interpolation transforms

For a graded family and a nonempty node sequence, the public constructors are

```
evaluation_transform(
    family: PolynomialFamily,
    nodes: Sequence[Scalar],
    *,
    budget: CoordinateBudget = DEFAULT_COORDINATE_BUDGET,
) -> CoordinateTransform

interpolation_transform(
    family: PolynomialFamily,
```

```
    nodes: Sequence[Scalar],
    *,
    budget: CoordinateBudget = DEFAULT_COORDINATE_BUDGET,
) -> CoordinateTransform
```

If there are m nodes, the declared polynomial degree is $d = m - 1$. The evaluation matrix is

$$V_{ij} = P_j(\xi_i), \qquad 0 \le i, j \le d.$$

The forward transform maps family coefficients to node values. The interpolation transform is its exact inverse.

```
from fractions import Fraction

from komorebi_math.coordinates import (
    evaluation_transform,
    get_polynomial_family,
)

nodes = (Fraction(-1), Fraction(0), Fraction(2))
legendre = get_polynomial_family("legendre")
evaluate = evaluation_transform(legendre, nodes)

values = evaluate.apply((1, 2, 3))
recovered = evaluate.inverse().apply(values)

print(evaluate.matrix)
print(values)
print(recovered)
```

Mathematically simplified values:

```
((1, -1, 1),
 (1, 0, -1/2),
 (1, 2, 11/2))
(2, -1/2, 43/2)
(1, 2, 3)
```

Distinct nodes are required for Newton and Lagrange basis constructors. `evaluation_transform` detects a nondetermining node set by its zero determinant and raises `ValidationError`.

17.2.6 Fixed-basis failures

Condition	Exception
Bernstein index $k > n$	`DimensionError`
Empty interpolation node sequence	`DimensionError`
Duplicate Newton or Lagrange nodes	`ValidationError`
Singular evaluation matrix	`ValidationError`
Ambient or basis dimension mismatch	`DimensionError`
Dependent vectors in a constructed `FiniteBasis`	`ValidationError`

17.3 Bernoulli, Euler, Hermite, Laguerre, Legendre, Chebyshev

The classical constructors in this section provide exact finite coefficient formulas. Their names do not, by themselves, certify orthogonality integrals, weight functions, normalization constants, zero locations, approximation bounds, or quadrature rules.

17.3.1 Bernoulli polynomials

The public constructors are

```
bernoulli_number(
    index: int,
) -> Fraction

bernoulli_polynomial(
    degree: int,
) -> Polynomial

bernoulli_polynomial_family(
) -> PolynomialFamily
```

The convention is

$$B_0 = 1, \qquad B_1 = -\frac{1}{2}.$$

The implementation obtains successive values from

$$B_n = -\frac{1}{n+1} \sum_{k=0}^{n-1} \binom{n+1}{k} B_k$$

and constructs

$$B_n(x) = \sum_{k=0}^{n} \binom{n}{k} B_{n-k} x^k.$$

For example,

$$B_2(x) = x^2 - x + \frac{1}{6},$$

which is stored as

```
(1/6, -1, 1)
```

17.3.2 Euler polynomials

The public constructors are

```
euler_polynomial_at_zero(
    index: int,
) -> Fraction

euler_polynomial(
    degree: int,
) -> Polynomial

euler_polynomial_family(
) -> PolynomialFamily
```

The implemented convention is determined by

$$\frac{2e^{xt}}{e^t+1}=\sum_{n\ge 0}E_n(x)\frac{t^n}{n!}.$$

At zero,

$$E_0(0)=1,\qquad E_n(0)=-\frac{1}{2}\sum_{k=0}^{n-1}\binom{n}{k}E_k(0),$$

and

$$E_n(x)=\sum_{k=0}^{n}\binom{n}{k}E_{n-k}(0)x^k.$$

The convention matters because several sequences called Euler numbers occur in the literature. The signed secant specialization used elsewhere in the package is recovered from

$$\mathcal{E}_n=2^nE_n\left(\frac{1}{2}\right).$$

17.3.3 Generic finite Appell families

The coordinate-classical Appell API has these exact signatures:

```
appell_polynomial(
    degree: int,
    values_at_zero: Sequence[Scalar],
) -> Polynomial

appell_polynomial_family(
    values_at_zero: Sequence[Scalar],
    *,
    name: str = "custom Appell polynomials",
) -> PolynomialFamily
```

For a supplied seed table $P_n(0)$, it constructs

$$P_n(x)=\sum_{k=0}^{n}\binom{n}{k}P_{n-k}(0)x^k.$$

Hence

$$P_n'(x)=nP_{n-1}(x).$$

The import should remain namespace-qualified:

```
from fractions import Fraction

import komorebi_math.coordinates as coordinates

seed = (
    Fraction(1),
    Fraction(-1, 2),
    Fraction(1, 6),
    Fraction(0),
    Fraction(-1, 30),
```

```
    Fraction(0),
)

bernoulli_appell = coordinates.appell_polynomial_family(
    seed,
    name="Bernoulli via Appell",
)

for degree in range(1, 6):
    derivative = coordinates.polynomial_derivative(
        bernoulli_appell.polynomial(degree)
    )
    expected = tuple(
        degree * coefficient
        for coefficient in bernoulli_appell.polynomial(degree - 1)
    )
    assert derivative == expected
```

The seed must begin with a nonzero value and extend through the highest degree requested later. It is a finite live callback, not an implicitly extensible symbolic generating function.

17.3.4 Chebyshev families

The exact constructors are

```
chebyshev_t_polynomial(degree: int) -> Polynomial
chebyshev_t_polynomial_family() -> PolynomialFamily

chebyshev_u_polynomial(degree: int) -> Polynomial
chebyshev_u_polynomial_family() -> PolynomialFamily
```

They satisfy

$$T_0 = 1, \qquad T_1 = x, \qquad T_{n+1} = 2xT_n - T_{n-1},$$

and

$$U_0 = 1, \qquad U_1 = 2x, \qquad U_{n+1} = 2xU_n - U_{n-1}.$$

For $n \geq 1$, the leading coefficient of T_n is 2^{n-1}, while the leading coefficient of U_n is 2^n.

17.3.5 Legendre polynomials

```
legendre_polynomial(
    degree: int,
) -> Polynomial

legendre_polynomial_family(
) -> PolynomialFamily
```

The implementation uses

$$P_0 = 1, \qquad P_1 = x,$$

$$(n+1)P_{n+1} = (2n+1)xP_n - nP_{n-1}.$$

The leading coefficient is

$$[x^n]P_n(x) = 2^{-n}\binom{2n}{n}.$$

17.3.6 Hermite conventions

The two conventions are exposed separately:

```
hermite_probabilists_polynomial(degree: int) -> Polynomial
hermite_probabilists_polynomial_family() -> PolynomialFamily

hermite_physicists_polynomial(degree: int) -> Polynomial
hermite_physicists_polynomial_family() -> PolynomialFamily
```

Probabilists' Hermite polynomials satisfy

$$He_0 = 1, \qquad He_1 = x, \qquad He_{n+1} = xHe_n - nHe_{n-1}.$$

Physicists' Hermite polynomials satisfy

$$H_0 = 1, \qquad H_1 = 2x, \qquad H_{n+1} = 2xH_n - 2nH_{n-1}.$$

The two families have leading coefficients 1 and 2^n, respectively. The explicit names prevent a silent convention change.

17.3.7 Ordinary Laguerre polynomials

```
laguerre_polynomial(
    degree: int,
) -> Polynomial

laguerre_polynomial_family(
) -> PolynomialFamily
```

Only the ordinary, unparameterized Laguerre family is implemented:

$$L_n(x) = \sum_{k=0}^{n}(-1)^k\binom{n}{k}\frac{x^k}{k!}.$$

Generalized Laguerre, Jacobi, Gegenbauer, and other parameterized orthogonal families are not supplied by this catalog.

17.3.8 Degree-four reference table

All rows below are exact ascending coefficient tuples returned by the installed implementation.

Family	Degree-four tuple
Bernoulli	$(-1/30, 0, 1, -2, 1)$
Euler	$(0, 1, 0, -2, 1)$
Chebyshev T	$(1, 0, -8, 0, 8)$
Chebyshev U	$(1, 0, -12, 0, 16)$
Legendre	$(3/8, 0, -15/4, 0, 35/8)$
Probabilists' Hermite	$(3, 0, -6, 0, 1)$
Physicists' Hermite	$(12, 0, -48, 0, 16)$
Laguerre	$(1, -4, 3, -2/3, 1/24)$

17.3.9 Classical-family boundaries

The implementation constructs these finite coefficient tuples with exact rational arithmetic, and the cited verification suites compare the formulas and coordinate conversions exactly. `PolynomialFamily` itself does not issue a family-level mathematical certificate. A derived `CoordinateTransform` certificate records finite matrix shape and determinant diagnostics. Neither mechanism, in this namespace, certifies:

- An orthogonality measure or interval.
- A norm or normalization integral.
- The location or separation of roots.
- Convergence of an infinite expansion.
- Approximation error for a truncated expansion.
- Gaussian quadrature weights.
- Analytic continuation of a generating function.

Those claims require separate mathematical objects and evidence.

17.4 Fibonacci, Lucas, Bell, Touchard, and combinatorial families

17.4.1 Fibonacci polynomial family

The standard Fibonacci polynomials satisfy

$$F_0(x) = 0, \qquad F_1(x) = 1, \qquad F_{n+1}(x) = xF_n(x) + F_{n-1}(x).$$

Their public constructors are

```
fibonacci_polynomial(
    index: int,
) -> Polynomial

fibonacci_polynomial_family(
) -> PolynomialFamily
```

Since F_n has degree $n-1$ for $n \geq 1$, the graded family is shifted:

$$G_n(x) = F_{n+1}(x).$$

This shift is part of the API contract. The degree-three family member is

$$G_3(x) = F_4(x) = x^3 + 2x,$$

stored as

```
(0, 2, 0, 1)
```

17.4.2 Lucas polynomial family

```
lucas_polynomial(
    index: int,
) -> Polynomial

lucas_polynomial_family(
) -> PolynomialFamily
```

The recurrence is

$$L_0(x) = 2, \qquad L_1(x) = x, \qquad L_n(x) = xL_{n-1}(x) + L_{n-2}(x).$$

Unlike the Fibonacci constructor, this sequence already has degree equal to its index, including a nonzero constant at degree zero. No index shift is required.

17.4.3 Pell polynomial family

```
pell_polynomial(
    index: int,
) -> Polynomial

pell_polynomial_family(
) -> PolynomialFamily
```

The implemented convention is

$$P_0(x) = 0, \qquad P_1(x) = 1, \qquad P_n(x) = 2xP_{n-1}(x) + P_{n-2}(x).$$

As with Fibonacci polynomials, the graded family uses P_{n+1}. Its leading coefficient is 2^n.

17.4.4 Recurrence-family comparison

At degree four, the three installed family members are

Family	Polynomial	Coefficient tuple
Fibonacci graded	$F_5 = x^4 + 3x^2 + 1$	$(1, 0, 3, 0, 1)$
Lucas	$L_4 = x^4 + 4x^2 + 2$	$(2, 0, 4, 0, 1)$
Pell graded	$P_5 = 16x^4 + 12x^2 + 1$	$(1, 0, 12, 0, 16)$

These are polynomial-coordinate families. The recurrence-defect and companion state coordinates of Chapter 18 are different objects even when they use the same family names.

17.4.5 Bell and Touchard ownership boundary

Bell and Touchard coefficient rows are owned by `komorebi_math.generating`, not by the built-in polynomial coordinate catalog. The relevant public signatures are

```
bell_numbers(
    count: int,
) -> tuple[int, ...]

generalized_bell_numbers(
    power: int,
    count: int,
) -> tuple[int, ...]

generalized_bell_polynomials(
    power: int,
    count: int,
) -> tuple[tuple[int, ...], ...]

weighted_generalized_bell_polynomials(
    power: int,
    count: int,
    weights: Iterable[int | Fraction] | Callable[[int], int | Fraction],
) -> tuple[tuple[Fraction, ...], ...]
```

```
weighted_generalized_bell_numbers(
    power: int,
    count: int,
    weights: Iterable[int | Fraction] | Callable[[int], int | Fraction],
) -> tuple[Fraction, ...]

audit_touchard(
    values: Sequence[int],
    prime: int,
) -> RelationAudit
```

The factorial-power Bell polynomials are defined by

$$\exp\left(x\sum_{m\geq 1}\frac{z^m}{(m!)^s}\right)=\sum_{n\geq 0}B_n^{(s)}(x)\frac{z^n}{(n!)^s}.$$

Their exact recurrence is

$$B_n^{(s)}(x)=x\sum_{m=1}^{n}\binom{n-1}{m-1}\binom{n}{m}^{s-1}B_{n-m}^{(s)}(x).$$

When $s=1$, these rows are the ordinary Touchard polynomials. Evaluation at $x=1$ gives the ordinary Bell numbers. The first six rows are

```
(1,)
(0, 1)
(0, 1, 1)
(0, 1, 3, 1)
(0, 1, 7, 6, 1)
(0, 1, 15, 25, 10, 1)
```

and their values at $x=1$ begin

```
1, 1, 2, 5, 15, 52
```

This lookup intentionally fails:

```
from komorebi_math.coordinates import get_polynomial_family

get_polynomial_family("touchard")
```

with

```
ValidationError: unknown polynomial family 'touchard'
```

17.4.6 Finite Touchard adapter

Generated rows can be adapted explicitly when an exact finite family connection is needed:

```
from fractions import Fraction

from komorebi_math.coordinates import (
    PolynomialFamily,
    connection_transform,
    get_polynomial_family,
)
from komorebi_math.generating import generalized_bell_polynomials

maximum_degree = 5
rows = generalized_bell_polynomials(1, maximum_degree + 1)

touchard = PolynomialFamily(
    "Touchard polynomials",
    lambda degree: tuple(Fraction(value) for value in rows[degree]),
)

to_monomials = connection_transform(
    touchard,
    get_polynomial_family("monomial"),
    maximum_degree,
)

assert to_monomials.roundtrip_valid()
print(to_monomials.matrix)
```

Mathematically simplified values:

```
((1, 0, 0, 0, 0, 0),
 (0, 1, 1, 1, 1, 1),
 (0, 0, 1, 3, 7, 15),
 (0, 0, 0, 1, 6, 25),
 (0, 0, 0, 0, 1, 10),
 (0, 0, 0, 0, 0, 1))
```

The captured row table must extend through every degree later requested from the callback. This adapter does not mutate the built-in catalog and does not make the callback-bearing `PolynomialFamily` portable.

17.4.7 Touchard congruence audit

For a prime p, the classical Touchard congruence is

$$B_{n+p} \equiv B_{n+1} + B_n \pmod{p}.$$

The finite audit is

```
from komorebi_math.generating import audit_touchard, bell_numbers

audit = audit_touchard(bell_numbers(30), 5)

print(audit.modulus)
print(audit.tested_cases)
print(audit.failures)
```

Output:

```
5
25
0
```

The function names its second argument `prime`, but it does not internally test primality or impose the number-theoretic hypothesis required by Touchard's theorem. Callers should supply a positive prime. The returned record counts modular failures on exactly the available prefix indices $0 \le n < \text{len}(\texttt{values}) - p$. It is a finite audit of the supplied data, not a new proof of the congruence for all indices.

17.4.8 Bell-family validation boundaries

`generalized_bell_polynomials` and `generalized_bell_numbers` explicitly reject a Boolean, noninteger, or nonpositive factorial power and reject a negative count. A count of zero returns an empty tuple. Their current runtime does not perform a separate explicit integer-type check for `count`. A nonintegral value will fail when Python attempts to use it as a finite range. Weighted families accept either a callable on positive block sizes or a table whose zeroth entry is ignored. A finite table that is too short for the requested coefficient range raises `ValueError`.

The Bell generators use exact integer or rational recurrence arithmetic. They do not require SymPy. The modular audit layer and its hypotheses remain separate from the coordinate-transform layer.

17.5 `connection_transform`

$$p_n(x) = \sum_{k=0}^{n} C_{kn} q_k(x).$$

17.5.1 Exact signature and direction

```
connection_transform(
    source: PolynomialFamily,
    target: PolynomialFamily,
    degree: int,
    *,
    budget: CoordinateBudget = DEFAULT_COORDINATE_BUDGET,
) -> CoordinateTransform
```

Let $P = (p_n)$ be the source family and $Q = (q_n)$ the target family. A source coefficient vector a and target coefficient vector b represent the same polynomial when

$$\sum_{n=0}^{d} a_n p_n(x) = \sum_{k=0}^{d} b_k q_k(x).$$

In monomial coefficient matrices this becomes

$$M_P a = M_Q b.$$

Therefore

$$b = C_{Q \leftarrow P} a, \qquad C_{Q \leftarrow P} = M_Q^{-1} M_P.$$

The returned `CoordinateTransform` maps source coordinates to target coordinates. Its column n is the target coefficient vector of the source basis polynomial p_n. This is the matrix convention expressed by the displayed equation at the beginning of this section.

Choosing the connection method. `PolynomialFamily` has no `.connection_to()` method. Use `connection_transform(source, target, degree)`. The similarly named `FiniteBasis.connection_to(target)` method belongs to the arbitrary finite basis API and is used for Bernstein, Newton, and Lagrange bases.

17.5.2 Triangularity, determinant, and inverse

Let $\lambda_n(P) = [x^n]p_n(x)$ and $\lambda_n(Q) = [x^n]q_n(x)$. Since both coefficient matrices are upper triangular,

$$[C_{Q\leftarrow P}]_{nn} = \frac{\lambda_n(P)}{\lambda_n(Q)}.$$

Consequently,

$$\det C_{Q\leftarrow P} = \prod_{n=0}^{d} \frac{\lambda_n(P)}{\lambda_n(Q)} \neq 0.$$

Every valid graded-family connection is therefore exactly invertible. Its inverse is the connection in the opposite direction:

$$C_{P\leftarrow Q} = C_{Q\leftarrow P}^{-1}.$$

For three compatible families,

$$C_{R\leftarrow P} = C_{R\leftarrow Q}C_{Q\leftarrow P}.$$

The API uses the same order:

```
source_to_middle.then(middle_to_target)
```

forms `middle_to_target.matrix @ source_to_middle.matrix`.

17.5.3 Returned transform interface

The most relevant methods and properties are

```
CoordinateTransform.apply(
    self,
    coordinates: Sequence[Scalar],
) -> Vector

CoordinateTransform.inverse(
    self,
    *,
    theorem: str | None = None,
) -> CoordinateTransform

CoordinateTransform.then(
    self,
    following: CoordinateTransform,
    *,
    theorem: str | None = None,
) -> CoordinateTransform

CoordinateTransform.roundtrip_valid(
    self,
) -> bool

CoordinateTransform.certificate(
```

```
    self,
) -> Certificate
```

and

```
source_dimension
target_dimension
square
determinant
```

For an invertibility claim, use a nonzero determinant, `roundtrip_valid()`, or successful exact inversion. The generic transform certificate records finite shape and determinant diagnostics. Its `valid` flag is not, by itself, a generic nonsingularity assertion for every possible manually constructed square `CoordinateTransform`. A transform returned by `connection_transform` is nonsingular because both validated graded coefficient matrices are nonsingular.

17.5.4 Legendre-to-Chebyshev worked example

```
from fractions import Fraction

from komorebi_math.stable import (
    connection_transform,
    get_polynomial_family,
)

legendre = get_polynomial_family("legendre")
chebyshev = get_polynomial_family("chebyshev-t")

change = connection_transform(legendre, chebyshev, 3)
source = tuple(Fraction(value) for value in (1, 2, 3, 4))
target = change.apply(source)
recovered = change.inverse().apply(target)

print(change.matrix)
print(change.determinant)
print(target)
print(recovered)
print(change.roundtrip_valid())
```

Mathematically simplified values:

```
((1, 0, 1/4, 0),
 (0, 1, 0, 3/8),
 (0, 0, 3/4, 0),
 (0, 0, 0, 5/8))
15/32
(7/4, 7/2, 9/4, 5/2)
(1, 2, 3, 4)
True
```

The first matrix columns encode

$$P_0 = T_0, \qquad P_1 = T_1,$$

$$P_2 = \frac{1}{4}T_0 + \frac{3}{4}T_2,$$

and

$$P_3 = \frac{3}{8}T_1 + \frac{5}{8}T_3.$$

17.5.5 CLI form

The same connection can be emitted as exact JSON:

```
python -m komorebi_math coordinates polynomial --source legendre --target chebyshev-t --degree 3
```

The result includes

```
{
  "degree": 3,
  "determinant": "15/32",
  "source": "Legendre polynomials coordinates through degree 3",
  "target": "Chebyshev T polynomials coordinates through degree 3",
  "verified": true
}
```

The complete JSON also contains the exact string-valued matrix. The committed degree-four behavioral record has determinant

$$\frac{525}{2048}.$$

Available catalog entries can be inspected with

```
python -m komorebi_math coordinates catalog
```

17.5.6 Named Euler-to-Fibonacci specialization

The generic connection mechanism underlies the named specialization

```
euler_to_fibonacci_transform(
    degree: int,
    *,
    budget: CoordinateBudget = DEFAULT_COORDINATE_BUDGET,
) -> CoordinateTransform
```

That constructor independently compares the general matrix with the explicit coefficient formula and raises `ValidationError` if they disagree. Through degree four its matrix is

$$\begin{bmatrix} 1 & -1/2 & -1 & 7/4 & 2 \\ 0 & 1 & -1 & -2 & 5 \\ 0 & 0 & 1 & -3/2 & -3 \\ 0 & 0 & 0 & 1 & -2 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

Chapter 18's sequence-level Euler-to-Fibonacci construction is a separate map. It analyzes a finite sequence into an initial Fibonacci companion state and a recurrence-defect stream. It is not this polynomial-family connection, nor an alternative interpretation of this connection matrix. The sequence-level construction and its worked state path appear in Chapter 18.

17.5.7 Resource budget

The default finite coordinate budget is

```
CoordinateBudget(
    maximum_matrix_dimension=512,
    maximum_polynomial_degree=512,
    maximum_horizon=4096,
    maximum_exact_entries=1_000_000,
)
```

Before materializing a family connection, the implementation checks both the degree and the $(d+1)\times(d+1)$ exact matrix allocation. Because degree d requires dimension $d+1$, the default matrix-dimension limit makes degree 511 the largest possible connection under the default budget even though the independent degree limit is 512.

A deliberately small budget rejects this request before the matrix is allocated:

```
from komorebi_math.coordinates import (
    CoordinateBudget,
    connection_transform,
    get_polynomial_family,
)

small = CoordinateBudget(maximum_matrix_dimension=4)

connection_transform(
    get_polynomial_family("monomial"),
    get_polynomial_family("legendre"),
    4,
    budget=small,
)
```

Diagnostic:

```
ResourceLimitError: polynomial family connection requires a 5 by 5 matrix,
exceeding the coordinate dimension limit 4
```

The budget is a resource contract, not a performance prediction. Exact rational coefficient growth can make a computation expensive before it reaches the nominal dimension ceiling.

17.5.8 Arithmetic complexity

Let $N = d+1$. The table below counts exact scalar operations and suppresses the potentially dominant bit complexity of growing rational numerators and denominators.

Operation	Arithmetic scale	Stored exact entries
Apply a dense family connection	$O(N^2)$	$O(N)$ output
Store one coefficient matrix	$O(N^2)$	$O(N^2)$
Exact matrix inversion	$O(N^3)$	$O(N^2)$
Dense matrix product	$O(N^3)$	$O(N^2)$
Complete family connection	$O(N^3)$ plus family generation	$O(N^2)$
Newton basis construction	$O(N^2)$	$O(N^2)$
Lagrange basis construction	$O(N^3)$	$O(N^2)$
Bell rows through degree d	$O(N^3)$	$O(N^2)$

Family generation varies. Closed coefficient formulas can fill one polynomial in $O(n)$ or $O(n^2)$ arithmetic, while recurrence constructors that are restarted independently for each degree can add another cubic-scale component

across a complete coefficient matrix. Exact fraction size, rather than matrix dimension alone, often controls practical runtime.

17.5.9 Persistence boundary

`PolynomialFamily` contains an executable callback and has no portable codec. Named families should be reconstructed by catalog name. Custom families should be reconstructed from their declared finite data and rule.

The registered data-only types used here are portable. Portability is not an automatic property of every object derived from a family callback. In particular, a `CoordinateTransform` returned by `connection_transform` can use the specialized transform functions

```
save_transform(
    path: str | Path,
    transform: CoordinateTransform,
    *,
    overwrite: bool = False,
) -> Path

load_transform(
    path: str | Path,
) -> CoordinateTransform
```

For example:

```
from komorebi_math.coordinates import (
    connection_transform,
    get_polynomial_family,
    load_transform,
    save_transform,
)

change = connection_transform(
    get_polynomial_family("legendre"),
    get_polynomial_family("chebyshev-t"),
    8,
)

path = save_transform("legendre_to_chebyshev.json", change)
restored = load_transform(path)

assert restored == change
```

The portable registry includes these four types:

- `FiniteBasis`
- `CoordinateTransform`
- `PolynomialCoordinateOperator`
- `CoordinateBudget`

Objects of these types can be written with `save_coordinate_object` and read with `load_coordinate_object`. A custom callback, an arbitrary closure captured by that callback, and an unregistered derived class are not made portable merely because their outputs are rational.

The version-1 portable envelope records a payload SHA-256 digest. Loading rejects a changed payload or a schema mismatch. This is an integrity mechanism, not a cryptographic signature of authorship or origin.

17.5.10 Connection failure matrix

Condition	Exception	Meaning
Source or target is not `PolynomialFamily`	`ValidationError`	Family protocol not supplied
Negative, Boolean, or noninteger degree	`ValidationError`	Invalid finite truncation
Family callback violates exact grade	`ValidationError`	Coefficient matrix is not a graded basis
Degree or matrix exceeds budget	`ResourceLimitError`	Allocation refused before construction
Applied vector has length other than $d+1$	`DimensionError`	Coordinate dimension mismatch
Composed transform names do not meet	`ValidationError`	Endpoint labels do not compose
Composed transform dimensions differ	`DimensionError`	Matrix shapes do not compose
Requested inverse is rectangular	`DimensionError`	Only square transforms are invertible
Exact square matrix is singular	`ValidationError`	Inverse does not exist
Appell seed is empty or starts at zero	`ValidationError`	Not a valid graded Appell family
Appell seed is too short	`DimensionError`	Requested polynomial is undeclared
Unknown family alias such as `bell`	`ValidationError`	Object is outside the built-in catalog

17.5.11 Verification and evidence map

The implementation is exercised at several levels.

Evidence source	Relevant checks
`tests/test_coordinates_general_classical.py`	Classical formulas, all catalog families, Bernstein partition of unity, Newton/Lagrange cardinality, Appell lowering
`tests/test_coordinates_polynomials.py`	Fibonacci companion identity, monomial/Fibonacci formula, Euler/Fibonacci matrix, composition, operator conjugacy, secant specialization
`tests/test_coordinates_general_calculus.py`	Derivative/integral operators, falling-factorial finite difference, transported operators
`tests/test_coordinates_general_persistence.py`	Direct `FiniteBasis` and `PolynomialCoordinateOperator` round trips, `CoordinateTransform` edges inside an atlas round trip, and tamper rejection for a formal-coordinate record
`tests/test_coordinates_normalized_persistence.py`	Normalization-change `CoordinateTransform` persistence, recurrence-record persistence, and transform-envelope tamper rejection
`tests/test_block14_cli_api.py`	Catalog, default polynomial connection, Legendre/Chebyshev CLI, golden determinant
`verification/block14_general_coordinate_audit.py`	Every catalog family through degree 10 and exact evaluation at 13 rational points
`verification/block14_deep_audit.py`	Independent Fibonacci recurrence and independent Euler/Fibonacci triangular resolution through degree 30
`tests/test_generating_foundation.py`	Bell row integrality, Bell-number evaluation, and finite Touchard audits
`examples/classical_coordinate_families.py`	Executable Legendre/Chebyshev and operator-transport demonstration

The focused source replay for the four principal coordinate test modules reports

```
15 passed
```

and the installed coordinate verification reports

```
verification passed 24/24 checks
```

Relevant named verification checks include:

- `Euler to Fibonacci polynomial connection.`
- `operator conjugation.`
- `portable coordinate records and tamper rejection.`
- `coordinate resource contract.`
- `classical polynomial-family atlas.`
- `coordinate differential and difference calculus.`
- `general portable coordinate records.`

All claims in this chapter are finite. A successful transform proves an exact identity in the declared polynomial space through degree d. A successful prefix audit proves that the checked cases passed. Neither result silently extends its evidence beyond the declared finite boundary.

Chapter 17 summary. A graded `PolynomialFamily` turns exact coefficient rules into upper-triangular basis matrices. Built-in families cover monomial, factorial, Bernoulli, Euler, recurrence, Chebyshev, Legendre, Hermite, and Laguerre coordinates. Bernstein and interpolation objects are fixed `FiniteBasis` records. Bell and Touchard rows remain owned by the generating-function namespace and enter the coordinate layer only through an explicit finite adapter. `connection_transform` maps source coefficient vectors to target coefficient vectors by $M_Q^{-1} M_P$, subject to an explicit resource budget and a data-only persistence boundary.

18. Combinatorial, recurrence, and state-space coordinates

First route. If your input is a finite list, the square-sequence example in Section 18.2 is the simplest exact roundtrip. To study a proposed recurrence, use the direct analysis and reconstruction in Section 18.3.4, then inspect the defects. A nonzero defect is a coordinate of the supplied data. The dense transform and state-space sections become useful when you need to compose coordinate maps or compare internal representations.

Three exact coordinate languages encode finite data. The first replaces a sequence or polynomial coefficient vector by triangular combinatorial coordinates. The second separates a finite sequence into an initial recurrence state and a forcing, or defect, stream. The third changes coordinates inside finite realizations and discrete-time state-space models without changing their observable behavior.

Every matrix in this chapter is finite. Exact constructors convert integer and `Fraction` inputs to immutable rational matrices. They do not invoke a symbolic algebra system, a numerical eigensolver, or a GPU backend. This gives the identities in this chapter exact finite semantics, but it does not turn finite agreement into a theorem about an unspecified infinite sequence.

The matrix direction, composition order, inversion behavior, and certificate semantics of `CoordinateTransform` are defined in Chapter 16. This chapter uses that common contract rather than repeating it. In particular, if

```
target_coordinates = transform.apply(source_coordinates)
```

then rows of `transform.matrix` index target coordinates and columns index source coordinates.

> **API tier.** The complete interface documented here is public through `komorebi_math.coordinates`. A selected convenience subset is re-exported at the `komorebi_math` root. Of the functions in this chapter, `forward_difference_transform` is also part of the frozen `komorebi_math.stable` interface. The remaining names are research-tier public APIs in `1.0.0b4`. Applications using them should pin the package version. The shared `CoordinateTransform` and `FiniteBasis` result types are themselves also available from the stable namespace. This tier statement is about the chapter-specific constructors and algorithms.

> **Chapter 18 summary.** Stirling, Lah, binomial, difference, zeta, and Möbius matrices are exact finite changes of coordinates. A recurrence model maps a prefix to its initial state plus the unique defect stream that makes the recurrence true. Companion Green weights reconstruct the same prefix by variation of constants. Realization and state-space coordinates then expose observability, controllability, intertwiners, and transfer invariance. The implementation also contains one confirmed convenience-method defect, disclosed in Section 18.3, with a fully working lower-level path.

18.1 Binomial and Stirling transforms

18.1.1 Exact triangular conventions

For nonnegative integers n and k, the package uses the Stirling recurrence

$$S(n,k) = S(n-1,k-1) + kS(n-1,k)$$

for the second kind and

$$s(n,k) = s(n-1,k-1) - (n-1)s(n-1,k)$$

for the signed first kind. The unsigned first-kind value is

$$c(n,k) = (-1)^{n-k}s(n,k).$$

The unsigned Lah number uses

$$L(n,k) = \begin{cases} 1, & n = k = 0, \\ \binom{n-1}{k-1}\dfrac{n!}{k!}, & 1 \le k \le n, \\ 0, & \text{otherwise.} \end{cases}$$

These scalar functions are public:

Function	Exact signature	Meaning
`stirling_second`	`stirling_second(n: int, k: int) -> int`	$S(n,k)$
`stirling_first_signed`	`stirling_first_signed(n: int, k: int) -> int`	$s(n,k)$
`stirling_first_unsigned`	`stirling_first_unsigned(n: int, k: int) -> int`	$c(n,k)$
`lah_number`	`lah_number(n: int, k: int) -> int`	$L(n,k)$
`mobius_integer`	`mobius_integer(value: int) -> int`	Classical integer Möbius function $\mu(n)$

For $k > n$, `stirling_second`, `stirling_first_signed`, and `lah_number` return the integer zero. The current `stirling_first_unsigned` implementation multiplies that zero by $(-1)^{n-k}$. Because a negative exponent produces a Python float, this out-of-triangle edge returns `0.0` or `-0.0` despite its declared `-> int` annotation. Values inside the triangle remain integers, and the transform constructors normalize the zero to an exact `Fraction(0)`. At $(0,0)$, both Stirling functions and the Lah function return one. Negative indices and Boolean inputs are rejected. `mobius_integer` requires a positive integer.

The basis identities that fix the matrix orientation are

$$x^n = \sum_{k=0}^{n} S(n,k)x^{\underline{k}}, \qquad x^{\underline{n}} = \sum_{k=0}^{n} s(n,k)x^k,$$

$$x^n = \sum_{k=0}^{n} (-1)^{n-k}S(n,k)x^{\overline{k}}, \qquad x^{\overline{n}} = \sum_{k=0}^{n} c(n,k)x^k,$$

and

$$x^{\overline{n}} = \sum_{k=0}^{n} L(n,k) x^{\underline{k}}.$$

Here

$$x^{\underline{k}} = x(x-1)\cdots(x-k+1), \qquad x^{\overline{k}} = x(x+1)\cdots(x+k-1).$$

If a polynomial has monomial coefficient vector $a = (a_0, \dots, a_N)^T$, the matrix returned by `monomial_to_falling_factorial_transform(N)` has entry

$$T_{k,n} = S(n,k),$$

so `T.apply(a)` is the coefficient vector in the falling-factorial basis. The other constructors follow the same target-row, source-column convention.

18.1.2 Transform constructors

All combinatorial constructors accept an optional `CoordinateBudget`. In the table below, `budget=DEFAULT_COORDINATE_BUDGET` is written as `budget=DEFAULT` to keep signatures readable.

Constructor	Exact public signature	Theorem metadata
`monomial_to_falling_factorial_transform`	`(degree: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C1`
`falling_factorial_to_monomial_transform`	`(degree: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C2`
`monomial_to_rising_factorial_transform`	`(degree: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C3`
`rising_factorial_to_monomial_transform`	`(degree: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C4`
`rising_to_falling_factorial_transform`	`(degree: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C5`
`binomial_transform`	`(size: int, *, inverse: bool = False, source: str = "sequence values", target: str = "binomial transform", budget=DEFAULT) -> CoordinateTransform`	`CC.C6` or `CC.C7`
`forward_difference_transform`	`(size: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C8`
`newton_evaluation_transform`	`(size: int, *, budget=DEFAULT) -> CoordinateTransform`	`CC.C9`
`divisor_zeta_transform`	`(size: int, *, inverse: bool = False, budget=DEFAULT) -> CoordinateTransform`	`CC.C10` or `CC.C11`
`subset_zeta_transform`	`(rank: int, *, inverse: bool = False, budget=DEFAULT) -> CoordinateTransform`	`CC.C12` or `CC.C13`
`transform_sequence`	`(values: Sequence[int | Fraction], transform: CoordinateTransform) -> tuple[Fraction, ...]`	Uses the supplied transform

`degree` means the largest polynomial degree, so a degree-N connection is an $(N+1) \times (N+1)$ matrix. `size` means the number of sequence coordinates, so a size-N transform is $N \times N$.

18.1.3 Binomial coordinates

The forward finite binomial transform is

$$b_n = \sum_{k=0}^{n} \binom{n}{k} a_k, \qquad 0 \le n < N.$$

Its inverse is

$$a_n = \sum_{k=0}^{n} (-1)^{n-k} \binom{n}{k} b_k.$$

The inverse can be requested directly:

```
from komorebi_math.coordinates import binomial_transform

values = (1, 2, 3, 4)
forward = binomial_transform(4)
inverse = binomial_transform(4, inverse=True)

coordinates = forward.apply(values)
recovered = inverse.apply(coordinates)

print("coordinates:", coordinates)
print("recovered:", recovered)
```

Output:

```
coordinates: (Fraction(1, 1), Fraction(3, 1), Fraction(8, 1), Fraction(20, 1))
recovered: (Fraction(1, 1), Fraction(2, 1), Fraction(3, 1), Fraction(4, 1))
```

The input integers are converted to `Fraction` objects. Exact output does not imply that the transformed numbers are integers for an arbitrary rational input. It means the rational result is represented without floating-point roundoff.

18.1.4 Divisor zeta and Möbius coordinates

Indices of the dense divisor transform correspond to the positive integers $1, \dots, N$. The forward map is

$$b_n = \sum_{d \mid n} a_d, \qquad 1 \le n \le N,$$

and its inverse is

$$a_n = \sum_{d \mid n} \mu(n/d) b_d.$$

For example:

```
from komorebi_math.coordinates import divisor_zeta_transform

values = (1, 2, 3, 4, 5, 6)
zeta = divisor_zeta_transform(6)
mobius = divisor_zeta_transform(6, inverse=True)

divisor_sums = zeta.apply(values)
assert mobius.apply(divisor_sums) == values
print(divisor_sums)
```

Output:

```
(Fraction(1, 1), Fraction(3, 1), Fraction(4, 1),
 Fraction(7, 1), Fraction(6, 1), Fraction(12, 1))
```

Although the mathematical divisor matrix is sparse, the current constructor materializes a dense exact matrix. The resource discussion in Section 18.5 is therefore part of the operational contract.

18.1.5 Boolean-lattice zeta and Möbius coordinates

Subsets are encoded by bit masks from 0 through $2^r - 1$. For a rank-r Boolean lattice,

$$b(S) = \sum_{T \subseteq S} a(T),$$

with inverse

$$a(S) = \sum_{T \subseteq S} (-1)^{|S \setminus T|} b(T).$$

At rank two, the input order is $\emptyset, \{0\}, \{1\}, \{0, 1\}$. Thus:

```python
from komorebi_math.coordinates import subset_zeta_transform

values = (1, 2, 3, 4)
zeta = subset_zeta_transform(2)
inverse = subset_zeta_transform(2, inverse=True)

subset_sums = zeta.apply(values)
assert inverse.apply(subset_sums) == values
print(subset_sums)
```

Output:

```
(Fraction(1, 1), Fraction(3, 1), Fraction(4, 1), Fraction(10, 1))
```

The coordinate count is 2^r, so a dense matrix contains 4^r entries. Under the default matrix-dimension budget, rank nine is the largest accepted rank. Rank ten would request a 1024×1024 matrix and is rejected before allocation.

18.2 Forward-difference coordinates

$$\Delta^k a_0 = \sum_{j=0}^{k} (-1)^{k-j} \binom{k}{j} a_j.$$

18.2.1 Analysis and Newton synthesis

For samples

$$a = (f(0), f(1), \dots, f(N-1))^T,$$

`forward_difference_transform(N)` returns the lower-triangular analysis matrix

$$D_{k,j} = \begin{cases} (-1)^{k-j}\binom{k}{j}, & j \le k, \\ 0, & j > k. \end{cases}$$

Its output is

$$(f(0), \Delta f(0), \ldots, \Delta^{N-1} f(0))^T.$$

`newton_evaluation_transform(N)` is the exact inverse. It implements

$$f(n) = \sum_{k=0}^{n} \binom{n}{k} \Delta^k f(0), \qquad 0 \le n < N.$$

The inverse is constructed from the analysis transform and exact rational matrix inversion. Both transforms are square, and their exact determinant is one.

18.2.2 Worked example: the square sequence

A quadratic sequence has no forward differences above order two. The complete round trip is:

```
from komorebi_math.stable import forward_difference_transform
from komorebi_math.coordinates import newton_evaluation_transform

squares = (0, 1, 4, 9, 16, 25)
analysis = forward_difference_transform(6)
synthesis = newton_evaluation_transform(6)

differences = analysis.apply(squares)
recovered = synthesis.apply(differences)

assert recovered == squares
print("differences:", differences)
print("recovered:", recovered)
```

Output:

```
differences: (Fraction(0, 1), Fraction(1, 1), Fraction(2, 1),
              Fraction(0, 1), Fraction(0, 1), Fraction(0, 1))
recovered: (Fraction(0, 1), Fraction(1, 1), Fraction(4, 1),
            Fraction(9, 1), Fraction(16, 1), Fraction(25, 1))
```

The equivalent command-line workflow is:

```
python -m komorebi_math coordinates combinatorial --kind forward-difference --size 6 --values "0,1,4,9,16,25"
```

Its JSON result includes the exact 6×6 matrix, the six output coordinates, source and target names, and `"verified": true`.

18.2.3 Interpretation boundary

Vanishing differences through a finite sample horizon prove a finite matrix identity. If $\Delta^{d+1} f(0) = 0$ throughout a sufficiently long declared sample grid, Newton interpolation returns a degree-at-most-d polynomial on that grid. The package does not infer that an externally supplied infinite sequence must continue to obey the same polynomial law.

`transform_sequence(values, transform)` is a convenience wrapper around `transform.apply(values)`. It requires the sequence length to equal the transform's source dimension. It does not truncate or pad.

18.3 Recurrence defect coordinates

18.3.1 A recurrence as a coordinate system

Let $c = (c_0, \dots, c_{d-1})$ be a nonempty exact coefficient vector. The package convention is

$$a_{n+d} = \sum_{i=0}^{d-1} c_i a_{n+i} + \delta_n.$$

The associated polynomial, stored in ascending coefficient order, is

$$p_c(x) = x^d - \sum_{i=0}^{d-1} c_i x^i,$$

so

```
recurrence_polynomial((c0, c1, ..., c_last))
```

returns

```
(-c0, -c1, ..., -c_last, 1)
```

The consecutive-state companion matrix is

$$C_c = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 0 \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & 1 \\ c_0 & c_1 & \cdots & c_{d-2} & c_{d-1} \end{pmatrix}.$$

With

$$x_n = (a_n, a_{n+1}, \dots, a_{n+d-1})^T,$$

the forced state equation is

$$x_{n+1} = C_c x_n + e_d \delta_n, \qquad a_n = e_1^T x_n.$$

For a finite prefix of length $L \geq d$, the unique recurrence coordinates are

$$\mathcal{A}_c(a) = (a_0, \dots, a_{d-1}, \delta_0, \dots, \delta_{L-d-1})^T.$$

The first d rows of the analysis matrix are identity rows. For $0 \leq n < L - d$, row $d + n$ has entries $-c_i$ in columns $n + i$ and a one in column $n + d$. Therefore the full matrix is unit lower triangular:

$$\det \mathcal{A}_c = 1.$$

This is stronger than nonsingularity over $\mathbb{Q}$: the same triangular formula is invertible over every coefficient field containing the recurrence coefficients.

18.3.2 Core recurrence API

`RecurrenceLike` means either an iterable of exact scalars or an arithmetic `LinearRecurrence`. The coordinate module reads only its coefficient vector.

Name	Exact public signature	Result
`recurrence_polynomial`	`(coefficients: RecurrenceLike) -> Vector`	Ascending coefficients of p_c
`companion_matrix`	`(coefficients: RecurrenceLike) -> Matrix`	Exact $d \times d$ companion matrix
`apply_recurrence_defect`	`(values: Sequence[Scalar], coefficients: RecurrenceLike) -> Vector`	The defect stream (δ_n)
`recurrence_analysis_transform`	`(coefficients, length: int, *, name: str | None = None, budget= DEFAULT) -> CoordinateTransform`	Dense analysis matrix, `CC.R1`
`recurrence_synthesis_transform`	`(coefficients, length: int, *, name: str | None = None, budget= DEFAULT) -> CoordinateTransform`	Exact inverse, `CC.R1`
`analyze_recurrence_coordinates`	`(values, coefficients, *, name: str = "recurrence") -> Recurrence CoordinateRecord`	Direct $O(Ld)$ analysis
`synthesize_recurrence_coordinates`	`(record: RecurrenceCoordinate Record) -> Vector`	Direct $O(Ld)$ reconstruction
`coordinate_change_between_recurrences`	`(source_coefficients, target_ coefficients, length, *, source_ name="source recurrence", target_ name="target recurrence", budget= DEFAULT) -> CoordinateTransform`	Exact bridge, `CC.R2`
`defect_green_weights`	`(coefficients, count: int) -> Vector`	Companion impulse-response prefix
`variation_of_constants_prefix`	`(record: RecurrenceCoordinate Record) -> Vector`	Green-kernel reconstruction

The dense transform constructors obey `CoordinateBudget`. The direct record functions do not build an $L \times L$ matrix and therefore are not subject to the matrix-dimension limit. They still materialize the finite input and output vectors in memory.

18.3.3 `RecurrenceCoordinateRecord`

The immutable exact record is

```
RecurrenceCoordinateRecord(
    name: str,
    coefficients: Vector,
    initial: Vector,
    defects: Vector,
) -> None
```

Its fields and derived properties are:

Member	Meaning
`.name`	Nonempty coordinate-system name
`.coefficients`	Exact recurrence vector c
`.initial`	Initial state of length d
`.defects`	Forcing coordinates of length $L - d$
`.order`	d
`.length`	$L = d + \lvert\text{defects}\rvert$
`.homogeneous`	`True` exactly when every defect is zero

Member	Meaning
`.coordinates()`	`.initial + .defects`
`.reconstruct()`	Direct synthesis of the finite prefix
`.certificate()`	Reanalyzes the reconstruction and compares both coordinate parts
`.as_linear_recurrence()`	Homogeneous arithmetic recurrence using the same coefficients and initial state

`.as_linear_recurrence()` intentionally ignores `.defects`. It represents the recorded prefix only when `.homogeneous` is true. Otherwise it returns the unforced comparison model rather than another encoding of the forced record.

The exact certificate has theorem identifier `CC.R1`. Its checked assumptions are a finite sequence prefix and a constant-coefficient recurrence. Diagnostics record the length, order, and homogeneous flag. A valid certificate means the stored coordinates reconstruct and reanalyze exactly. It does not claim that a nonzero defect stream eventually vanishes.

18.3.4 Working analysis and synthesis path

Use this recommended path for the recorded `1.0.0b4` baseline:

```
from komorebi_math.coordinates import (
    analyze_recurrence_coordinates,
    synthesize_recurrence_coordinates,
)

values = (1, 2, 3, 4, 5, 6)
record = analyze_recurrence_coordinates(
    values,
    (1, 1),
    name="Fibonacci companion",
)

recovered = synthesize_recurrence_coordinates(record)
record.certificate().require()

assert recovered == values
print("initial:", record.initial)
print("defects:", record.defects)
print("homogeneous:", record.homogeneous)
```

Output:

```
initial: (Fraction(1, 1), Fraction(2, 1))
defects: (Fraction(0, 1), Fraction(-1, 1),
          Fraction(-2, 1), Fraction(-3, 1))
homogeneous: False
```

Synthesis executes the forced recurrence directly:

$$a_{n+d} = \delta_n + \sum_{i=0}^{d-1} c_i a_{n+i}.$$

It does not invert the dense analysis matrix.

18.3.5 Recorded `RecurrenceModel.synthesize()` erratum

> **Recorded baseline defect.** In the audited `1.0.0b4` source, the convenience method `RecurrenceModel.synthesize(coordinates)` passed an obsolete fifth data argument to the four-field `RecurrenceCoordinateRecord` constructor. Every otherwise valid invocation reached:
>
> ```
> TypeError: RecurrenceCoordinateRecord.__init__() takes 5 positional arguments but 6 were given
> ```
>
> This failure was confirmed by direct execution in the recorded baseline and was not covered by its shipped tests. It was a constructor-call defect, not a failure of recurrence synthesis itself.

For the recorded baseline, the working lower-level path is:

```python
from komorebi_math.coordinates import (
    RecurrenceCoordinateRecord,
    get_recurrence_model,
    synthesize_recurrence_coordinates,
)

model = get_recurrence_model("Fibonacci")
values = (0, 1, 1, 2, 3, 5, 8, 13)
record = model.analyze(values)
coordinates = record.coordinates()

# To synthesize coordinates obtained elsewhere:
rebuilt_record = RecurrenceCoordinateRecord(
    model.name,
    model.coefficients,
    coordinates[: model.order],
    coordinates[model.order :],
)
recovered = synthesize_recurrence_coordinates(rebuilt_record)
assert recovered == values
```

Do not present `model.synthesize(...)` as a passing `1.0.0b4` workflow. The direct function, record method `.reconstruct()`, dense synthesis transform, and coordinate bridges all passed their focused tests.

18.3.6 Change between two recurrence systems

Let A_c denote the analysis matrix of one recurrence and $S_c = A_c^{-1}$ its synthesis matrix. The exact bridge from source recurrence c to target recurrence $\tilde{c}$ is

$$T_{c\to\tilde{c}} = A_{\tilde{c}} S_c.$$

Both factors have determinant one, so

$$\det T_{c\to\tilde{c}} = 1.$$

For every finite raw prefix a,

$$T_{c\to\tilde{c}}\, A_c a = A_{\tilde{c}} a.$$

A runnable bridge is:

```
from komorebi_math.coordinates import (
    analyze_recurrence_coordinates,
    coordinate_change_between_recurrences,
)

values = (1, 2, 3, 4, 5, 6)
source = analyze_recurrence_coordinates(values, (1, 1), name="source")
target = analyze_recurrence_coordinates(values, (2, -1, 3), name="target")

bridge = coordinate_change_between_recurrences(
    (1, 1),
    (2, -1, 3),
    len(values),
)

mapped = bridge.apply(source.coordinates())
assert mapped == target.coordinates()

print("source:", source.coordinates())
print("target:", mapped)
print("determinant:", bridge.determinant)
```

Output:

```
source: (Fraction(1, 1), Fraction(2, 1), Fraction(0, 1),
         Fraction(-1, 1), Fraction(-2, 1), Fraction(-3, 1))
target: (Fraction(1, 1), Fraction(2, 1), Fraction(3, 1),
         Fraction(-5, 1), Fraction(-8, 1), Fraction(-11, 1))
determinant: 1
```

The equivalent CLI command is:

```
python -m komorebi_math coordinates recurrence --values "1,2,3,4,5,6" --source "1,1" --target "2,-1,3"
```

The emitted JSON includes both coordinate vectors, the complete exact bridge matrix, determinant one, and `"verified": true`.

18.3.7 Companion Green weights and variation of constants

For order d, let e_d be the last standard basis vector and e_1^T the first-coordinate covector. The implemented Green weights are

$$g_\ell = e_1^T C_c^{\ell-1} e_d, \qquad 1 \le \ell \le M.$$

If h_n is the homogeneous sequence with the record's initial state, then the finite variation-of-constants formula is

$$a_n = h_n + \sum_{\substack{0 \le j < L-d \\ n-j \ge 1}} g_{n-j}\delta_j.$$

The index condition automatically delays a defect until it can reach the first output coordinate. For Fibonacci coefficients $(1, 1)$,

$$(g_1, g_2, g_3, \ldots) = (0, 1, 1, 2, 3, 5, \ldots).$$

`variation_of_constants_prefix(record)` computes this finite convolution and is independently compared with direct recurrence synthesis in the tests.

18.3.8 Named recurrence models

`RecurrenceModel` is the immutable named wrapper

```
RecurrenceModel(
    name: str,
    coefficients: Vector,
    initial_values: Vector = (),
    description: str = "",
) -> None
```

It provides `.order`, `.companion`, `.sequence()`, `.analyze()`, `.coordinate_transform_to()`, and `.homogeneous_basis()`. Its `.synthesize()` method is subject to the preceding erratum.

The built-in catalog is:

Model	Coefficients	Initial values	First terms
Fibonacci	$(1, 1)$	$(0, 1)$	$0, 1, 1, 2, 3, 5, 8, 13$
Lucas	$(1, 1)$	$(2, 1)$	$2, 1, 3, 4, 7, 11, 18, 29$
Pell	$(1, 2)$	$(0, 1)$	$0, 1, 2, 5, 12, 29, 70, 169$
Jacobsthal	$(2, 1)$	$(0, 1)$	$0, 1, 1, 3, 5, 11, 21, 43$
Tribonacci	$(1, 1, 1)$	$(0, 0, 1)$	$0, 0, 1, 1, 2, 4, 7, 13, 24$
Padovan	$(1, 1, 0)$	$(1, 1, 1)$	$1, 1, 1, 2, 2, 3, 4, 5, 7$

The model helpers are:

```
custom_recurrence_model(
    coefficients: Sequence[Scalar],
    *,
    initial_values: Sequence[Scalar] = (),
    name: str = "custom recurrence",
    description: str = "",
) -> RecurrenceModel

fibonacci_recurrence_model() -> RecurrenceModel
lucas_recurrence_model() -> RecurrenceModel
pell_recurrence_model() -> RecurrenceModel
jacobsthal_recurrence_model() -> RecurrenceModel
tribonacci_recurrence_model() -> RecurrenceModel
padovan_recurrence_model() -> RecurrenceModel
recurrence_model_catalog() -> tuple[RecurrenceModel, ...]
get_recurrence_model(name: str) -> RecurrenceModel
```

`get_recurrence_model` lowercases a name and removes nonalphanumeric characters before matching. It rejects an unknown name rather than silently constructing a custom model.

`model.homogeneous_basis(L)` returns the d fundamental prefixes obtained by starting the recurrence from each standard initial state. These vectors span the homogeneous solution subspace inside the L-dimensional prefix space. The basis dimension is d and its ambient dimension is L.

18.3.9 Pell-to-Tribonacci worked bridge

`sequence_coordinates_between_models(values, source, target)` analyzes one prefix in both named systems, builds the exact bridge, and refuses to return if the bridge does not reproduce the target coordinates.

```
from komorebi_math.coordinates import (
    get_recurrence_model,
    sequence_coordinates_between_models,
)
```

```
pell = get_recurrence_model("Pell")
tribonacci = get_recurrence_model("Tribonacci")
values = pell.sequence(8)

source, target, bridge = sequence_coordinates_between_models(
    values,
    pell,
    tribonacci,
)

assert bridge.apply(source.coordinates()) == target.coordinates()
assert target.reconstruct() == values

print("values:", values)
print("Pell coordinates:", source.coordinates())
print("Tribonacci coordinates:", target.coordinates())
```

Output:

```
values: (Fraction(0, 1), Fraction(1, 1), Fraction(2, 1), Fraction(5, 1),
         Fraction(12, 1), Fraction(29, 1), Fraction(70, 1), Fraction(169, 1))
Pell coordinates: (Fraction(0, 1), Fraction(1, 1), Fraction(0, 1),
                   Fraction(0, 1), Fraction(0, 1), Fraction(0, 1),
                   Fraction(0, 1), Fraction(0, 1))
Tribonacci coordinates: (Fraction(0, 1), Fraction(1, 1), Fraction(2, 1),
                         Fraction(2, 1), Fraction(4, 1), Fraction(10, 1),
                         Fraction(24, 1), Fraction(58, 1))
```

The nonzero Tribonacci defects do not mean the bridge failed. They are the coordinates needed to express a homogeneous Pell prefix in a different recurrence system.

A useful check is to reconstruct the raw prefix from each record and compare those reconstructed values. The initial states and defect streams can differ while representing exactly the same data. Preserve the recurrence coefficients with either record so that the meaning of its coordinates remains clear.

18.4 Companion and state-space realizations

18.4.1 Boundary with Section 16.9

Section 16.9 is the canonical implementation page for the scalar realization layer. It already documents

- `LinearRealization`,
- scalar `observability_matrix`,
- `recover_initial_state` and `StateRecovery`,
- `cyclic_krylov_matrix`,
- `intertwiner_space` and `IntertwinerSpace`,
- `similarity_from_cyclic_vectors`, and
- `realization_defect`.

It also records two important edges: scalar recovery should use a positive horizon, because horizon zero can return a degenerate empty result, and `IntertwinerSpace.contains_invertible_basis_element()` tests only the displayed basis matrices rather than every linear combination in their span.

Those signatures and examples are not repeated here. Their conclusions form the bridge from recurrence coordinates to controlled input-output systems. In that bridge,

$$a_n = h^T A^n v$$

is the no-input, scalar-output specialization, while the state-space layer adds input and feedthrough matrices:

$$x_{k+1} = Ax_k + Bu_k, \qquad y_k = Cx_k + Du_k.$$

The recurrence companion system from Section 18.3 fits the same picture. Its defect stream enters through the last standard basis vector:

$$x_{n+1} = C_c x_n + e_d \delta_n, \qquad a_n = e_1^T x_n.$$

Refer to Section 16.9 for exact state recovery, Krylov similarity, intertwiner-space construction, and realization-defect execution. The remaining subsections document the separate `StateSpaceModel`, controllability, block observability, coordinate transport, and Markov parameter APIs.

18.4.2 Controlled state-space models

`StateSpaceModel` represents the discrete-time exact system

$$x_{k+1} = Ax_k + Bu_k, \qquad y_k = Cx_k + Du_k.$$

The constructor is

```
StateSpaceModel(
    name: str,
    transition: Matrix,
    input_matrix: Matrix,
    output_matrix: Matrix,
    feedthrough: Matrix,
) -> None
```

If A is $d \times d$, then B must have d rows, C must have d columns, and D must have the same output count as C and input count as B. The properties `.state_dimension`, `.input_dimension`, and `.output_dimension` expose those sizes.

For a single input and output, use

```
siso_state_space(
    transition: Iterable[Iterable[Scalar]],
    input_vector: Sequence[Scalar],
    output_covector: Sequence[Scalar],
    *,
    feedthrough: Scalar = 0,
    name: str = "SISO state-space model",
) -> StateSpaceModel
```

It converts a length-d input vector to a $d \times 1$ matrix, a length-d output vector to a $1 \times d$ matrix, and the scalar feedthrough to a 1×1 matrix.

18.4.3 State coordinate changes

Let `transform.matrix` be T and let target coordinates satisfy

$$z = Tx.$$

`model.change_coordinates(transform)` returns

$$A' = TAT^{-1}, \qquad B' = TB, \qquad C' = CT^{-1}, \qquad D' = D.$$

Its signature is

```
model.change_coordinates(
    transform: CoordinateTransform,
    *,
    name: str | None = None,
) -> StateSpaceModel
```

The transform must be square and match the state dimension. Exact inversion then rejects a singular matrix. Coordinate-system names label the transform, but the method does not require a particular literal source name. Dimensional and algebraic validity are the operative checks.

18.4.4 Markov parameters and transfer invariance

The exact Markov parameters are

$$H_0 = D, \qquad H_k = CA^{k-1}B \quad (k \geq 1).$$

They are returned by

```
model.markov_parameter(index: int) -> Matrix
```

and compared by

```
model.transfer_equivalent(
    other: StateSpaceModel,
    *,
    count: int | None = None,
) -> bool
```

The comparison first requires equal input and output dimensions. With no explicit count, it compares

$$2\max(d_{\text{source}}, d_{\text{target}}) + 1$$

parameters, beginning at H_0. This is an exact finite comparison. It is not an approximate frequency-response test.

The coordinate-change factory is

```
certify_state_coordinate_change(
    model: StateSpaceModel,
    transform: CoordinateTransform,
    *,
    markov_count: int | None = None,
) -> StateSpaceCoordinateCertificate
```

Its default count is $2d+1$. The record stores source model, transformed model, transform, comparison count, and the Boolean result. Calling `.certificate()` produces exact theorem metadata `CC.R3` with checked assumptions `"invertible state transform"` and `"exact Markov parameters"`.

Use the factory rather than manually constructing a `StateSpaceCoordinateCertificate`: the dataclass accepts a caller-supplied `valid` field, whereas the factory computes it from the two models.

18.4.5 Controllability coordinates

For a requested number of steps s, the finite controllability matrix is

$$\mathcal{C}_s = [B, AB, \ldots, A^{s-1}B].$$

The public functions are

```
controllability_matrix(
    transition: Iterable[Iterable[Scalar]],
    input_matrix: Iterable[Iterable[Scalar]],
    *,
    steps: int | None = None,
) -> Matrix

controllability_basis(model: StateSpaceModel) -> FiniteBasis

controllability_coordinate_transform(
    model: StateSpaceModel,
) -> CoordinateTransform
```

When `steps` is omitted, the matrix uses $s = d$. The basis factory scans controllability columns in their generated order and retains each column that increases exact rank. It therefore returns a maximal independent reachable basis when at least one reachable direction exists, even when the system is not fully controllable. A completely zero reachable subspace cannot currently be represented by `FiniteBasis`, whose contract requires at least one vector. That edge case raises `DimensionError`.

`controllability_coordinate_transform` requires that basis to be square. If its positive dimension is less than d, it raises `ValidationError("model is not controllable")`. For a controllable model, it returns the inverse of the basis synthesis matrix, mapping original state coordinates to controllability coordinates.

18.4.6 Observability coordinates for multiple outputs

For p outputs and s steps, the block observability matrix is

$$\mathcal{O}_s = \begin{pmatrix} C \\ CA \\ \vdots \\ CA^{s-1} \end{pmatrix}.$$

The functions are

```
observability_block_matrix(
    transition: Iterable[Iterable[Scalar]],
    output_matrix: Iterable[Iterable[Scalar]],
    *,
    steps: int | None = None,
) -> Matrix

observability_coordinate_transform(
    model: StateSpaceModel,
) -> CoordinateTransform
```

With omitted `steps`, the block matrix uses d steps. If it has more than d rows, the transform factory scans rows in order and retains the first rows that increase exact rank. It then requires exactly d independent rows. A rank-deficient model raises `ValidationError("model is not observable")`.

The target coordinate vector is a selected output jet. It is an exact state coordinate system only when the selected observability matrix is square and invertible.

18.4.7 Worked state-space coordinate change

The shipped example uses

$$A = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 2 & -1 & 3 \end{pmatrix}, \quad B = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}, \quad C = \begin{pmatrix} 1 & 2 & -1 \end{pmatrix}, \quad D = \begin{pmatrix} 2 \end{pmatrix}.$$

```
from fractions import Fraction

from komorebi_math.coordinates import (
    certify_state_coordinate_change,
    controllability_coordinate_transform,
    observability_coordinate_transform,
    siso_state_space,
)

model = siso_state_space(
    ((0, 1, 0), (0, 0, 1), (2, -1, 3)),
    (0, 0, 1),
    (1, 2, -1),
    feedthrough=2,
    name="third-order model",
)

controllability = controllability_coordinate_transform(model)
certificate = certify_state_coordinate_change(model, controllability)
certificate.certificate().require()

transformed = model.change_coordinates(controllability)
assert model.transfer_equivalent(transformed, count=12)

observability = observability_coordinate_transform(model)
state = (Fraction(2), Fraction(-3), Fraction(5))
observable_state = observability.apply(state)
assert observability.inverse().apply(observable_state) == state

print("controllability transform:", controllability.matrix)
print("observable state:", observable_state)
print("Markov count:", certificate.markov_count)
print("valid:", certificate.valid)
```

Output:

```
controllability transform:
((Fraction(1, 1), Fraction(-3, 1), Fraction(1, 1)),
 (Fraction(-3, 1), Fraction(1, 1), Fraction(0, 1)),
 (Fraction(1, 1), Fraction(0, 1), Fraction(0, 1)))
observable state: (Fraction(-9, 1), Fraction(-15, 1), Fraction(-6, 1))
Markov count: 7
valid: True
```

The first Markov parameters of the original model are

$$2, -1, -1, -1, -4, -13, -37.$$

The transformed model produces the same exact sequence. This is the relevant invariant. The entries of A, B, C are expected to change.

18.5 Euler-to-Fibonacci worked path

18.5.1 Signed secant Euler numbers

The signed secant Euler numbers in this module are defined by

$$\operatorname{sech}(t) = \sum_{n \geq 0} E_n \frac{t^n}{n!}.$$

The finite helper

```
signed_secant_euler_numbers(count: int) -> tuple[int, ...]
```

uses $E_0 = 1$ and the coefficient recurrence obtained from $\cosh(t)\operatorname{sech}(t) = 1$:

$$E_n = -\sum_{\substack{2 \leq k \leq n \\ k \text{ even}}} \binom{n}{k} E_{n-k}.$$

Consequently,

$$(E_0, E_1, E_2, E_3, E_4, E_5, E_6, E_7, \ldots) = (1, 0, -1, 0, 5, 0, -61, 0, \ldots).$$

This convention includes odd entries explicitly as zeros. It should not be confused with an indexing convention that stores only the nonzero even secant numbers.

18.5.2 Fibonacci defect coordinates

The convenience function

```
euler_fibonacci_coordinates(count: int) -> RecurrenceCoordinateRecord
```

analyzes the first `count` signed secant Euler numbers in the Fibonacci companion recurrence

$$a_{n+2} = a_n + a_{n+1} + \delta_n.$$

It requires `count >= 2`. The first two Euler entries become the initial state

$$(a_0, a_1) = (1, 0),$$

and the defects are

$$\delta_n = E_{n+2} - E_{n+1} - E_n.$$

Their exponential generating function is

$$\sum_{n \geq 0} \delta_n \frac{t^n}{n!} = \operatorname{sech}(t)\tanh(t) - 2\operatorname{sech}^3(t).$$

The identity follows from

$$\operatorname{sech}'(t) = -\operatorname{sech}(t)\tanh(t),$$

and

$$\operatorname{sech}''(t) = \operatorname{sech}(t) - 2\operatorname{sech}^3(t).$$

The complete executed path is:

```
from komorebi_math.coordinates import (
    euler_fibonacci_coordinates,
    variation_of_constants_prefix,
)

record = euler_fibonacci_coordinates(18)
record.certificate().require()

direct = record.reconstruct()
green = variation_of_constants_prefix(record)

assert direct == green

print("initial", tuple(str(value) for value in record.initial))
print("defects", tuple(str(value) for value in record.defects))
print("reconstructed", tuple(str(value) for value in direct))
```

Output:

```
initial ('1', '0')
defects ('-2', '1', '6', '-5', '-66', '61', '1446', '-1385',
         '-51906', '50521', '2753286', '-2702765', '-202063746',
         '199360981', '19590873126', '-19391512145')
reconstructed ('1', '0', '-1', '0', '5', '0', '-61', '0', '1385',
               '0', '-50521', '0', '2702765', '0', '-199360981',
               '0', '19391512145', '0')
```

The same finite prefix has two exact decompositions that agree:

1. direct forced recurrence synthesis, and
2. homogeneous Fibonacci evolution plus convolution with the companion Green weights.

The nonzero defect sequence proves that the signed Euler prefix is not an unforced Fibonacci prefix. It does not imply that the coordinate representation is approximate.

18.5.3 Command-line path

The dedicated command is

```
python -m komorebi_math coordinates euler-fibonacci --count 18
```

It emits JSON fields for system name, count, initial state, defects, reconstruction, homogeneous flag, and the defect generating function. Before printing, the command requires the record certificate and independently reconstructs by variation of constants.

The named recurrence catalog and bridge are available through

```
python -m komorebi_math coordinates catalog
python -m komorebi_math coordinates model --source pell --target tribonacci --count 16
```

There is no separate state-space CLI subcommand in `1.0.0b4`. Use the Python API for controllability, observability, Markov parameters, and transfer certificates.

18.5.4 Portable persistence

The chapter's exact executable records use the portable format described in Section 16.5. The relevant version-one codec tags are:

Type	Portable tag
`CoordinateTransform`	`coordinates.transform`
`RecurrenceCoordinateRecord`	`coordinates.recurrence_record`
`RecurrenceModel`	`coordinates.recurrence_model`
`LinearRealization`	`coordinates.linear_realization`
`StateRecovery`	`coordinates.state_recovery`
`IntertwinerSpace`	`coordinates.intertwiner_space`
`StateSpaceModel`	`coordinates.state_space_model`

The specialized recurrence-record calls are

```
save_coordinate_record(
    path: str | Path,
    record: RecurrenceCoordinateRecord,
    *,
    overwrite: bool = False,
) -> Path

load_coordinate_record(
    path: str | Path,
) -> RecurrenceCoordinateRecord
```

The generic calls are

```
save_coordinate_object(
    path: str | Path,
    value: Any,
    *,
    overwrite: bool = False,
) -> Path

load_coordinate_object(path: str | Path) -> Any
```

A recurrence-record round trip is:

```
from pathlib import Path

from komorebi_math.coordinates import (
    euler_fibonacci_coordinates,
    load_coordinate_record,
    save_coordinate_record,
)

path = Path("euler_fibonacci_coordinates.json")
record = euler_fibonacci_coordinates(18)

save_coordinate_record(path, record)
restored = load_coordinate_record(path)

assert restored == record
restored.certificate().require()
```

Saving is atomic. By default, an existing destination is not overwritten. The JSON envelope has exactly five top-level fields:

```
schema
schema_version
producer_version
payload_sha256
payload
```

The payload is hashed after canonical JSON encoding. Loading verifies the digest before decoding. Duplicate JSON keys, nonfinite numbers, an unknown schema, an unknown codec tag, unsupported future versions, unexpected data fields, and a SHA-256 mismatch are rejected.

The recurrence-record decoder additionally reconstructs and requires its exact certificate. A restored `StateRecovery` is self-contained over its stored state, prediction, and residual, so its zero-residual certificate takes no arguments. It cannot independently rederive those fields from the original transition, output, and prefix because those inputs are not stored. A restored `IntertwinerSpace` stores no source or target transitions. Certify it with `.certificate(source, target)` before relying on its matrix equations.

Combinatorial matrices can be saved with `save_transform` or the generic `save_coordinate_object`. Persistence stores the materialized exact matrix. It does not regenerate the matrix from `degree`, `rank`, or `size`.

18.5.5 Default resource contract

The default budget is

```
CoordinateBudget(
    maximum_matrix_dimension=512,
    maximum_polynomial_degree=512,
    maximum_horizon=4096,
    maximum_exact_entries=1_000_000,
)
```

It is checked before the budget-aware constructors allocate their exact matrices.

Operation	Relevant default limit
Degree-N Stirling or Lah connection	$N + 1 \leq 512$, hence $N \leq 511$
Size-N binomial, difference, or divisor matrix	$N \leq 512$
Rank-r subset zeta matrix	$2^r \leq 512$, hence $r \leq 9$
Dense recurrence analysis or synthesis matrix	$L \leq 512$
Scalar realization observability matrix	Effective default $H \leq 512$ because the matrix-dimension limit binds before the separate 4096 horizon cap

The direct `analyze_recurrence_coordinates` and `synthesize_recurrence_coordinates` functions are not dense matrix constructors. They can represent prefixes longer than 512, subject to ordinary available memory and integer-growth costs.

The controlled `StateSpaceModel` functions do not currently take a `CoordinateBudget`. A caller constructing large exact state models must impose its own dimension and horizon limits.

18.5.6 Complexity and scaling

These bounds describe the current implementation, not the best known algorithm for each mathematical transform. They count exact arithmetic operations and omit coefficient bit complexity.

Operation	Time	Materialized space	Implementation note
Binomial or forward-difference construction, size N	$O(N^2)$	$O(N^2)$	Dense triangular matrix
Stirling connection through degree N	Up to $O(N^4)$	$O(N^2)$	Each matrix entry independently recomputes a dynamic-programming row
Lah connection through degree N	$O(N^2)$ scalar formula calls	$O(N^2)$	Dense exact matrix
Divisor zeta construction, size N	At least $O(N^2)$ dense scan	$O(N^2)$	Does not use a sparse divisor representation
Subset zeta, rank r	$O(4^r)$	$O(4^r)$	Matrix dimension 2^r
Applying any dense size-N transform	$O(N^2)$	$O(N)$ output	Sparsity is not specialized by `CoordinateTransform.apply`
Direct recurrence analysis or synthesis	$O(Ld)$	$O(L)$	d is recurrence order
Dense recurrence analysis construction	$O(L^2)$ allocation	$O(L^2)$	Only $O(Ld)$ entries are nonzero
Dense recurrence inverse or bridge	$O(L^3)$	$O(L^2)$	Generic exact row reduction and matrix multiplication
Green weights, count M	$O(Md^2)$	$O(M + d^2)$	Repeated companion matrix-vector multiplication
Current variation-of-constants reconstruction	$O(L^2 + Ld^2)$	$O(L + d^2)$	Includes L companion Green-weight steps plus the direct defect convolution
`RecurrenceModel.sequence(count)`	$O(Ld)$	$O(L)$	Direct recurrence sweep
`LinearRealization.term(n)`	$O(d^3 \log n)$	$O(d^2)$	Exact matrix exponentiation
Current `LinearRealization.prefix(L)`	Sum of independent term costs	$O(L + d^2)$	Does not reuse the preceding state
Scalar observability construction	$O(Hd^3)$	$O(Hd)$	Iteratively multiplies a full matrix by A
State recovery	$O(Hd^3)$ observability construction plus elimination on an $H \times d$ system	$O(Hd + d^2)$	Current observability path multiplies full $d \times d$ matrices before exact row reduction
Cyclic Krylov matrix	$O(d^3)$	$O(d^2)$	d matrix-vector steps
Intertwiner space	Dense nullspace in $d_t d_s$ variables	$O((d_t d_s)^2)$ matrix	Cubic elimination in the variable count
One Markov parameter H_k	$O(d^3 \log k)$ plus input/output products	$O(d^2)$	Recomputes A^{k-1}

Exact rational coefficient sizes can grow substantially under inversion, matrix powers, and recurrence evolution. Runtime may therefore grow faster than the arithmetic-operation count suggests.

There are no optional SymPy, SciPy, JAX, Torch, or CUDA dependencies in the direct combinatorial, recurrence, realization, or exact state-space modules. The generic persistence layer imports NumPy because the wider portable registry also supports numerical arrays.

18.5.7 Failure contracts and edge cases

The principal controlled failures are:

Situation	Failure behavior
Negative or Boolean Stirling/Lah index	`ValidationError`
Nonpositive transform size	`DimensionError`
Nonpositive Möbius argument	`ValidationError`
Sequence length differs from transform source dimension	`DimensionError`
Dense matrix exceeds dimension or entry budget	`ResourceLimitError` before allocation
Empty recurrence coefficient vector	`ValidationError` or `DimensionError` at the model layer
Prefix shorter than recurrence order	`DimensionError`
Initial state length differs from recurrence order	`DimensionError`
Empty recurrence name	`ValidationError`
Euler-to-Fibonacci count below two	`DimensionError`
Named model lookup fails	`ValidationError`
Model has no complete initial state and `.sequence()` receives none	`DimensionError`
`RecurrenceModel.synthesize()` in the recorded `1.0.0b4` baseline	Confirmed unintended `TypeError`. Use the lower-level record path for that baseline
Realization transition is empty or nonsquare	`DimensionError`
Realization state or output has wrong length	`DimensionError`
Negative realization index or count	`ValidationError`
Scalar state recovery or observability called with horizon zero	Uncovered edge can return a degenerate empty result. Require $H \geq 1$ in caller code
Observability horizon exceeds the budget	`ResourceLimitError`
Source or target transition for an intertwiner is nonsquare	`DimensionError`
Similarity matrices have unequal shape	`DimensionError`
Selected similarity vector is noncyclic	`ValidationError`
State-space A, B, C, D shapes disagree	`DimensionError`
State coordinate transform has wrong dimension	`DimensionError`
State coordinate transform is singular	`ValidationError` during exact inversion
Controllability steps, observability steps, Markov index, or comparison count is invalid	`ValidationError`
Full controllability coordinates requested with positive but deficient reachable rank	`ValidationError`
Controllability basis requested for a zero reachable subspace	`DimensionError`, because `FiniteBasis` is nonempty by contract
Full output-jet coordinates requested for an unobservable model	`ValidationError`
Portable destination exists and `overwrite=False`	`ValidationError`
Portable payload is altered	`ValidationError` reporting SHA-256 or integrity mismatch

Passing Python floating-point values lies outside the declared `Scalar` type, which is `int | Fraction`. Although `Fraction` can convert some other runtime objects, callers seeking the chapter's exact rational semantics should create `Fraction` values explicitly rather than pass binary floats.

18.5.8 Verification evidence

The recorded Chapter 18 audit executed its source baseline rather than relying only on stored reports.

Check	Result
Focused combinatorial tests	Pass
Focused recurrence-coordinate tests	Pass
Named recurrence and state-space tests	Pass

Check	Result
Realization, state-recovery, Krylov, and intertwiner tests	Pass
General coordinate persistence tests	Pass
Normalized recurrence-record persistence tests	Pass
Coordinate and coordinate-calculus CLI/API tests	Pass
Unique focused tests across those files	**26 passed**
`python -m komorebi_math verify coordinates`	**24/24 passed**
`recurrence_state_coordinate_atlas.py`	Executed successfully
`coordinate_calculus.py`	Executed successfully
`euler_to_fibonacci_coordinates.py`	Executed successfully
Direct `RecurrenceModel.synthesize()` probe	**Failed with the disclosed TypeError**

The stored randomized coordinate-calculus audit records additional historical evidence:

Audit category	Checks	Failures
Combinatorial inverse identities	23,450	0
General recurrence-coordinate comparisons	15,732	0
Recurrence coordinate round trips	72,225	0
Companion variation of constants	72,225	0
Cross-recurrence coordinate changes	9,396	0
Unit-triangular recurrence certificates	5,175	0

Those stored counts are provenance from the recorded audit run. They are not relabeled as a fresh execution. The focused tests and 24-check coordinate verifier describe the source baseline used for the recorded chapter audit.

The focused suite's passing result did not erase the convenience-method failure found by the separate probe. Both outcomes belong to the recorded baseline evidence, which is why the erratum appears in Section 18.3.

18.5.9 Theorem metadata and interpretation

The combinatorial constructors use identifiers `CC.C1` through `CC.C13`. Recurrence analysis and cross-system change use `CC.R1` and `CC.R2`. State recovery and intertwiners use `CC.S2` and `CC.S3`, while the state-space coordinate certificate uses `CC.R3`.

Some state coordinate helpers reuse the short labels `CC.R1` and `CC.R2` for controllability and observability transforms. Treat these strings as local implementation metadata, not as globally unique theorem database keys. The object type, source and target names, description, and certificate diagnostics are needed to identify the actual claim.

> **Chapter boundary.** Chapter 18 proves exact finite coordinate identities, exact reconstruction, and exact transfer preservation under the stated hypotheses. It does not infer an infinite recurrence from finite samples, prove minimality from one finite realization, or equate state-coordinate similarity with equality of internal representations. Defects, residuals, noncontrollability, and nonobservability are exposed as mathematical data or controlled failures rather than hidden by an approximate fallback.

19. Spectral, packet, tensor, and operator transport

Choose by the data you need. Section 19.1 provides explicit small spectral matrices. Section 19.2 reorders indices, with order-only helpers when you do not need a dense matrix. Sections 19.3 to 19.4 transport tensors and operators through a declared coordinate change. In every case, compare the represented vector, pairing, or operator action when checking a result; the new coordinate entries are expected to differ.

Finite data can move among four coordinate views without changing the mathematical object represented by that data. Spectral transforms replace samples by Fourier, cosine, Walsh, or Haar coefficients. Packet permutations replace natural index order by a structural order. Tensor transport extends one coordinate change to covectors, forms, operators, and higher tensors. Operator conjugation closes the loop by expressing the same linear map in a new basis.

The implementation has two distinct arithmetic layers:

Layer	Main type	Scalar model	Typical use
numerical spectral	`NumericCoordinateTransform`	NumPy real or complex arrays	Fourier, DCT, Walsh, Haar, and modal coordinates
exact structural	`CoordinateTransform`	immutable `Fraction` matrices	index permutations and tensor or operator transport

Chapter 16 defines the general construction, composition, inversion, certificate, and persistence contracts for these two transform types. This chapter does not repeat that material. It specializes those contracts to the spectral and tensor families and records the conventions that determine every matrix entry.

The recommended public import surface for the complete chapter is `komorebi_math.coordinates`:

```
from komorebi_math.coordinates import (
    NumericCoordinateTransform,
    ModalCoordinateSystem,
    chinese_remainder_transform,
    coordinate_pairing,
    digit_reversal_transform,
    direct_sum_transform,
    discrete_cosine_transform,
    discrete_fourier_transform,
    haar_wavelet_transform,
    modal_coordinate_system,
    pairing_invariant,
    residue_class_transform,
    sorted_coordinate_transform,
    tensor_axis_permutation_transform,
    tensor_coordinate_transform,
    tensor_product_transform,
    transport_bilinear_form,
    transport_covector,
    transport_operator,
    transport_rectangular_operator,
    transport_tensor_components,
    walsh_hadamard_transform,
)
```

Only a smaller convenience subset is re-exported at package top level. Code that uses the full Chapter 19 surface should import from `komorebi_math.coordinates` so that the identity of every function is clear.

19.1 Fourier, cosine, Hadamard, and Haar coordinates

All four constructors return a dense `NumericCoordinateTransform`. They build an explicit matrix and use ordinary dense matrix-vector multiplication on application. They are coordinate constructors, not fast FFT, fast cosine, FWHT, or lifting-scheme executors.

19.1.1 Constructor reference

```
discrete_fourier_transform(
    size: int,
    *,
    unitary: bool = True,
    inverse: bool = False,
    tolerance: float = 1e-12,
) -> NumericCoordinateTransform

discrete_cosine_transform(
    size: int,
    *,
    orthonormal: bool = True,
    tolerance: float = 1e-12,
) -> NumericCoordinateTransform

walsh_hadamard_transform(
    size: int,
    *,
    orthonormal: bool = True,
    tolerance: float = 1e-12,
) -> NumericCoordinateTransform

haar_wavelet_transform(
    size: int,
    *,
    orthonormal: bool = True,
    tolerance: float = 1e-12,
) -> NumericCoordinateTransform

modal_coordinate_system(
    operator: Any,
    *,
    state_name: str = "state coordinates",
    modal_name: str = "modal coordinates",
    tolerance: float = 1e-10,
) -> ModalCoordinateSystem
```

Constructor	Theorem identifier	Admissible size	Default normalization	Output direction
`discrete_fourier_transform`	`CC.S1`	every $N \geq 1$	unitary	samples to Fourier coefficients
`discrete_cosine_transform`	`CC.S2`	every $N \geq 1$	orthonormal DCT-II	samples to cosine coefficients
`walsh_hadamard_transform`	`CC.S3`	positive powers of two	orthonormal	samples to Sylvester Walsh coefficients
`haar_wavelet_transform`	`CC.S4`	positive powers of two	orthonormal	samples to complete Haar coefficients

Constructor	Theorem identifier	Admissible size	Default normalization	Output direction
`modal_coordinate_system`	`CC.S5`	finite square matrix with complete numerical eigenbasis	not applicable	state and modal coordinates in both directions

The returned transforms expose the Chapter 16 numerical interface:

```
transform.apply(coordinates: Any) -> np.ndarray
transform.inverse() -> NumericCoordinateTransform
transform.then(following: NumericCoordinateTransform) -> NumericCoordinateTransform
transform.condition_number() -> float
transform.certificate() -> Certificate
```

The source and target names are part of composition validation. Two matrices with compatible shapes do not compose through `then` unless the first target name exactly equals the second source name.

19.1.2 Discrete Fourier convention

For $N =$ `size`, the default forward matrix is

$$F_{kn} = \frac{1}{\sqrt{N}} \exp\left(-\frac{2\pi i k n}{N}\right), \qquad 0 \le k, n < N.$$

Thus

$$\hat{x}_k = \sum_{n=0}^{N-1} F_{kn} x_n, \qquad F^* F = F F^* = I_N, \qquad \|\hat{x}\|_2 = \|x\|_2.$$

`inverse=True` reverses the sign in the exponential. With the default `unitary=True`, both directions retain the factor $N^{-1/2}$. With `unitary=False`, the forward matrix is unscaled and the inverse constructor uses the factor N^{-1}:

$$(F_0)_{kn} = e^{-2\pi i k n/N}, \qquad (F_0^{-1})_{nk} = \frac{1}{N} e^{2\pi i k n/N}.$$

The `inverse` flag constructs the analytic inverse convention. The inherited `.inverse()` method instead numerically inverts whatever dense matrix is stored. Both routes agree to floating precision for the standard Fourier matrices.

19.1.3 DCT-II convention

The cosine constructor forms

$$C_{kn} = \alpha_k \cos\left(\frac{\pi(n + \frac{1}{2})k}{N}\right),$$

where

$$\alpha_0 = \sqrt{\frac{1}{N}}, \qquad \alpha_k = \sqrt{\frac{2}{N}} \quad (k > 0)$$

when `orthonormal=True`. This gives $CC^T = I_N$. The `orthonormal=False` matrix omits every α_k. There is no separate DCT-III constructor in this API. Call `.inverse()` when the inverse of the constructed matrix is required.

19.1.4 Sylvester Walsh-Hadamard convention

The unnormalized matrices are generated recursively:

$$H_1 = (1), \qquad H_{2N} = \begin{pmatrix} H_N & H_N \\ H_N & -H_N \end{pmatrix}.$$

The default constructor returns $N^{-1/2} H_N$, so its matrix is orthogonal and self-inverse. The row order is the recursive Sylvester order. No Gray-code or sequency reordering is applied.

19.1.5 Complete finite Haar convention

At each active dyadic level the Haar constructor replaces adjacent pairs by a sum and a difference. In the orthonormal case,

$$a_j = \frac{x_{2j} + x_{2j+1}}{\sqrt{2}}, \qquad d_j = \frac{x_{2j} - x_{2j+1}}{\sqrt{2}}.$$

It recurses on the averages until one global coefficient remains. For length four, the explicit matrix is

$$\begin{pmatrix} \frac{1}{2} & \frac{1}{2} & \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} & -\frac{1}{2} & -\frac{1}{2} \\ \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} & 0 & 0 \\ 0 & 0 & \frac{1}{\sqrt{2}} & -\frac{1}{\sqrt{2}} \end{pmatrix}.$$

The coefficient order is the global average, followed by the coarsest detail, then successively finer details. Setting `orthonormal=False` replaces every pair scale by one. In that mode the transform remains invertible, but it does not preserve Euclidean energy.

19.1.6 First runnable spectral example

This is the shipped `examples/spectral_packet_coordinates.py` path, reduced to the two spectral transforms:

```
import numpy as np

from komorebi_math.coordinates import (
    discrete_fourier_transform,
    haar_wavelet_transform,
)

samples = np.arange(8, dtype=float)
fourier = discrete_fourier_transform(8)
haar = haar_wavelet_transform(8)

fourier.certificate().require()
haar.certificate().require()

f = fourier.apply(samples)
h = haar.apply(samples)

assert np.allclose(fourier.inverse().apply(f), samples)
assert np.allclose(haar.inverse().apply(h), samples)

print(np.round(f, 8))
print(np.round(h, 8))
```

Output:

```
[ 9.89949494+0.j         -1.41421356+3.41421356j
 -1.41421356+1.41421356j -1.41421356+0.58578644j
 -1.41421356-0.j         -1.41421356-0.58578644j
 -1.41421356-1.41421356j -1.41421356-3.41421356j]
[ 9.89949494 -5.65685425 -2.         -2.
 -0.70710678 -0.70710678 -0.70710678 -0.70710678]
```

The leading value in both arrays is $\sum_{n=0}^{7} n/\sqrt{8} = 28/\sqrt{8}$. The remaining coefficients encode different orthonormal decompositions of the same sample vector.

19.1.7 Modal coordinates

`modal_coordinate_system(A)` uses `np.linalg.eig` and writes the returned eigenvectors as columns of V. Its two transforms are

$$\texttt{synthesis} : z \longmapsto Vz, \qquad \texttt{analysis} : x \longmapsto V^{-1}x.$$

The represented identity is

$$V^{-1}AV = \operatorname{diag}(\lambda_0, \dots, \lambda_{N-1}) + E,$$

with recorded residual

$$\delta_{\text{modal}} = \left\| V^{-1}AV - \operatorname{diag}(\lambda) \right\|_{\infty}.$$

The result record is:

```python
@dataclass(frozen=True, slots=True)
class ModalCoordinateSystem:
    eigenvalues: np.ndarray
    synthesis: NumericCoordinateTransform
    analysis: NumericCoordinateTransform
    diagonal_residual: float

    def certificate(self) -> Certificate: ...
```

A minimal execution is:

```python
import numpy as np
from komorebi_math.coordinates import modal_coordinate_system

A = np.array([
    [2.0, 1.0, 0.0],
    [0.0, 3.0, 1.0],
    [0.0, 0.0, 5.0],
])
modal = modal_coordinate_system(A)
modal.certificate().require()

D = modal.analysis.matrix @ A @ modal.synthesis.matrix
print(np.round(modal.eigenvalues, 12))
print(np.round(D, 12))
print(modal.diagonal_residual)
```

The eigenvalues are $2, 3, 5$, and `D` is diagonal to the declared numerical tolerance. Eigenvalue ordering, eigenvector phases, eigenvector scales, and bases inside repeated eigenspaces are not portable identities. They can differ between NumPy and LAPACK builds. Tests and user code should compare the diagonalization residual and the represented invariant subspaces, not literal eigenvector arrays.

The helper rejects an eigenvector matrix whose numerical rank is less than the operator size under `np.linalg.matrix_rank(eigenvectors, tol=tolerance)`. A large condition number is reported and used in certificate scaling, but it is not a separate constructor rejection threshold.

19.1.8 Numerical certificates

For a square numerical transform C, the certificate computes

$$\delta_L = \|C^{-1}C - I\|_\infty, \qquad \delta_R = \|CC^{-1} - I\|_\infty, \qquad \delta = \max(\delta_L, \delta_R).$$

It is valid when

$$\delta \leq \texttt{tolerance}\ \max\{1, \kappa_2(C)\}.$$

Certificate component	Numerical transform value
exactness	`Exactness.NUMERICAL`
residual	`{"inverse": delta}`
tolerance	transform tolerance
assumptions checked	finite matrix and numerical nonsingularity
diagnostics	source dimension, target dimension, condition number
theorem identifier	constructor theorem such as `CC.S1` through `CC.S4`

A finite rectangular `NumericCoordinateTransform` receives a valid shape certificate without an inverse or full-rank claim. A square singular matrix receives an invalid certificate. This differs from the exact certificate boundary discussed in Section 19.4.

The modal certificate uses

$$\delta_{\text{modal}} \leq \texttt{tolerance}\ \max\{1, \kappa_2(V)\}$$

with theorem identifier `CC.S5`.

19.1.9 Spectral CLI

The command-line route is:

```
python -m komorebi_math coordinates spectral --kind haar --size 4 --values 0,1,2,3
```

The four choices are `dft`, `dct`, `hadamard`, and `haar`. The JSON response contains the source and target names, condition number, dense matrix, optional output vector, and `"verified": true`. Complex values use objects with `real` and `imag` fields.

The CLI exposes only the default direction, normalization, and tolerance. Use the Python constructors when an inverse Fourier convention, unnormalized matrix, or custom tolerance is required.

For the command above, the core output values are:

```
condition_number: 1.0000000000000002
output: [2.999999999999999, -1.9999999999999996,
         -0.7071067811865475, -0.7071067811865475]
verified: true
```

19.2 Residue, digit-reversal, and CRT permutations

Packet coordinate functions reorder entries without changing their values. Every transform is an exact permutation matrix P satisfying

$$(Px)_i = x_{\pi(i)}, \qquad P^{-1} = P^T, \qquad \det P \in \{-1, 1\}.$$

The orientation matters: the stored order tells which source entry becomes each target entry. It does not tell the destination of each source entry.

19.2.1 API reference

```
residue_class_order(length: int, modulus: int) -> tuple[int, ...]
residue_class_transform(length: int, modulus: int) -> CoordinateTransform

digit_reversal_order(length: int, radix: int = 2) -> tuple[int, ...]
digit_reversal_transform(length: int, radix: int = 2) -> CoordinateTransform

tensor_axis_permutation_order(
    shape: Sequence[int],
    axes: Sequence[int],
) -> tuple[int, ...]

tensor_axis_permutation_transform(
    shape: Sequence[int],
    axes: Sequence[int],
) -> CoordinateTransform

chinese_remainder_order(moduli: Sequence[int]) -> tuple[int, ...]
chinese_remainder_transform(moduli: Sequence[int]) -> CoordinateTransform

sorted_coordinate_transform(
    length: int,
    key: Callable[[int], object],
    *,
    source: str = "original index order",
    target: str = "key-sorted index order",
) -> CoordinateTransform
```

Each `*_order` function returns only the integer permutation. Each transform constructor passes that order to `permutation_transform`, which builds a dense exact matrix with theorem identifier `CC.B2`.

19.2.2 Residue lanes

For length N and modulus M, the residue order is

$$0, M, 2M, \dots; \quad 1, 1+M, 1+2M, \dots; \quad \dots \quad ; M-1, 2M-1, \dots,$$

with indices at least N omitted. Equivalently,

$$\pi_{M,N} = (r + kM : 0 \le r < M, 0 \le k, r + kM < N).$$

For $N = 12$ and $M = 4$,

```
(0, 4, 8, 1, 5, 9, 2, 6, 10, 3, 7, 11)
```

This is the finite polyphase order used in Chapter 14. The present function only permutes a finite coordinate vector. It does not construct a filter bank, refinement tower, or packet projector family.

An $M > N$ modulus is legal. Some residue lanes are then empty, while the nonempty lanes still cover every index exactly once.

19.2.3 Fixed-width digit reversal

Suppose $N = b^w$. Write

$$i = \sum_{j=0}^{w-1} d_j b^j, \qquad 0 \le d_j < b.$$

The reversed index is

$$\mathrm{rev}_{b,w}(i) = \sum_{j=0}^{w-1} d_j b^{w-1-j}.$$

For $N = 8$ and $b = 2$,

```
natural:       (0, 1, 2, 3, 4, 5, 6, 7)
bit reversed:  (0, 4, 2, 6, 1, 5, 3, 7)
```

The width is determined from `length`. A length that is not an exact power of the radix raises `DimensionError`.

> **Known `1.0.0b4` defect: do not use radix one.** The implementation's positive-integer validator currently accepts `radix=1`. For every `length > 1`, the width-discovery loop then fails to advance and does not terminate. Use `radix >= 2`. A calling application that accepts an external radix must reject one before invoking `digit_reversal_order` or `digit_reversal_transform`. This guide does not treat radix one as a supported degenerate case.

19.2.4 Tensor-axis order

For a tensor with row-major shape

$$(n_0, n_1, \ldots, n_{r-1}),$$

`tensor_axis_permutation_transform(shape, axes)` reproduces

```
array.reshape(shape).transpose(axes).ravel()
```

as one exact flat-coordinate permutation. The `axes` tuple must contain every axis `0` through `r-1` exactly once.

```python
import numpy as np
from komorebi_math.coordinates import tensor_axis_permutation_transform

array = np.arange(24).reshape(2, 3, 4)
change = tensor_axis_permutation_transform((2, 3, 4), (2, 0, 1))

observed = np.array(change.apply(array.ravel())).reshape(4, 2, 3)
expected = np.transpose(array, (2, 0, 1))
assert np.array_equal(observed, expected)
```

The first part of the stored order is

```
(0, 4, 8, 12, 16, 20, 1, 5, 9, 13, 17, 21, ...)
```

19.2.5 Chinese-remainder order

Given pairwise coprime positive moduli $m_1, \dots, m_r$, let

$$M = \prod_{j=1}^{r} m_j.$$

The implementation sorts each $n \in \{0, \dots, M-1\}$ by the key

$$\rho(n) = (n \bmod m_1, \dots, n \bmod m_r)$$

in lexicographic order. The returned values are still the integer indices. They are not residue tuples and are not the coefficients of a symbolic CRT isomorphism.

For moduli 2 and 3,

n	$\rho(n)$
0	$(0, 0)$
4	$(0, 1)$
2	$(0, 2)$
3	$(1, 0)$
1	$(1, 1)$
5	$(1, 2)$

so the order is

```
(0, 4, 2, 3, 1, 5)
```

Noncoprime moduli raise `ValidationError`. A modulus equal to one is permitted as a trivial factor because it is coprime to every integer.

19.2.6 Stable custom sorting

`sorted_coordinate_transform` evaluates `key(index)` once through Python's sorting machinery and materializes the resulting order as an exact transform. Python sorting is stable, so equal keys retain natural index order.

```python
from komorebi_math.coordinates import sorted_coordinate_transform

change = sorted_coordinate_transform(
    8,
    key=lambda index: (index % 3, index),
    source="natural order",
    target="modulo-three order",
)

print(tuple(int(value) for value in change.apply(tuple(range(8)))))
```

Output:

```
(0, 3, 6, 1, 4, 7, 2, 5)
```

The callable is construction logic, not persisted state. Saving the result stores the materialized permutation matrix and its names. Loading it does not reconstruct the Python callable.

19.2.7 Combined packet example

```
from komorebi_math.coordinates import (
    chinese_remainder_order,
    digit_reversal_transform,
    residue_class_transform,
)

x = tuple(range(8))
lanes = residue_class_transform(8, 2)
bits = digit_reversal_transform(8, 2)

lane_values = lanes.apply(x)
bit_values = bits.apply(x)

assert lanes.inverse().apply(lane_values) == x
assert bits.inverse().apply(bit_values) == x

print(tuple(int(value) for value in lane_values))
print(tuple(int(value) for value in bit_values))
print(chinese_remainder_order((2, 3)))
```

Output:

```
(0, 2, 4, 6, 1, 3, 5, 7)
(0, 4, 2, 6, 1, 5, 3, 7)
(0, 4, 2, 3, 1, 5)
```

19.2.8 Packet CLI

The three command-line choices are:

```
python -m komorebi_math coordinates packet --kind residue --length 12 --modulus 4
python -m komorebi_math coordinates packet --kind digit-reversal --length 8 --radix 2
python -m komorebi_math coordinates packet --kind crt --moduli 2,3
```

The response contains the exact matrix as rational strings, the source and target names, and `"verified": true`. The CLI does not apply the matrix to a user vector. Tensor-axis and custom sorted permutations have no Chapter 19 CLI route and must be constructed through Python.

The radix-one defect also applies to the digit-reversal CLI. Do not pass `--radix 1`.

19.3 Tensor coordinate transport

Let T_V map old vector components to new vector components. On a tensor power, a purely contravariant rank-k tensor uses the Kronecker power

$$T_{V^{\otimes k}} = T_V^{\otimes k}.$$

Mixed tensors require one factor per slot. A contravariant slot uses T_V, while a covariant slot uses the contragredient matrix T_V^{-T}.

19.3.1 Exact transport API

```
contragredient_transform(
    transform: CoordinateTransform,
) -> CoordinateTransform

transport_covector(
    covector: Sequence[Scalar],
    transform: CoordinateTransform,
) -> Vector

tensor_coordinate_transform(
    transform: CoordinateTransform,
    variance: Sequence[Literal["contravariant", "covariant"]],
) -> CoordinateTransform

transport_tensor_components(
    components: Sequence[Scalar],
    transform: CoordinateTransform,
    variance: Sequence[Literal["contravariant", "covariant"]],
) -> Vector

tensor_product_transform(
    left: CoordinateTransform,
    right: CoordinateTransform,
) -> CoordinateTransform

direct_sum_transform(
    left: CoordinateTransform,
    right: CoordinateTransform,
) -> CoordinateTransform

coordinate_pairing(
    covector: Sequence[Scalar],
    vector: Sequence[Scalar],
) -> Fraction

pairing_invariant(
    covector: Sequence[Scalar],
    vector: Sequence[Scalar],
    transform: CoordinateTransform,
) -> bool
```

These functions belong to the exact coordinate layer. Inputs are converted to `Fraction` values and outputs are immutable exact tuples. They are not NumPy tensor routines.

19.3.2 Variance convention

Write the vector-coordinate rule as

$$x' = Cx.$$

For the scalar pairing to remain unchanged, a covector must obey

$$\phi' = C^{-T}\phi,$$

because

$$(\phi')^T x' = (C^{-T}\phi)^T (Cx) = \phi^T x.$$

For a variance word

$$\nu = (\nu_1, \dots, \nu_r), \qquad \nu_j \in \{\text{contravariant}, \text{covariant}\},$$

define

$$K_j = \begin{cases} C, & \nu_j = \text{contravariant}, \\ C^{-T}, & \nu_j = \text{covariant}. \end{cases}$$

Then the flattened component transform is

$$T_\nu = K_1 \otimes \cdots \otimes K_r.$$

Axes use the listed variance order. Components are flattened lexicographically, which agrees with row-major flattening for a tensor whose every axis has dimension n.

An empty variance sequence represents a scalar. Its coordinate transform is the 1×1 identity.

Constructor	Theorem identifier	Result
`contragredient_transform`	`CC.T1`	exact transform on covectors
`tensor_coordinate_transform`	`CC.T2`	exact transform on flattened mixed tensors
`tensor_product_transform`	`CC.T3`	Kronecker product of two transform matrices
`direct_sum_transform`	`CC.T4`	block-diagonal sum of two transform matrices

`transport_covector` and `transport_tensor_components` apply the corresponding transform immediately and return a raw exact vector. They do not return a separate certificate.

19.3.3 Exact pairing example

```
from komorebi_math.coordinates import (
    CoordinateTransform,
    coordinate_pairing,
    pairing_invariant,
    transport_covector,
)

C = CoordinateTransform(
    "old",
    "new",
    ((2, 1), (1, 1)),
    "EXAMPLE.T",
)
x = (3, -2)
phi = (5, 7)

x_new = C.apply(x)
phi_new = transport_covector(phi, C)

print(tuple(map(str, x_new)))
print(tuple(map(str, phi_new)))
print(coordinate_pairing(phi, x))
print(coordinate_pairing(phi_new, x_new))
print(pairing_invariant(phi, x, C))
```

Output:

```
('4', '1')
('-2', '9')
1
1
True
```

The equality is exact. No numerical tolerance enters the comparison.

19.3.4 Mixed tensor example

Use the same C and flatten the matrix

$$A = \begin{pmatrix} 1 & 2 \\ 3 & 4 \end{pmatrix}$$

as $(1, 2, 3, 4)$. One contravariant and one covariant axis gives

$$C \otimes C^{-T}.$$

```
from komorebi_math.coordinates import (
    tensor_coordinate_transform,
    transport_tensor_components,
)

variance = ("contravariant", "covariant")
tensor_change = tensor_coordinate_transform(C, variance)
components = (1, 2, 3, 4)

direct = transport_tensor_components(components, C, variance)
through_object = tensor_change.apply(components)

assert direct == through_object
assert tensor_change.roundtrip_valid()
print(tuple(map(str, direct)))
```

Output:

```
('-3', '11', '-2', '8')
```

With the library's flattening convention, this is also the row-major flattening of the transported operator in Section 19.4.

19.3.5 Tensor products and direct sums

For $C : V \to V'$ and $D : W \to W'$,

$$C \otimes D : V \otimes W \longrightarrow V' \otimes W'$$

is built by `tensor_product_transform(C, D)`. Rectangular transforms are allowed because this constructor does not invert either factor.

For $C : V \to V'$ and $D : W \to W'$,

$$C \oplus D = \begin{pmatrix} C & 0 \\ 0 & D \end{pmatrix}$$

is built by `direct_sum_transform(C, D)`. It is also permitted for rectangular factors. Inversion is available later only when the resulting transform is square and nonsingular.

19.3.6 Tensor scale boundary

If C is $n \times n$ and the tensor rank is r, then

$$T_\nu \in \mathbb{Q}^{n^r \times n^r}.$$

The current implementation stores every entry. Its matrix therefore contains

$$n^{2r}$$

exact rational values. Applying the dense transform has the same scalar-entry scale. The function is suitable for small, finite symbolic tensors. It is not a lazy tensor network, sparse Kronecker operator, or implicit contraction engine.

n	r	component dimension n^r	dense matrix entries n^{2r}
2	2	4	16
2	6	64	4,096
3	4	81	6,561
4	5	1,024	1,048,576

There is no `CoordinateBudget` check inside these tensor constructors. The caller must choose a dimension and rank that fit memory and exact-arithmetic cost.

19.4 Operator conjugation

Suppose B_s and B_t are bases of one finite vector space and T maps source coordinate columns to target coordinate columns. The same endomorphism has matrices related by

$$[A]_{B_t} = T[A]_{B_s}T^{-1}.$$

The implementation follows this convention exactly.

19.4.1 Operator, rectangular-map, and form API

```
transport_operator(
    operator: Iterable[Iterable[Scalar]],
    transform: CoordinateTransform,
) -> Matrix

transport_rectangular_operator(
    operator: Iterable[Iterable[Scalar]],
    domain_transform: CoordinateTransform,
    codomain_transform: CoordinateTransform,
) -> Matrix

transport_bilinear_form(
    form: Iterable[Iterable[Scalar]],
    transform: CoordinateTransform,
) -> Matrix
```

For $x' = Cx$, the three rules are

$$A' = CAC^{-1},$$

$$L' = C_{\text{cod}} L C_{\text{dom}}^{-1},$$

and

$$G' = C^{-T} G C^{-1}.$$

The first applies to an endomorphism. The second applies to a map between different domain and codomain spaces. The third applies to a bilinear form $g(x, y) = x^T G y$.

The transport helpers return raw exact matrices. The theorem-bearing object is the coordinate transform C, not the resulting operator matrix. A caller that needs a reusable named map can wrap the result in an appropriate exact record after transport.

19.4.2 Commuting identities

Operator transport is characterized by

$$A'(Cx) = C(Ax).$$

For a rectangular map $L : V \to W$,

$$L'(C_V x) = C_W(Lx).$$

Bilinear-form transport is characterized by

$$(Cx)^T G'(Cy) = x^T G y.$$

These are component identities. The abstract vector, operator, and bilinear form have not changed.

19.4.3 Exact worked conjugation

```
from komorebi_math.coordinates import (
    CoordinateTransform,
    transport_bilinear_form,
    transport_operator,
)

C = CoordinateTransform(
    "old",
    "new",
    ((2, 1), (1, 1)),
    "EXAMPLE.T",
)
A = ((1, 2), (3, 4))
G = ((2, 1), (1, 3))
x = (3, -2)

A_new = transport_operator(A, C)
G_new = transport_bilinear_form(G, C)
x_new = C.apply(x)

Ax = (
    A[0][0] * x[0] + A[0][1] * x[1],
    A[1][0] * x[0] + A[1][1] * x[1],
```

```
)
A_new_x_new = (
    A_new[0][0] * x_new[0] + A_new[0][1] * x_new[1],
    A_new[1][0] * x_new[0] + A_new[1][1] * x_new[1],
)

assert A_new_x_new == C.apply(Ax)

q_old = sum(G[i][j] * x[i] * x[j] for i in range(2) for j in range(2))
q_new = sum(
    G_new[i][j] * x_new[i] * x_new[j]
    for i in range(2)
    for j in range(2)
)
assert q_new == q_old

print(tuple(tuple(map(str, row)) for row in A_new))
print(tuple(tuple(map(str, row)) for row in G_new))
print(q_old, q_new)
```

Output:

```
(('-3', '11'), ('-2', '8'))
(('3', '-5'), ('-5', '10'))
18 18
```

This example simultaneously verifies the operator commuting square and the quadratic-form invariant.

19.4.4 Exactness and certificate boundary

`CoordinateTransform` converts entries through `Fraction`. Integer and `Fraction` inputs therefore remain literal exact rationals. A Python float is also accepted, but `Fraction(float)` represents its exact binary floating value, which can produce a large denominator. Use integers or explicit `Fraction` values when the intended mathematics is rational.

There is one certificate distinction that must remain explicit:

> `CoordinateTransform.certificate()` validates the finite rational matrix and reports its determinant and `invertible` diagnostic. In `1.0.0b4`, a square singular transform can still have `certificate.valid == True`. The certificate is therefore not an invertibility proof.

For an inverse-dependent operation, use one of these stronger paths:

```
assert transform.roundtrip_valid()
inverse = transform.inverse()
```

`roundtrip_valid()` returns `False` for a nonsquare or singular exact transform. `.inverse()` and the tensor or operator helpers raise when exact inversion fails. Exact permutation transforms are always invertible because their matrices contain every coordinate index exactly once.

Numerical behavior is different. As recorded in Section 19.1, a singular square `NumericCoordinateTransform` receives an invalid numerical certificate.

19.4.5 Failure and edge table

Operation	Invalid boundary	Behavior
numerical transform construction	matrix not two dimensional or empty	`DimensionError`
numerical transform construction	matrix has NaN or infinity	`ValidationError`
numerical transform construction	blank coordinate name	`ValidationError`
numerical transform construction	nonpositive or nonfinite tolerance	`ValidationError`

Operation	Invalid boundary	Behavior
numerical `.apply`	input not a finite vector of exact source length	`DimensionError` or `ValidationError`
numerical `.inverse`	rectangular matrix	`DimensionError`
numerical `.inverse`	singular square matrix	`ValidationError`
spectral constructor	Boolean, noninteger, or nonpositive size	`DimensionError`
Walsh or Haar constructor	size not a power of two	`DimensionError`
modal construction	nonsquare operator	`DimensionError`
modal construction	incomplete numerical eigenvector basis	`ValidationError`
packet input	nonpositive or Boolean length, modulus, radix, or shape entry	`ValidationError`
digit reversal	length not an exact radix power	`DimensionError`
digit reversal	`radix=1`, `length>1`	known nontermination defect, reject before call
tensor-axis order	empty shape	`DimensionError`
tensor-axis order	axes repeat or omit an axis	`ValidationError`
CRT order	empty modulus sequence	`DimensionError`
CRT order	moduli not pairwise coprime	`ValidationError`
exact permutation	order does not contain each index once	`ValidationError`
covector or tensor transport	transform not square or is singular	`DimensionError` or `ValidationError`
tensor transport	variance word contains another string	`ValidationError`
tensor application	flattened component length is not n^r	`DimensionError`
pairing	vector and covector lengths differ	`DimensionError`
operator transport	operator and transform dimensions disagree	`DimensionError`
form transport	form not a matching square matrix	`DimensionError`

Direct construction of `ModalCoordinateSystem` is shallow because it is a frozen result record. Use `modal_coordinate_system(...)` as the validated producer.

19.4.6 Persistence

Chapter 16 gives the complete portable-envelope contract. For the present objects, the relevant helpers are:

```
save_transform(
    path: str | Path,
    transform: CoordinateTransform,
    *,
    overwrite: bool = False,
) -> Path

load_transform(path: str | Path) -> CoordinateTransform

save_coordinate_object(
    path: str | Path,
    value: Any,
    *,
    overwrite: bool = False,
) -> Path

load_coordinate_object(path: str | Path) -> Any
```

Persisted object	Codec tag	Codec version	Recommended helper
exact packet or tensor transform	`coordinates.transform`	1	`save_transform` or `save_coordinate_object`

Persisted object	Codec tag	Codec version	Recommended helper
numerical spectral transform	`coordinates.numeric_transform`	1	`save_coordinate_object`
modal coordinate result	`coordinates.modal_system`	1	`save_coordinate_object`

The outer JSON envelope records schema `komorebi-math.portable`, schema version one, producer version, canonical payload SHA-256, and the encoded payload. Complex numbers, exact fractions, and NumPy arrays with dtype and shape are supported. Writes are atomic and refuse to overwrite an existing path unless `overwrite=True`. Loading rejects an altered digest, duplicate JSON keys, nonfinite values, unsupported future versions, and mismatched codec schemas.

```
from pathlib import Path
from tempfile import TemporaryDirectory

import numpy as np

from komorebi_math.coordinates import (
    NumericCoordinateTransform,
    discrete_fourier_transform,
    load_coordinate_object,
    save_coordinate_object,
)

with TemporaryDirectory() as directory:
    path = Path(directory) / "dft4.json"
    original = discrete_fourier_transform(4)
    save_coordinate_object(path, original)
    restored = load_coordinate_object(path)

    assert isinstance(restored, NumericCoordinateTransform)
    assert restored.source == original.source
    assert restored.target == original.target
    assert restored.tolerance == original.tolerance
    assert np.array_equal(restored.matrix, original.matrix)
    print(restored.certificate().valid)
```

Output:

```
True
```

Persistence proves envelope integrity and schema validity. It does not turn a singular transform into an invertible one. Require the appropriate certificate or roundtrip check after loading when later logic needs inversion.

The raw tuple returned by `transport_operator` or `transport_tensor_components` is not accepted by `save_coordinate_object`, whose type set is closed by design. The broader `save_portable` function can store primitive tuple data when a typed coordinate object is unnecessary.

19.4.7 Complexity and resource profile

Let N be a spectral or permutation length, n a square operator degree, r a tensor rank, $m \times n$ a rectangular operator shape, and $M = \prod_j m_j$ a CRT index count.

Construction or operation	Stored representation	Dominant implementation scale
DFT or DCT construction	dense $N \times N$ NumPy matrix	$O(N^2)$ time and memory
Walsh construction	recursively doubled dense matrix	$O(N^2)$ time and memory
current Haar construction	repeated dense $N \times N$ stage products	nominal $O(N^3 \log N)$ construction, $O(N^2)$ memory
numerical transform application	dense matrix-vector product	$O(N^2)$

Construction or operation	Stored representation	Dominant implementation scale
numerical inverse, condition, or certificate	dense linear algebra	$O(N^3)$
modal construction	eigendecomposition, rank, inverse, residual	$O(n^3)$
residue order only	integer tuple	$O(N)$
digit-reversal order only	integer tuple	$O(N \log_b N)$
tensor-axis order only	integer tuple	$O(Nr)$
CRT order only	keys and stable sort	approximately $O(Mr + M \log M)$
any exact permutation transform	dense $N \times N$ Fraction matrix	$O(N^2)$ time and memory
exact permutation `.apply`	generic dense exact multiply	$O(N^2)$
exact permutation `.inverse`	generic exact inversion	$O(N^3)$ plus rational bit cost
exact $n \times n$ operator or form transport	dense exact inverses and products	$O(n^3)$ arithmetic operations plus rational bit growth
exact rectangular transport	two inverses and two dense products	$O(m^3 + n^3 + m^2n + mn^2)$ at the ordinary dense scale
rank-r tensor transport	dense $n^r \times n^r$ Fraction matrix	$O(n^{2r})$ entries
portable save or load	JSON proportional to stored entries	linear in encoded payload size

The logical permutation operations are linear-time reorderings, but the returned exact transforms intentionally use the common dense `CoordinateTransform` representation. For large arrays, call the `*_order` function and apply that order directly rather than materializing the dense exact matrix.

Likewise, applications needing production FFT, DCT, Walsh, or Haar throughput should use a fast signal backend. The Chapter 19 numerical matrices are most useful for small finite examples, matrix inspection, coordinate composition, certificate testing, and reproducible teaching cases.

19.4.8 What the shipped tests establish

A focused replay of the four most relevant modules completed with 13 passes:

```
tests/test_coordinates_general_numeric_packet.py
tests/test_coordinates_general_tensor_modular.py
tests/test_coordinates_general_persistence.py
tests/test_block14_cli_api.py

13 passed
```

The full coordinate verifier also passed all 24 checks. Three named checks directly cover this chapter:

```
[PASS] Fourier, cosine, Hadamard, and Haar coordinates
[PASS] packet, residue, digit, and CRT coordinates
[PASS] tensor, covector, form, and operator transport
verification passed 24/24 checks
```

The exercised cases establish:

- default DFT, DCT-II, Walsh-Hadamard, and Haar roundtrips on finite vectors
- numerical modal diagonalization of a matrix with a complete eigenbasis
- exact residue, bit-reversal, tensor-axis, and CRT permutation roundtrips
- exact vector-covector pairing invariance
- exact operator and bilinear-form transport identities
- a mixed contravariant-covariant tensor roundtrip
- numeric and modal portable persistence, including digest tamper rejection
- the spectral and packet CLI paths

The focused suite does not directly exercise every option or helper. No direct test was found for the nondefault normalization flags, inverse Fourier flag, `sorted_coordinate_transform`, standalone `contragredient_transform`, `tensor_product_transform`, `direct_sum_transform`, or the standalone rectangular transport path. `transport_rectangular_operator` is exercised indirectly by polynomial operator transport elsewhere in the coordinate suite. These functions have implementation contracts, but the guide does not inflate their present test coverage.

Chapter 19 summary. Spectral constructors provide explicit dense numerical matrices for Fourier, DCT-II, Sylvester Walsh, complete Haar, and modal coordinates. Packet constructors provide exact dense permutations for residue lanes, fixed-width digit reversal, tensor axes, CRT order, and stable custom keys. Exact tensor transport follows variance: vectors use C, covectors use C^{-T}, operators use CAC^{-1}, and bilinear forms use $C^{-T}GC^{-1}$. Pairings and represented maps are invariant, but cost is governed by the stored dense matrices. Keep spectral matrices finite, tensor ranks small, require a real invertibility check when inversion matters, and reject radix one before calling the `1.0.0b4` digit-reversal implementation.

20. Analysis-synthesis and redundant frames

First route. Follow the four-coordinate, two-dimensional example in Sections 20.1 to 20.2 and check reconstruction first. Then read Sections 20.3 to 20.4 before treating individual reconstruction components as projectors. If you need to compose maps in redundant coordinates, continue to the coefficient lifts and bridges in Section 20.5. Keep the physical dimension and the coefficient dimension written separately throughout the calculation.

An analysis/synthesis presentation separates a physical vector from the coefficients used to represent it. In a basis the coefficients are unique. In a redundant frame they are not, and that nonuniqueness changes the algebra: the coefficient identity becomes a projection, coefficient vectors acquire a gauge freedom, and maps between physical spaces require supported lifts and, occasionally, transition bridges.

Section 16.11 is the canonical stable method page for `AnalysisSynthesisSystem` and `AnalysisSynthesisBlocks`. The discussion below uses that construction contract and develops the full redundant-frame algebra. It is authoritative for coefficient gauges, quotient metrics, lifted maps, coefficient blocks, adjoints, direct sums, tensor products, and the exact rational mirror.

The chapter is finite-dimensional. It makes no claim about infinite frame completion, convergence of infinite expansions, measurable direct integrals, or a CUDA/device implementation. Numerical objects use dense NumPy arrays. Exact objects use immutable rational tuples.

20.1 `AnalysisSynthesisSystem`

$$A : X \to C, \qquad S : C \to X, \qquad SA = I_X.$$

20.1.1 Dimensions and data model

Write

$$A \in \mathbb{F}^{m \times n}, \qquad S \in \mathbb{F}^{n \times m}.$$

Here $n = \dim X$ is the source dimension and $m = \dim C$ is the coefficient dimension. The package uses these cases.

Case	Dimension relation	Meaning
square	$m = n$	invertible coordinate presentation when the certificate passes
redundant	$m > n$	more analysis coefficients than source coordinates
undercomplete proposal	$m < n$	constructible only through the bare numerical record. Its left-inverse certificate cannot pass

The stable numerical record has the frozen signature

```
AnalysisSynthesisSystem(
    analysis: np.ndarray,
    synthesis: np.ndarray,
    source: str = "source",
    coordinates: str = "coordinates",
    tolerance: float = 1e-12,
```

```
    theorem: str = "KM-AS-01",
)
```

The matrices are copied, made read-only, and checked for two dimensions, nonempty shape, compatible transposed rectangular shapes, and finite entries. The two labels must be nonempty after stripping. The tolerance must be finite and strictly positive.

Direct construction separates a *well-formed proposal* from a *verified left inverse*. Thus

```
system = AnalysisSynthesisSystem(A, S)
```

can succeed even when $SA \neq I$. Use

```
system.certificate().require()
```

before treating the object as a valid presentation. This separation lets verification code inspect failed proposed systems instead of losing their diagnostics during construction.

> **Terminology.** In this API `frame_operator()` returns the source-space reconstruction operator SA. Some frame-theory texts instead use "frame operator" for A^*A. The method name follows the package's frozen stable contract.

20.1.2 Analysis, synthesis, and roundtrip

For $x \in X$ and $c \in C$,

$$c = Ax, \qquad S(c) = Sc, \qquad \text{reconstruct}(x) = SAx.$$

The core properties and methods are

Member	Return	Contract
`source_dimension`	`int`	n, the number of analysis columns
`coordinate_dimension`	`int`	m, the number of analysis rows
`square`	`bool`	`m == n`
`redundant`	`bool`	`m > n`
`frame_operator()`	`np.ndarray`	$SA \in \mathbb{F}^{n\times n}$
`analyze(value)`	`np.ndarray`	Ax, requiring a finite length-n vector
`synthesize(value)`	`np.ndarray`	Sc, requiring a finite length-m vector
`reconstruct(value)`	`np.ndarray`	SAx
`certificate()`	`Certificate`	global finite left-inverse check
`reconstruction_certificate(value)`	`Certificate`	one concrete roundtrip check

The system certificate computes

$$r_{AS} = \|SA - I_n\|_F$$

and is valid precisely when

$$r_{AS} \leq \texttt{tolerance}\,\max(1, \|I_n\|_F)$$

and `np.linalg.matrix_rank(A) == n`. Its residual key is `analysis_synthesis_left_inverse`. Diagnostics record both dimensions, the observed rank, and the square/redundant flags. The exactness label is `Exactness.NUMERICAL`, even if an input array happens to contain integers.

The pointwise certificate instead records

$$r_x = \|SAx - x\|_2$$

under `analysis_synthesis_roundtrip`. It also requires the global system certificate to be valid.

20.1.3 Minimal stable example

```
import numpy as np
from komorebi_math.stable import AnalysisSynthesisSystem

A = np.array([
    [1.0, 0.0],
    [0.0, 1.0],
    [1.0, 1.0],
    [1.0, -1.0],
])

system = AnalysisSynthesisSystem.canonical_dual(
    A,
    source="signal",
    coordinates="four redundant coefficients",
)
x = np.array([3.0, -2.0])

system.certificate().require()
system.reconstruction_certificate(x).require()

print(system.source_dimension)
print(system.coordinate_dimension)
print(system.redundant)
print(system.analyze(x))
print(system.reconstruct(x))
```

Output, up to ordinary floating representation, is

```
2
4
True
[ 3. -2.  1.  5.]
[ 3. -2.]
```

20.2 Canonical dual synthesis

$$S = (A^*A)^{-1}A^*.$$

20.2.1 Square inverse and Moore-Penrose constructors

Two constructors derive S from A:

```
AnalysisSynthesisSystem.from_invertible(
    matrix,
    *,
    source="source",
    coordinates="coordinates",
    tolerance=1e-12,
    theorem="KM-AS-01",
)

AnalysisSynthesisSystem.canonical_dual(
    analysis,
    *,
    source="source",
    coordinates="coordinates",
    tolerance=1e-12,
    theorem="KM-AS-01",
)
```

`from_invertible` requires a square matrix and calls `np.linalg.inv`. A singular inverse is translated to `ValidationError`. The factory returns the record without implicitly requiring its numerical certificate, so callers retain the standard explicit pattern

```
square = AnalysisSynthesisSystem.from_invertible(A)
square.certificate().require()
```

`canonical_dual` supports square or redundant full-column-rank analysis. Its explicit rank precheck uses the relative SVD threshold

$$r_\tau(A) = \#\{i : \sigma_i > \tau\sigma_{\max}\}, \qquad \tau = \texttt{tolerance}.$$

The method requires $r_\tau(A) = n$ and calls `np.linalg.pinv(A, rcond=tolerance)`, so the explicit precheck and pseudoinverse truncation share the declared relative cutoff. It then constructs the system and separately requires its certificate. That certificate tests the left-inverse residual with the declared tolerance, but its `np.linalg.matrix_rank(A)` call uses NumPy's default rank threshold rather than the declared cutoff. The final certificate is therefore an independent safeguard, not a third use of one universal rank threshold. A matrix can have nonzero entries in every singular direction yet be rejected as numerically rank deficient at the declared precheck resolution or by the subsequent certificate.

For complex NumPy arrays, A^* means conjugate transpose. For the exact rational class in Section 20.6, all coefficients are real rationals and the formula uses the ordinary transpose.

20.2.2 Canonical-dual output

For the four-by-two analysis matrix in Section 20.1,

$$A^*A = 3I_2, \qquad S = \frac{1}{3}A^* = \begin{pmatrix} 1/3 & 0 & 1/3 & 1/3 \\ 0 & 1/3 & 1/3 & -1/3 \end{pmatrix}.$$

The resulting coefficient projection AA^+ is orthogonal. That minimum-Euclidean-norm property belongs to the Moore-Penrose construction. An arbitrary valid left inverse produces the generally oblique gauge algebra of Section 20.5.

20.2.3 Threshold boundary

```
import numpy as np
from komorebi_math.coordinates import AnalysisSynthesisSystem
from komorebi_math.exceptions import ValidationError

near_singular = np.diag([1.0, 9e-16])

try:
    AnalysisSynthesisSystem.canonical_dual(near_singular)
except ValidationError as error:
    print(type(error).__name__)
```

With the default tolerance, output is

```
ValidationError
```

This regression is part of the installed frame-algebra verifier. It prevents rank testing and pseudoinverse truncation from silently using inconsistent thresholds.

20.3 Components and blocks

$$C_i = SE_iA, \qquad \sum_i C_i = I_X.$$

20.3.1 Coordinate selectors and additive reconstruction

For an index set $I \subseteq \{0, \dots, m-1\}$, let E_I be the diagonal coefficient selector. The API constructs

$$C_I = SE_IA \in \mathbb{F}^{n\times n}.$$

```
component(indices)
components(groups=None)
```

An integer selects one coordinate. A sequence selects one nonempty set of unique coordinates. `groups=None` uses the singleton partition. A supplied grouping must be nonempty, disjoint, and cover every coefficient coordinate exactly once.

For a complete partition $\{I_\alpha\}$,

$$\sum_\alpha C_{I_\alpha} = S\left(\sum_\alpha E_{I_\alpha}\right)A = SA = I_n.$$

The aliases `projector()` and `projectors()` call these same methods. They are retained for compatibility. They do not add an idempotence check.

20.3.2 Physical operator blocks

For a source-space endomorphism $T \in \mathbb{F}^{n\times n}$,

$$T = \left(\sum_\beta C_\beta\right) T \left(\sum_\alpha C_\alpha\right) = \sum_{\beta,\alpha} C_\beta T C_\alpha.$$

```
blocks = system.operator_blocks(T, groups=groups)
```

returns the stable record

```
AnalysisSynthesisBlocks(
    system: AnalysisSynthesisSystem,
    groups: tuple[tuple[int, ...], ...],
    blocks: tuple[tuple[np.ndarray, ...], ...],
    operator: np.ndarray,
)
```

Each stored block is a physical $n \times n$ matrix. If there are p groups, `blocks` is a $p \times p$ tuple grid. Its methods are

Member	Meaning
`reconstruct()`	sum all stored physical blocks
`certificate()`	compare that sum with the stored operator

The certificate residual is

$$r_B = \left\| \sum_{\beta,\alpha} B_{\beta\alpha} - T \right\|_F$$

under `operator_block_reconstruction`, with theorem identifier `KM-AS-02`. It also requires the associated system certificate.

Construct blocks through `operator_blocks()`. Directly instantiating `AnalysisSynthesisBlocks` verifies grid and matrix shapes and can certify the sum, but it does not independently prove that arbitrary supplied matrices equal $C_\beta T C_\alpha$.

20.3.3 Grouped block example

```
T = np.array([[2.0, -1.0], [3.0, 4.0]])
groups = ((0, 2), (1, 3))

physical_blocks = system.operator_blocks(T, groups=groups)
physical_blocks.certificate().require()

print(np.allclose(physical_blocks.reconstruct(), T))
print([[block.shape for block in row] for row in physical_blocks.blocks])
```

Output is

```
True
[[(2, 2), (2, 2)], [(2, 2), (2, 2)]]
```

These stable physical blocks should not be confused with the small coefficient blocks in Section 20.5.6.

20.4 Square projectors versus redundant reconstruction components

20.4.1 Square algebra

If $m = n$ and A is invertible, then $S = A^{-1}$ and $AS = I_m$. Hence

$$C_I C_J = S E_I A S E_J A = S E_I E_J A.$$

For disjoint I and J, $C_I C_J = 0$. For $I = J$, $C_I^2 = C_I$. The square components are therefore algebraic projectors transported from the coordinate selectors.

20.4.2 Redundant algebra

In a redundant system,

$$P = AS \neq I_m$$

in general, and

$$C_I C_J = S E_I P E_J A.$$

No selector identity removes P. Individual components may fail both idempotence and pairwise annihilation even though their complete sum remains I_n.

For the four-coordinate canonical-dual example, the singleton components are

$$C_0 = \begin{pmatrix} 1/3 & 0 \\ 0 & 0 \end{pmatrix}, \quad C_1 = \begin{pmatrix} 0 & 0 \\ 0 & 1/3 \end{pmatrix},$$

$$C_2 = \frac{1}{3}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \quad C_3 = \frac{1}{3}\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}.$$

They sum to I_2, but each has

$$\|C_i^2 - C_i\|_F = \frac{2}{9} \approx 0.22222222.$$

```
components = system.components()

print(np.allclose(sum(components), np.eye(2)))
print([np.linalg.norm(C @ C - C) for C in components])
```

Output is

```
True
[0.22222222, 0.22222222, 0.22222222, 0.22222222]
```

20.4.3 Why one-index physical block multiplication fails

Suppose $T : X \to X$ and $U : X \to X$. The tempting rule

$$C_\beta U T C_\alpha \stackrel{?}{=} \sum_\gamma (C_\beta U C_\gamma)(C_\gamma T C_\alpha)$$

would require the middle components to resolve identity through a single index after multiplication. In a redundant system, the right side contains C_γ^2, not C_γ, and the rule is generally false.

The always-valid physical expansion uses two middle indices:

$$C_\beta U T C_\alpha = \sum_{\gamma,\delta} (C_\beta U C_\gamma)(C_\delta T C_\alpha).$$

Ordinary one-index block multiplication is recovered in coefficient space, where the small blocks are literal submatrices of the coefficient lift.

20.5 Coefficient gauges, quotient metrics, lifts, and bridges

20.5.1 `AnalysisSynthesisGauge`

The research record

```
AnalysisSynthesisGauge(system: AnalysisSynthesisSystem)
```

requires an `AnalysisSynthesisSystem` whose certificate passes. It delegates the public presentation properties and supplies the quotient algebra.

Define

$$P = AS, \qquad Q = I_m - P.$$

Then

$$P^2 = P, \qquad Q^2 = Q, \qquad P + Q = I_m,$$

and every coefficient vector decomposes as

$$c = Pc + Qc, \qquad Qc \in \ker S.$$

The principal methods are

Member	Formula or result
`coefficient_projection()`	$P = AS$
`gauge_projection()`	$Q = I - P$
`canonical_coefficients(c)`	Pc
`gauge_part(c)`	Qc
`gauge_equivalent(c,d)`	tolerance-aware test of $S(c-d) = 0$
`coefficient_metric()`	$H = S^*S$
`coefficient_seminorm(c)`	$\|Sc\|_2$
`dual()`	the presentation (S^*, A^*)
`transition_to(other)`	$A_{\text{other}} S_{\text{self}}$
`direct_sum(other)`	block-diagonal presentation
`tensor_product(other)`	Kronecker presentation
`certificate()`	projection, support, and metric laws

Gauge equivalence is

$$c \sim d \iff S(c-d) = 0.$$

The metric

$$H = S^*S$$

is positive semidefinite and realizes the physical inner product:

$$\langle c, Hd \rangle = \langle Sc, Sd \rangle.$$

It is a seminorm on raw coefficient space and a norm on the quotient $C/\ker S$.

The gauge certificate checks

$$P^2 = P, \quad Q^2 = Q, \quad P + Q = I, \quad PA = A, \quad SP = S, \quad P^*H = H, \quad HP = H.$$

Its residual keys are `projection_idempotence`, `gauge_idempotence`, `projection_complement`, `analysis_support`, `synthesis_support`, `metric_left_support`, and `metric_right_support`. The theorem identifier is `KM-AS-GAUGE-01`.

20.5.2 Oblique gauge example

```
from komorebi_math.coordinates import AnalysisSynthesisGauge

A_oblique = np.array([
    [1.0, 0.0],
    [0.0, 1.0],
    [1.0, 1.0],
])
S_oblique = np.array([
    [0.5, -0.5, 0.5],
    [-0.25, 0.75, 0.25],
])

oblique = AnalysisSynthesisSystem(
    A_oblique,
    S_oblique,
    source="physical",
    coordinates="oblique coefficients",
)
gauge = AnalysisSynthesisGauge(oblique)
gauge.certificate().require()

c = np.array([3.0, -4.0, 5.0])
k = np.array([-2.0, -1.0, 1.0])

print(gauge.coefficient_projection())
print(gauge.canonical_coefficients(c))
print(gauge.gauge_part(c))
print(gauge.gauge_equivalent(c, c + k))
print(gauge.coefficient_seminorm(k))
```

Output is

```
[[ 0.5  -0.5   0.5 ]
 [-0.25  0.75  0.25]
 [ 0.25  0.25  0.75]]
[ 6.  -2.5  3.5]
[-3.  -1.5  1.5]
True
0.0
```

The displayed projection is idempotent but not symmetric. The vector k is a nonzero element of `ker(S_oblique)`, so `c` and `c + k` are distinct arrays representing the same physical vector.

20.5.3 Duals, direct sums, and tensor products

The dual presentation is

$$(A, S)^\vee = (S^*, A^*).$$

It remains valid because

$$A^* S^* = (SA)^* = I.$$

Direct sums use

$$A_{X\oplus Y} = A_X \oplus A_Y, \qquad S_{X\oplus Y} = S_X \oplus S_Y,$$

and tensor products use

$$A_{X\otimes Y} = A_X \otimes A_Y, \qquad S_{X\otimes Y} = S_X \otimes S_Y.$$

The numerical result uses the larger input tolerance. Direct-sum dimensions add. Tensor dimensions multiply. The latter can expand dense storage rapidly.

20.5.4 `AnalysisSynthesisMap` and coefficient lifts

The physical-map record is

```
AnalysisSynthesisMap(
    domain: AnalysisSynthesisSystem,
    codomain: AnalysisSynthesisSystem,
    operator: np.ndarray,
    theorem: str = "KM-AS-MAP-01",
)
```

Both endpoint certificates are required during construction. If $T : X \to Y$, its canonical coefficient lift is

$$\widehat{T} = A_Y T S_X.$$

Let $P_X = A_X S_X$ and $P_Y = A_Y S_Y$. Then

$$P_Y \widehat{T} P_X = \widehat{T}, \qquad S_Y \widehat{T} A_X = T.$$

Consequently,

$$\widehat{T}(I - P_X) = 0, \qquad (I - P_Y)\widehat{T} = 0.$$

The lifted physical identity is P_X, not the full identity on redundant coefficient space.

Member	Contract
`identity(system)`	physical identity map on one system
`tolerance`	maximum endpoint tolerance
`coefficient_lift()`	$A_Y T S_X$
`reconstruct()`	$S_Y \widehat{T} A_X$
`apply_source(x)`	Tx
`apply_coefficients(c)`	$\widehat{T}c$
`then(after)`	`after` $\circ$ `self` on physical operators
`compose(before)`	`self` $\circ$ `before`
`transition_bridge(after)`	bridge between middle presentations

Member	Contract
`adjoint()`	physical adjoint map
`dual_adjoint()`	raw coefficient adjoint on dual presentations
`scaled(scalar)`	finite numerical scalar multiple
`add(other)`	map sum with identical endpoint objects
`blocks(...)`	coefficient-space block record
`certificate()`	lift support and physical reconstruction

The map certificate records `coefficient_sandwich` and `physical_reconstruction`. Addition intentionally requires the same domain and codomain object identities. Merely compatible labels and dimensions are not enough.

20.5.5 Transition bridges and composition

If the first map ends in the same presentation in which the second begins,

$$\widehat{U \circ T} = \widehat{U}\,\widehat{T}.$$

If they use different presentations of the same physical middle space, define

$$R = A_{Y,\mathrm{in}} S_{Y,\mathrm{out}}.$$

Then

$$\widehat{U \circ T} = \widehat{U} R \widehat{T}.$$

Transitions are transitive:

$$R_{Z\leftarrow Y} R_{Y\leftarrow X} = R_{Z\leftarrow X}.$$

A self-transition is $AS = P$, not I_m. Compatibility requires equal physical source dimensions and exactly equal `source` strings. Coordinate labels may differ. The source label therefore participates in runtime identity. It is not only decorative metadata.

20.5.6 `CoefficientPartition` and compositional coefficient blocks

The strict ordered partition is

```
CoefficientPartition(
    dimension: int,
    groups: tuple[tuple[int, ...], ...],
)
```

It rejects Boolean and nonintegral dimensions or indices, nonpositive dimension, empty groups, duplicates, overlap, missing coordinates, and out-of-range indices. Each group is sorted internally. Group order is preserved.

```
CoefficientPartition.singletons(dimension)
CoefficientPartition.one_block(dimension)
fine.refines(coarse)
coarse.coarsens(fine)
```

For a domain partition $\{I_\alpha\}$ and target partition $\{J_\beta\}$, the compositional blocks are the small submatrices

$$L_{\beta\alpha} = \widehat{T}[J_\beta, I_\alpha].$$

They are represented by

```
AnalysisSynthesisCoefficientBlocks(
    mapping: AnalysisSynthesisMap,
    source_partition: CoefficientPartition,
    target_partition: CoefficientPartition,
)
```

Member	Contract
`blocks`	target-by-source tuple of small read-only arrays
`assemble()`	reconstruct the entire coefficient lift
`reblock(source_partition, target_partition)`	derive blocks for any valid new partitions
`physical_block(beta, alpha)`	recover $C_\beta^Y T C_\alpha^X$
`then(after, ...)`	compose underlying physical maps and derive fresh blocks
`certificate()`	certify coefficient-block assembly

The physical block is recovered by

$$S_Y[:, J_\beta] L_{\beta\alpha} A_X[I_\alpha, :] = C_\beta^Y T C_\alpha^X.$$

For an aligned middle partition, the coefficient blocks obey the ordinary one-index rule

$$(L_U L_T)_{\beta\alpha} = \sum_\gamma (L_U)_{\beta\gamma} (L_T)_{\gamma\alpha}.$$

When middle presentations differ, the bridge must appear between their lifts. `then()` does not multiply the stored block arrays. It composes the physical maps and constructs the requested result blocks.

20.5.7 Lift-and-block example

```
from komorebi_math.coordinates import (
    AnalysisSynthesisMap,
    CoefficientPartition,
)

codomain = AnalysisSynthesisSystem.canonical_dual(
    np.array([
        [1.0, 0.0],
        [0.0, 1.0],
        [1.0, -1.0],
        [2.0, 1.0],
    ]),
    source="codomain",
    coordinates="four target coefficients",
)
T = np.array([[2.0, -1.0], [3.0, 4.0]])
mapping = AnalysisSynthesisMap(oblique, codomain, T)

source_partition = CoefficientPartition(3, ((0, 2), (1,)))
target_partition = CoefficientPartition(4, ((0, 3), (1, 2)))
coefficient_blocks = mapping.blocks(source_partition, target_partition)

mapping.certificate().require()
coefficient_blocks.certificate().require()

print(mapping.coefficient_lift())
print([[block.shape for block in row] for row in coefficient_blocks.blocks])
```

```
print(np.allclose(coefficient_blocks.assemble(), mapping.coefficient_lift()))
print(np.allclose(mapping.reconstruct(), T))
```

Output is

```
[[ 1.25 -1.75  0.75]
 [ 0.5   1.5   2.5 ]
 [ 0.75 -3.25 -1.75]
 [ 3.   -2.    4.  ]]
[[(2, 2), (2, 1)], [(2, 2), (2, 1)]]
True
True
```

20.5.8 Physical and dual adjoints

The physical adjoint has lift

$$\widehat{T^*} = A_X T^* S_Y.$$

It is generally not the raw conjugate transpose of the original lift. With $H_X = S_X^* S_X$ and $H_Y = S_Y^* S_Y$,

$$\widehat{T}^* H_Y = H_X \widehat{T^*}.$$

`adjoint()` returns this physical adjoint. `dual_adjoint()` changes the endpoints to the dual presentations and then lifts T^*. Its coefficient lift is literally $\widehat{T}^*$. For Parseval endpoints, $S = A^*$, and the distinction disappears.

20.6 Rational frame algebra and dual/physical adjoints

20.6.1 Exact system signature and scalar domain

The exact rational presentation is

```
ExactAnalysisSynthesisSystem(
    analysis: Matrix,
    synthesis: Matrix,
    source: str = "source",
    coordinates: str = "coordinates",
    theorem: str = "KM-AS-EXACT-01",
)
```

Inputs must be integers or `fractions.Fraction`. Booleans, floats, complex numbers, ragged rows, and empty matrices are rejected. The immutable matrices are normalized to tuples of `Fraction` values. Construction requires the literal equality

$$SA = I_n.$$

Unlike the bare numerical record, an invalid exact left inverse cannot exist as a constructed exact system.

Factories are

```
ExactAnalysisSynthesisSystem.from_invertible(
    analysis,
    *, source="source", coordinates="coordinates",
    theorem="KM-AS-EXACT-01",
)

ExactAnalysisSynthesisSystem.canonical_dual(
    analysis,
```

```
    *, source="source", coordinates="coordinates",
    theorem="KM-AS-EXACT-01",
)
```

For full-column-rank rational A, the latter computes

$$S = (A^T A)^{-1} A^T$$

by exact elimination. There is no tolerance or numerical rank threshold.

20.6.2 Exact system members

Member	Exact result
`source_dimension`	source dimension
`coordinate_dimension`	coefficient dimension
`redundant`	coefficient dimension exceeds source dimension
`frame_operator()`	SA
`coefficient_projection()`	AS
`gauge_projection()`	$I - AS$
`coefficient_metric()`	$S^T S$
`analyze(x)`	exact vector Ax
`synthesize(c)`	exact vector Sc
`canonical_coefficients(c)`	exact ASc
`gauge_part(c)`	exact $(I - AS)c$
`gauge_equivalent(c,d)`	literal test $S(c - d) = 0$
`coefficient_seminorm_squared(c)`	$\sum_i (Sc)_i^2$
`dual()`	(S^T, A^T)
`transition_to(other)`	exact $A_{\text{other}} S_{\text{self}}$
`direct_sum(other)`	exact block-diagonal system
`tensor_product(other)`	exact Kronecker system
`certificate()`	exact reconstruction, projection, and metric identities

The exact certificate has `Exactness.EXACT`, no floating residuals, and checks

$$SA = I, \qquad P^2 = P, \qquad P^T H = H, \qquad HP = H.$$

20.6.3 Exact map signature and members

```
ExactAnalysisSynthesisMap(
    domain: ExactAnalysisSynthesisSystem,
    codomain: ExactAnalysisSynthesisSystem,
    operator: Matrix,
    theorem: str = "KM-AS-EXACT-MAP-01",
)
```

Its public methods are

Member	Exact contract
`identity(system)`	exact physical identity
`coefficient_lift()`	$A_Y T S_X$
`reconstruct()`	$S_Y \widehat{T} A_X = T$
`apply_coefficients(c)`	exact lifted coefficient action

Member	Exact contract
`then(after)`	`after ∘ self`
`compose(before)`	`self ∘ before`
`adjoint()`	transpose physical map
`dual_adjoint()`	transpose lift on dual systems
`scaled(scalar)`	integer or `Fraction` scaling
`add(other)`	exact sum with identical endpoint objects
`blocks(source_partition, target_partition)`	raw nested exact submatrices
`certificate()`	exact support and reconstruction equalities

The exact coefficient domain is rational and real, so "adjoint" means transpose. There is no complex-conjugation branch.

20.6.4 Exact worked example

```
from fractions import Fraction
from komorebi_math.coordinates import ExactAnalysisSynthesisSystem

exact = ExactAnalysisSynthesisSystem.canonical_dual(
    ((1, 0), (0, 1), (1, 1)),
    source="exact physical",
    coordinates="exact frame",
)

c = (3, -4, 5)
k = (-1, -1, 1)

print(exact.synthesis)
print(exact.canonical_coefficients(c))
print(exact.gauge_part(c))
print(exact.gauge_equivalent(c, tuple(a + b for a, b in zip(c, k))))
print(exact.coefficient_seminorm_squared(k))
```

Output is

```
((Fraction(2, 3), Fraction(-1, 3), Fraction(1, 3)),
 (Fraction(-1, 3), Fraction(2, 3), Fraction(1, 3)))
(Fraction(5, 1), Fraction(-2, 1), Fraction(3, 1))
(Fraction(-2, 1), Fraction(-2, 1), Fraction(2, 1))
True
0
```

The exact coefficient projection is

$$P = \begin{pmatrix} 2/3 & -1/3 & 1/3 \\ -1/3 & 2/3 & 1/3 \\ 1/3 & 1/3 & 2/3 \end{pmatrix}.$$

20.6.5 Deliberate numerical/exact asymmetries

The exact layer is not a method-for-method clone of the stable numerical record.

Available only in the numerical convenience layer	Exact-layer behavior
`square` property	infer from dimensions if needed
`reconstruct(x)` on a system	call `synthesize(analyze(x))`
`reconstruction_certificate(x)`	constructor and certificate already use literal identities
system `component(s)` and `operator_blocks()`	construct exact selectors and products explicitly
`apply_source(x)` on a map	multiply by the public exact `operator`
block record with `assemble()` and `physical_block()`	`ExactAnalysisSynthesisMap.blocks()` returns nested tuples
portable codec	no exact frame-algebra codec is registered

Exact arithmetic removes tolerance ambiguity but does not remove resource growth. Dense inversion, Kronecker products, and repeated composition can produce large numerators and denominators.

20.7 `coordinates.frame_algebra` public method and property reference

20.7.1 API tier and import boundaries

The stable surface contains exactly the original numerical system and physical-block record:

```
from komorebi_math.stable import (
    AnalysisSynthesisBlocks,
    AnalysisSynthesisSystem,
)
```

The same class objects are exported by `komorebi_math.v1` and `komorebi_math.api.v1`. Section 16.11 is their canonical stable implementation page.

The six coefficient-frame additions are research APIs:

```
from komorebi_math.coordinates import (
    AnalysisSynthesisCoefficientBlocks,
    AnalysisSynthesisGauge,
    AnalysisSynthesisMap,
    CoefficientPartition,
    ExactAnalysisSynthesisMap,
    ExactAnalysisSynthesisSystem,
)
```

They are also present at the package root. They are absent from both the stable and beta manifests. Top-level availability must not be described as a 1.x compatibility guarantee.

20.7.2 Complete class and member ledger

Class and constructor signature	Public members
`AnalysisSynthesisSystem(analysis, synthesis, source="source", coordinates="coordinates", tolerance=1e-12, theorem="KM-AS-01")`	`analysis`, `synthesis`, `source`, `coordinates`, `tolerance`, `theorem`, `from_invertible`, `canonical_dual`, `source_dimension`, `coordinate_dimension`, `redundant`, `square`, `frame_operator`, `analyze`, `synthesize`, `reconstruct`, `component`, `components`, `projector`, `projectors`, `operator_blocks`, `certificate`, `reconstruction_certificate`
`AnalysisSynthesisBlocks(system, groups, blocks, operator)`	`system`, `groups`, `blocks`, `operator`, `reconstruct`, `certificate`
`CoefficientPartition(dimension, groups)`	`dimension`, `groups`, `singletons`, `one_block`, `refines`, `coarsens`

Class and constructor signature	Public members
`AnalysisSynthesisGauge(system)`	`system`, `analysis`, `synthesis`, `source`, `coordinates`, `source_dimension`, `coordinate_dimension`, `tolerance`, `coefficient_projection`, `gauge_projection`, `coefficient_metric`, `canonical_coefficients`, `gauge_part`, `gauge_equivalent`, `coefficient_seminorm`, `dual`, `transition_to`, `direct_sum`, `tensor_product`, `certificate`
`AnalysisSynthesisMap(domain, codomain, operator, theorem="KM-AS-MAP-01")`	`domain`, `codomain`, `operator`, `theorem`, `identity`, `tolerance`, `coefficient_lift`, `reconstruct`, `apply_source`, `apply_coefficients`, `then`, `compose`, `transition_bridge`, `adjoint`, `dual_adjoint`, `scaled`, `add`, `blocks`, `certificate`
`AnalysisSynthesisCoefficientBlocks(mapping, source_partition, target_partition)`	`mapping`, `source_partition`, `target_partition`, `blocks`, `assemble`, `reblock`, `physical_block`, `then`, `certificate`

20.7.3 Theorem identifiers

Generated objects use these default provenance labels.

Operation	Identifier
numerical system	`KM-AS-01`
stable physical blocks	`KM-AS-02`
numerical gauge certificate	`KM-AS-GAUGE-01`
gauge dual	`KM-AS-GAUGE-DUAL-01`
gauge direct sum	`KM-AS-GAUGE-SUM-01`
gauge tensor product	`KM-AS-GAUGE-TENSOR-01`
numerical map	`KM-AS-MAP-01`
map identity	`KM-AS-MAP-ID-01`
map composition	`KM-AS-MAP-COMPOSE-01`
physical adjoint	`KM-AS-MAP-ADJOINT-01`
dual adjoint	`KM-AS-MAP-DUAL-ADJOINT-01`
map scaling	`KM-AS-MAP-SCALE-01`
map addition	`KM-AS-MAP-ADD-01`
coefficient blocks	`KM-AS-BLOCK-01`
exact system	`KM-AS-EXACT-01`
exact dual	`KM-AS-EXACT-DUAL-01`
exact direct sum	`KM-AS-EXACT-SUM-01`
exact tensor product	`KM-AS-EXACT-TENSOR-01`
exact map	`KM-AS-EXACT-MAP-01`
exact map composition	`KM-AS-EXACT-MAP-COMPOSE-01`
exact physical adjoint	`KM-AS-EXACT-MAP-ADJOINT-01`
exact dual adjoint	`KM-AS-EXACT-MAP-DUAL-ADJOINT-01`
exact map scaling	`KM-AS-EXACT-MAP-SCALE-01`
exact map addition	`KM-AS-EXACT-MAP-ADD-01`

The theorem field is provenance metadata attached to certificates. It is not a lookup into a separate theorem database.

20.7.4 Persistence contract

Only `AnalysisSynthesisSystem` has a registered frame-algebra codec.

Property	Value
tag	`coordinates.analysis_synthesis`
version	1
stable portable contract	yes
separately portable blocks, gauges, maps, partitions, exact systems	no

The payload data contains exactly

```
analysis
synthesis
source
coordinates
tolerance
theorem
```

The decoder rejects missing or extra fields, reconstructs the system, and immediately calls `certificate().require()`. A portable payload cannot silently load an invalid left inverse.

```
from komorebi_math.stable import dumps_portable, loads_portable

text = dumps_portable(system)
restored = loads_portable(text)

restored.certificate().require()
print(type(restored).__name__)
print(np.allclose(restored.reconstruct(x), x))
```

Output is

```
AnalysisSynthesisSystem
True
```

The envelope SHA-256 protects against accidental or untrusted payload changes only when the digest itself has not also been replaced. It is not a digital signature or message-authentication code.

20.7.5 Dense complexity and storage

Let one presentation have source dimension n, coefficient dimension m, and p coordinate groups. These costs describe the current dense implementation, not asymptotically optimized mathematical alternatives.

Operation	Approximate dense arithmetic	Principal storage
construct numerical system	$O(mn)$	$O(mn)$
square inverse	$O(n^3)$	$O(n^2)$
canonical dual, $m \geq n$	$O(mn^2)$	$O(mn + n^2)$
analyze or synthesize	$O(mn)$	output vector
source reconstruction operator	$O(mn^2)$	$O(n^2)$
system certificate with rank work	$O(mn^2)$	$O(mn)$
current dense `component()`	$O(nm^2 + n^2m)$	dense selector plus $n \times n$ result
$p \times p$ physical block grid	approximately $O(p^2n^3)$, plus components	$O(p^2n^2)$
coefficient projection or metric	$O(m^2n)$	$O(m^2)$

Operation	Approximate dense arithmetic	Principal storage
full gauge certificate	$O(m^3)$ dominant	$O(m^2)$
transition $m_X \to m_Y$	$O(m_Y n m_X)$	$O(m_Y m_X)$
lift $A_Y T S_X$	$O(m_Y n_Y n_X + m_Y n_X m_X)$	$O(m_Y m_X)$
reconstruct a lift	$O(n_Y m_Y m_X + n_Y m_X n_X)$	physical matrix
extract coefficient blocks	$O(m_Y m_X)$ copying	$O(m_Y m_X)$
direct sum	output-sized	dimensions add
tensor product	output-sized	dimensions multiply

The current `component()` implementation materializes a dense $m \times m$ selector. Users handling large m should account for that implementation cost rather than assuming a sparse diagonal selector.

Exact operations have the same algebraic operation counts but not constant scalar cost. Numerator and denominator bit lengths can grow under inversion, Kronecker product, and repeated composition.

20.7.6 Failure boundaries

These are controlled rejection boundaries or explicit semantic limits.

Boundary	Result
nonmatrix, empty, or nonfinite numerical data	`DimensionError` or `ValidationError`
incompatible synthesis shape	`DimensionError`
blank labels	`ValidationError`
nonpositive or nonfinite tolerance	`ValidationError`
nonsquare `from_invertible` input	`DimensionError`
singular square inverse	`ValidationError`
rank-deficient canonical-dual input	`ValidationError`
wrong vector length or nonfinite vector	`DimensionError` or `ValidationError`
missing, overlapping, duplicate, empty, or out-of-range groups	`ValidationError`
wrong source-operator shape	`DimensionError`
gauge or map endpoint with failed system certificate	construction fails through `Certificate.require()`
incompatible physical composition labels or dimensions	`ValidationError`
map addition with merely equivalent rather than identical endpoint objects	`ValidationError`
malformed strict coefficient partition	`ValidationError` or `DimensionError`
Boolean, float, or complex exact scalar	`ValidationError`
exact $SA \neq I$	construction-time `ValidationError`
exact transition between differently named physical sources	`ValidationError`
arbitrary callable or class persistence	unsupported. Codecs reconstruct only registered data objects

Component grouping performs historical integer coercion before validating the partition. This should not be used as permission to pass floats or strings. New code should use integer indices, and research coefficient partitions enforce that rule strictly.

`physical_block(target_index, source_index)` is intended for nonnegative valid block indices. The implementation currently inherits Python negative tuple indexing. That incidental behavior is not a documented compatibility promise.

Numerical linear algebra can also propagate a backend `LinAlgError` if an SVD itself fails. Certificates establish the listed finite residual laws only. They do not certify conditioning beyond the declared rank threshold or prove stability of an unbounded sequence of operations.

20.7.7 Verification and executable anchors

The canonical installed check is

```
python -m komorebi_math verify frame-algebra
```

It executes six checks:

1. oblique coefficient gauge
2. coefficient-map closure
3. cross-presentation bridge
4. ordinary coefficient-block multiplication
5. exact rational coefficient closure
6. consistent canonical-dual threshold

Expected final line is

```
verification passed 6/6 checks
```

The focused source replay is

```
python -m pytest -q tests/test_block16_analysis_synthesis.py tests/test_block16_contracts.py
    ↪ tests/test_block18_frame_algebra.py
```

The current chapter audit obtains

```
31 passed
```

The shipped stable worked example is

```
python examples/block16_analysis_synthesis.py
```

It validates the redundant canonical dual, reconstructs `[3, -2]`, certifies grouped physical operator blocks, and roundtrips the numerical system through the portable codec. Its floating operator-block residual is typically near machine precision and must be compared with the tolerance rather than frozen to one platform-specific decimal.

The independent source anchors for this chapter are

```
src/komorebi_math/coordinates/analysis_synthesis.py
src/komorebi_math/coordinates/frame_algebra.py
src/komorebi_math/coordinates/portable.py
src/komorebi_math/verify/frame_algebra.py
tests/test_block16_analysis_synthesis.py
tests/test_block16_contracts.py
tests/test_block18_frame_algebra.py
docs/ANALYSIS_SYNTHESIS_SYSTEMS.md
docs/REDUNDANT_FRAME_ALGEBRA.md
```

Chapter 20 summary. A valid presentation satisfies $SA = I$, but its redundant coefficient identity is the projection $P = AS$. Physical components always add to identity and need not themselves be projectors. Coefficient vectors are therefore gauge classes, physical maps lift to sandwiched coefficient matrices, and mismatched presentations compose through bridges. Small coefficient blocks recover ordinary block multiplication. The rational mirror turns every finite identity into literal equality.

Part V. Generating functions, arithmetic, sequences, and analytic packets

Reading route. Choose a representation before choosing an algorithm. This part offers several ways to describe related data, with different coefficient, index, and arithmetic conventions.

You want to work with	Start here	First decision
A finite coefficient tuple	Chapter 21	Ordinary or normalized coefficients, and which scalar domain
A rule that produces coefficient prefixes	Chapter 22	A declared provider or a candidate inferred from samples
A mask or digit transition system	Chapter 23	Radix, digit order, and the required finite range
Prime-power residues or modular support	Chapter 24	Prime, exponent, and affordable compiler-table size
Local arithmetic coordinates or recurrence packets	Chapter 25	The information retained by the modulus or precision
A catalog sequence or a custom term evaluator	Chapter 26	Prefix, single index, or modular evaluation
Cyclic analytic coefficients or zero diagnostics	Chapter 27	Exact coefficient work or numerical evaluation

Start with a small prefix whose entries you can inspect. Keep the normalization, scalar domain, and finite range with the resulting values. The same tuple can represent different series under different normalizations. Likewise, residue classes of *indices* and residues of *values* answer different questions. Chapter 23's carry and Cartier machines read digits least significant first, while Chapter 26's automatic sequences read them most significant first. Use each producer's documented digit convention when connecting the two subjects.

21. Formal series and weighted bases

Before computing. Decide which tuple you have, which normalization gives it meaning, and which domain allows the required divisions. The rational workflow in Section 21.5.1 is a useful starting point. Use the record comparison in Section 21.4 to choose between the stable rational interface and the explicit-domain interface. Set the desired output degree before a composition or product so the finite result has the intended range.

Komorebi Math represents a truncated generating function by separating three choices that are often conflated:

1. the ordinary coefficient of z^n
2. the normalization used to store that coefficient
3. the exact domain in which arithmetic is performed

This separation is the foundation for the generating-function subsystem. It lets the same finite formal object move between ordinary, exponential, factorial-power, q-factorial, Fibonacci-factorial, Pochhammer, and custom normalizations without changing the underlying polynomial. It also lets a domain-aware series state whether division takes place in $\mathbb{Z}$, $\mathbb{Q}$, a residue ring, a prime field, or a truncated p-adic ring.

The implementation is finite and coefficient based. It does not construct an infinite series object, prove analytic convergence, select a branch of an analytic continuation, or infer a radius of convergence. Numerical evaluation is an explicit final operation on a finite exact truncation.

21.0 API tier and import surface

Surface	Chapter 21 names	Contract
`komorebi_math.stable`	`FormalSeries`, `factorial_power_basis`, `ordinary_generating_basis`	frozen stable surface
`komorebi_math.beta`	no Chapter 21 names	curated beta surface does not include this subsystem
`komorebi_math`	`FormalSeries`, `FiniteNormalizedSeries`, `WeightedMonomialBasis`, `GeneratingBudget`, `ordinary_basis`, `factorial_power_basis`	selected top-level research exports
`komorebi_math.generating`	complete basis, domain, record, certificate, and codec API	domain research surface

The stable namespace renames the ordinary generating basis to `ordinary_generating_basis` so it cannot be confused with coordinate-basis constructors in other subsystems:

```
from komorebi_math.stable import (
    FormalSeries,
    factorial_power_basis,
    ordinary_generating_basis,
)
```

Use the complete research namespace for the explicit domain layer:

```
from komorebi_math.generating import (
    FiniteNormalizedSeries,
    FormalSeries,
    GeneratingBudget,
    PrimeFieldDomain,
    RationalDomain,
    WeightedMonomialBasis,
    exponential_basis,
    factorial_power_basis,
    ordinary_basis,
)
```

21.1 Coefficient domains and exact arithmetic

`FormalSeries` always stores Python `Fraction` values. Its domain is therefore implicitly $\mathbb{Q}$. `FiniteNormalizedSeries` makes the domain an explicit object satisfying `CoefficientDomain`.

For a domain R, the required arithmetic is

$$(R, 0, 1, +, -, \cdot),$$

together with coercion, equality, unit testing, inversion of units, and a closed data-only descriptor. A residue ring is permitted to contain nonunits. The protocol does not pretend that every nonzero element is invertible.

21.1.1 Domain constructors

```
IntegerDomain(
    name: str = "integers",
    zero: int = 0,
    one: int = 1,
)

RationalDomain(
    name: str = "rationals",
    zero: Fraction = Fraction(0, 1),
    one: Fraction = Fraction(1, 1),
)

ResidueRingDomain(
    modulus: int,
    name: str = "residue_ring",
)

PrimeFieldDomain(
    modulus: int,
    name: str = "prime_field",
)

TruncatedPadicDomain(
    prime: int,
    precision: int,
)

domain_from_descriptor(payload: Any) -> CoefficientDomain[Any]
```

`PrimeFieldDomain` names its constructor argument `modulus`, while its validated public property is `prime`. For `TruncatedPadicDomain(p, r)`, the stored modulus is p^r.

Domain	Elements	Units	Descriptor
`IntegerDomain()`	arbitrary integers	$1, -1$	`{"kind": "integers"}`
`RationalDomain()`	exact `Fraction` values	every nonzero value	`{"kind": "rationals"}`
`ResidueRingDomain(M)`	canonical residues modulo M	residues coprime to M	`{"kind": "residue_ring", "modulus": M}`
`PrimeFieldDomain(p)`	canonical residues modulo prime p	every nonzero residue	`{"kind": "prime_field", "prime": p}`
`TruncatedPadicDomain(p, r)`	canonical residues modulo p^r	residues not divisible by p	`{"kind": "truncated_padic", "prime": p, "precision": r}`

Every built-in domain provides these members:

Member	Exact contract
`.zero`, `.one`, `.name`	canonical identities and display name
`.coerce(value)`	normalize a supported input into the domain
`.add(left, right)`	exact domain sum
`.subtract(left, right)`	exact domain difference
`.multiply(left, right)`	exact domain product
`.is_unit(value)`	test whether `.inverse` is defined
`.inverse(value)`	exact inverse or `ValidationError`
`.equal(left, right)`	equality after coercion
`.encode(value)`, `.decode(payload)`	data-only element representation
`.descriptor()`	closed domain description

`TruncatedPadicDomain` additionally provides

```
valuation(value: int) -> int | float
```

and returns positive infinity for the zero residue.

21.1.2 Exact domain example

```
from fractions import Fraction

from komorebi_math.generating import (
    IntegerDomain,
    PrimeFieldDomain,
    RationalDomain,
    ResidueRingDomain,
    TruncatedPadicDomain,
)

integers = IntegerDomain()
rationals = RationalDomain()
residues = ResidueRingDomain(12)
field = PrimeFieldDomain(7)
padic = TruncatedPadicDomain(3, 4)

print(integers.multiply(6, -7))
print(rationals.inverse(Fraction(3, 5)))
print(residues.multiply(7, 5))
print(field.inverse(3))
print(padic.modulus, padic.valuation(27), padic.valuation(0))
```

Output:

```
-42
5/3
11
5
81 3 inf
```

Coercing a Python float into a rational domain preserves the exact binary floating-point value. Use integers, strings accepted by `Fraction`, or explicit `Fraction` objects when a small intended rational denominator matters.

21.2 `WeightedMonomialBasis`

Let $\gamma_0 = 1$ and require $\gamma_n \neq 0$ for every degree that will be used. The normalized basis elements are

$$e_n(z) = \frac{z^n}{\gamma_n}.$$

Equivalently, put $w_n = \gamma_n^{-1}$. Then the same normalized series can be written as:

$$F(z) = \sum_{n \geq 0} a_n w_n z^n.$$

The stored value is a_n, not the ordinary monomial coefficient. The ordinary coefficient is $a_n w_n = a_n / \gamma_n$.

For example, in the exponential basis the stored value at degree two is twice the ordinary quadratic coefficient. The ordinary basis leaves that coefficient unchanged. When comparing outputs from two providers, first compare their ordinary coefficients or explicitly convert them to the same basis.

21.2.1 Constructor and members

```
WeightedMonomialBasis(
    name: str,
    gamma: Callable[[int], int | Fraction],
    *,
    descriptor: BasisDescriptor | None = None,
)
```

Member	Signature or value	Meaning
`.name`	`str`	human-facing basis label
`.descriptor`	`BasisDescriptor | None`	closed portable description, when available
`.portable`	`bool`	whether a descriptor exists
`.gamma(n)`	`(n: int) -> Fraction`	exact γ_n, cached by degree
`.lowering_weight(n)`	`(n: int) -> Fraction`	γ_n / γ_{n-1} for $n \geq 1$
`.structure_constant(n, k)`	`(n: int, k: int) -> Fraction`	$\gamma_n / (\gamma_k \gamma_{n-k})$
`.packet_transfer_weight(...)`	`(modulus: int, residue: int, packet_index: int, target_basis: WeightedMonomialBasis) -> Fraction`	residue-packet normalization ratio
`.semantically_equivalent(other)`	`(other: WeightedMonomialBasis) -> bool`	descriptor equality, or identity for callback bases
`.equivalent_through(other, degree)`	`(other: WeightedMonomialBasis, degree: int) -> bool`	exact finite table comparison
`.finite_certificate(degree)`	`(degree: int) -> BasisCertificate`	finite nonzero and integrality audit
`.require_descriptor()`	`() -> BasisDescriptor`	descriptor or `ValueError` for a live callback

Member	Signature or value	Meaning

The exact product structure constant is

$$C(n,k) = \frac{\gamma_n}{\gamma_k \gamma_{n-k}}.$$

The custom lowering operator is specified on monomials by

$$D_\gamma z^n = \frac{\gamma_n}{\gamma_{n-1}} z^{n-1}, \qquad D_\gamma e_n = e_{n-1}.$$

`BasisCertificate` is the frozen record

```
BasisCertificate(
    name: str,
    degree: int,
    nonzero_normalization: bool,
    integral_structure_constants: bool,
    maximum_denominator: int,
    maximum_numerator_bits: int,
)
```

It is a finite diagnostic through the requested degree. It is not a theorem about all n.

21.2.2 Descriptor model

```
BasisDescriptor(
    name: str,
    kind: str,
    parameters: tuple[tuple[str, BasisParameter], ...] = (),
)

BasisDescriptor.create(
    name: str,
    kind: str,
    parameters: Mapping[str, BasisParameter] | None = None,
) -> BasisDescriptor

basis_from_descriptor(
    descriptor: BasisDescriptor,
) -> WeightedMonomialBasis
```

Descriptor parameter keys are sorted canonically and must be unique. The decoder accepts only the built-in closed kinds listed in Section 21.3. It does not import a callback by module path or execute source text from a file.

21.3 Ordinary, exponential, and factorial-power bases

The research namespace provides seven constructors:

```
ordinary_basis(
    *, name: str = "ordinary",
) -> WeightedMonomialBasis

exponential_basis(
    *, name: str = "exponential",
) -> WeightedMonomialBasis

factorial_power_basis(
    power: int,
    *, name: str | None = None,
) -> WeightedMonomialBasis

q_factorial_basis(
    q: int,
    *, name: str | None = None,
) -> WeightedMonomialBasis

fibonacci_factorial_basis(
    *, name: str = "fibonacci-factorial",
) -> WeightedMonomialBasis

pochhammer_basis(
    alpha: int | Fraction,
    *, name: str | None = None,
) -> WeightedMonomialBasis

basis_from_values(
    name: str,
    values: Iterable[int | Fraction],
) -> WeightedMonomialBasis
```

Constructor	γ_n	Basis element $e_n(z)$	Required parameter
`ordinary_basis()`	1	z^n	none
`exponential_basis()`	$n!$	$z^n/n!$	none
`factorial_power_basis(s)`	$(n!)^s$	$z^n/(n!)^s$	integer $s \geq 1$
`q_factorial_basis(q)`	$[n]_q!$	$z^n/[n]_q!$	integer $q \geq 1$
`fibonacci_factorial_basis()`	$\prod_{j=1}^{n} F_j$	$z^n/\prod_{j=1}^{n} F_j$	none
`pochhammer_basis(alpha)`	$(\alpha)_n$	$z^n/(\alpha)_n$	rational α not a nonpositive integer
`basis_from_values(name, table)`	supplied table entry	z^n/γ_n	finite nonzero table beginning with one

Here the q-factorial convention is

$$[j]_q = \frac{q^j - 1}{q - 1}, \qquad [n]_q! = \prod_{j=1}^{n} [j]_q,$$

with the $q = 1$ branch defined as $n!$. Every constructor in the table returns a descriptor-backed portable basis.

21.3.1 Normalization and integrality example

```
from komorebi_math.generating import factorial_power_basis

basis = factorial_power_basis(2)
audit = basis.finite_certificate(8)

print(tuple(str(basis.gamma(n)) for n in range(5)))
print(basis.structure_constant(5, 2))
print(audit.integral_structure_constants)
```

Output:

```
('1', '1', '4', '36', '576')
100
True
```

For a factorial-power basis,

$$C(n,k) = \binom{n}{k}^{s}.$$

This identity is why a same-basis divided-power product can remain meaningful in characteristic p, even when individual factorial normalizations are not invertible modulo p.

21.3.2 Live callback and finite-table boundary

A callback basis is valid for live finite computation:

```
from komorebi_math.generating import WeightedMonomialBasis

live = WeightedMonomialBasis("linear", lambda n: n + 1)
print(live.portable)
```

Output:

```
False
```

The basis itself cannot be serialized because its callback has no trusted data-only meaning. A `FormalSeries` that uses it can be serialized. The codec captures the finite normalization table only through the series degree. After loading, asking the restored basis for a higher degree raises `IndexError`.

`basis_from_values` has the same finite boundary by construction. It does not extrapolate a missing rule from a normalization prefix.

21.4 `FormalSeries` and finite series records

The package has two related records. Select them by arithmetic contract, not by name similarity.

Record	Coefficient domain	Mutability	Budget	Best use
`FormalSeries`	implicit $\mathbb{Q}$ through `Fraction`	public attributes are mutable	none	stable exact rational series API
`FiniteNormalizedSeries`	explicit `CoefficientDomain`	frozen dataclass	explicit `GeneratingBudget`	modular, field, p-adic, and resource-bounded work

Both are finite. An input iterable of length $d+1$ represents degrees zero through d. An empty iterable becomes the zero series of degree zero.

21.4.1 `FormalSeries` constructor and members

```
FormalSeries(
    basis: WeightedMonomialBasis,
    coefficients: Iterable[int | Fraction],
)
```

Member	Signature	Result
`.degree`	property	`len(coefficients) - 1`
`.truncate(degree)`	`(degree: int) -> FormalSeries`	cut or zero-pad through `degree`
`.ordinary_coefficients(degree=None)`	exact tuple	a_n/γ_n
`.from_ordinary_coefficients(basis, coefficients)`	class method	multiply ordinary coefficient c_n by γ_n
`.convert(basis)`	`(basis) -> FormalSeries`	same finite polynomial in a new normalization
`.add`, `.subtract`, `.scale`	exact finite arithmetic	normalized coefficients
`.multiply`, `.hadamard`	Cauchy or coefficientwise product	`FormalSeries`
`.ordinary_derivative`, `.ordinary_integral`	ordinary calculus	`FormalSeries` in the same basis
`.custom_lower()`	coefficient shift	$D_\gamma F$
`.reciprocal`, `.compose`, `.exp`, `.log`, `.power`	exact truncated formal operations	`FormalSeries`
`.project`, `.packet`, `.packet_identity`	residue-lane operations	series or `PacketIdentity`
`.evaluate(z)`	`(z: complex) -> complex`	numerical evaluation of the finite ordinary polynomial

Operators `+`, `-`, `*`, scalar multiplication, and integer `**` delegate to the named methods. `series[n]` returns the stored normalized coefficient.

The exact named-method signatures are:

```
truncate(degree: int) -> FormalSeries
ordinary_coefficients(degree: int | None = None) -> tuple[Fraction, ...]
from_ordinary_coefficients(
    basis: WeightedMonomialBasis,
    coefficients: Iterable[int | Fraction],
) -> FormalSeries
convert(basis: WeightedMonomialBasis) -> FormalSeries
add(other: FormalSeries, *, degree: int | None = None) -> FormalSeries
subtract(other: FormalSeries, *, degree: int | None = None) -> FormalSeries
scale(scalar: int | Fraction) -> FormalSeries
multiply(other: FormalSeries, *, degree: int | None = None) -> FormalSeries
hadamard(other: FormalSeries, *, degree: int | None = None) -> FormalSeries
ordinary_derivative() -> FormalSeries
ordinary_integral(constant: int | Fraction = 0) -> FormalSeries
custom_lower() -> FormalSeries
reciprocal(*, degree: int | None = None) -> FormalSeries
compose(inner: FormalSeries, *, degree: int | None = None) -> FormalSeries
exp(*, degree: int | None = None) -> FormalSeries
log(*, degree: int | None = None) -> FormalSeries
power(exponent: int, *, degree: int | None = None) -> FormalSeries
project(modulus: int, residue: int) -> FormalSeries
packet(
```

```
    modulus: int,
    residue: int,
    *,
    target_basis: WeightedMonomialBasis,
) -> FormalSeries
packet_identity(
    modulus: int,
    residue: int,
    *,
    target_basis: WeightedMonomialBasis,
) -> PacketIdentity
evaluate(z: complex) -> complex
```

`PacketIdentity` records the modulus, residue, source and target basis names, source and packet degrees, and an exact Boolean `valid` field. The packet system is developed in Chapter 23.

21.4.2 `FiniteNormalizedSeries` constructor and members

```
FiniteNormalizedSeries(
    basis: WeightedMonomialBasis,
    domain: CoefficientDomain[Any],
    coefficients: Iterable[Any],
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
)
```

Member	Signature	Result
`.degree`	property	largest represented degree
`.coefficient(index)`	`(index: int) -> Any`	stored value, or domain zero beyond the degree
`.truncate(degree)`	exact cut or zero padding	`FiniteNormalizedSeries`
`.ordinary_coefficients()`	no degree argument	coefficients after division by γ_n in the domain
`.from_ordinary_coefficients(...)`	class method with basis, domain, coefficients, and optional budget	normalized record
`.convert(target_basis)`	returns `(series, SeriesTransferCertificate)`	verified finite basis transfer
`.add`, `.subtract`, `.scale`, `.multiply`	exact domain arithmetic	budget-preserving record
`.reciprocal`, `.compose`, `.exp`, `.log`	formal operations with unit checks	budget-preserving record
`.project(modulus, residue)`	retain one residue lane	record in the same basis and domain
`.custom_lower()`	shift normalized coefficients	record in the same basis and domain
`.certificate()`	`Certificate`	exact construction certificate

`FiniteNormalizedSeries` intentionally has no numerical `.evaluate`, ordinary derivative or integral helper, Hadamard product, packet extraction, or general integer power method in `1.0.0b4`. Convert to a supported representation or compose the available primitives explicitly rather than assuming parity with `FormalSeries`.

Its exact named-method signatures are:

```
coefficient(index: int) -> Any
truncate(degree: int) -> FiniteNormalizedSeries
ordinary_coefficients() -> tuple[Any, ...]
from_ordinary_coefficients(
    basis: WeightedMonomialBasis,
    domain: CoefficientDomain[Any],
```

```
    coefficients: Iterable[Any],
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> FiniteNormalizedSeries
convert(
    target_basis: WeightedMonomialBasis,
) -> tuple[FiniteNormalizedSeries, SeriesTransferCertificate]
add(
    other: FiniteNormalizedSeries,
    *,
    degree: int | None = None,
) -> FiniteNormalizedSeries
subtract(
    other: FiniteNormalizedSeries,
    *,
    degree: int | None = None,
) -> FiniteNormalizedSeries
scale(scalar: Any) -> FiniteNormalizedSeries
multiply(
    other: FiniteNormalizedSeries,
    *,
    degree: int | None = None,
) -> FiniteNormalizedSeries
reciprocal(*, degree: int | None = None) -> FiniteNormalizedSeries
compose(
    inner: FiniteNormalizedSeries,
    *,
    degree: int | None = None,
) -> FiniteNormalizedSeries
exp(*, degree: int | None = None) -> FiniteNormalizedSeries
log(*, degree: int | None = None) -> FiniteNormalizedSeries
project(modulus: int, residue: int) -> FiniteNormalizedSeries
custom_lower() -> FiniteNormalizedSeries
certificate() -> Certificate
```

21.4.3 Transfer certificate

```
SeriesTransferCertificate(
    valid: bool,
    degree: int,
    source_basis: str,
    target_basis: str,
    domain: str,
    failures: tuple[int, ...] = (),
)
```

`.require()` raises `ValidationError` when `valid` is false. `.certificate()` lifts the record into the common theorem-bearing `Certificate` format under theorem identifier `NGF.UNIVERSAL_PRODUCT_AND_TRANSFER`.

For a transfer from normalization γ to η,

$$b_n = a_n \frac{\eta_n}{\gamma_n}.$$

The domain-aware implementation also checks the reverse ratio. If a ratio cannot be coerced because its denominator is a nonunit, conversion raises `ValidationError` before it can return a certificate.

21.4.4 Persistence

Import the general portable helpers from `komorebi_math.export` or their stable counterparts:

```
dumps_portable(
    value: Any,
    *,
    indent: int | None = 2,
    max_depth: int = 128,
) -> str

loads_portable(
    text: str | bytes,
    *,
    max_depth: int = 128,
) -> Any

save_portable(
    value: Any,
    path: str | os.PathLike[str],
    *,
    overwrite: bool = False,
    indent: int | None = 2,
    max_depth: int = 128,
) -> Path

load_portable(
    path: str | os.PathLike[str],
    *,
    max_depth: int = 128,
) -> Any
```

Object	Codec tag	Version	Persistence note
`BasisDescriptor`	`generating.basis_descriptor`	1	closed descriptor
`WeightedMonomialBasis`	`generating.weighted_monomial_basis`	1	requires a descriptor
`GeneratingBudget`	`generating.budget`	1	all eight limits retained
`FormalSeries`	`generating.formal_series`	1	callback basis becomes a finite table descriptor
`FiniteNormalizedSeries`	`generating.finite_normalized_series`	1	embeds basis, domain descriptor, coefficients, and budget

Domain objects do not have independent portable codecs in `1.0.0b4`. Their descriptors are persisted inside `FiniteNormalizedSeries`. Calling `dumps_portable(RationalDomain())` directly raises `ValidationError`.

```
from komorebi_math.export import dumps_portable, loads_portable
from komorebi_math.generating import (
    FiniteNormalizedSeries,
    RationalDomain,
    factorial_power_basis,
)

source = FiniteNormalizedSeries(
    factorial_power_basis(2),
    RationalDomain(),
    (1, 2, -3, 5),
```

```
)
restored = loads_portable(dumps_portable(source))

assert restored == source
print(restored.domain.descriptor())
print(restored.budget == source.budget)
```

Output:

```
{'kind': 'rationals'}
True
```

The portable envelope is canonical data with a payload digest. It does not execute arbitrary class names or callback imports while decoding.

21.5 Basis conversion, multiplication, differentiation, and composition

Let

$$F(z) = \sum_{n=0}^{d} a_n e_n(z), \qquad G(z) = \sum_{n=0}^{e} b_n e_n(z).$$

Addition is coefficientwise after basis conversion. Multiplication uses the weighted Cauchy law

$$[FG]_n = \sum_{k=0}^{n} \frac{\gamma_n}{\gamma_k \gamma_{n-k}} a_k b_{n-k}.$$

The ordinary derivative and integral, expressed back in the same normalized basis, are

$$[F']_n = (n+1)\frac{\gamma_n}{\gamma_{n+1}} a_{n+1},$$

and

$$\left[\int F(z)\,dz\right]_{n+1} = a_n \frac{\gamma_{n+1}}{(n+1)\gamma_n}.$$

The custom lowering operator is different from the ordinary derivative unless $\gamma_n = n!$:

$$[D_\gamma F]_n = a_{n+1}.$$

21.5.1 Exact rational workflow

```
from fractions import Fraction

from komorebi_math.generating import (
    FormalSeries,
    exponential_basis,
    factorial_power_basis,
    ordinary_basis,
)

basis = factorial_power_basis(2)
f = FormalSeries(basis, (1, 2, 3))
g = FormalSeries.from_ordinary_coefficients(basis, (0, 1, 1))

product = f.multiply(g, degree=4)
converted = f.convert(exponential_basis())
derivative = f.ordinary_derivative()
integral = f.ordinary_integral(Fraction(1, 2))
```

```
outer = FormalSeries(ordinary_basis(), (1, 2, 3))
inner = FormalSeries(ordinary_basis(), (0, 1, 1))
composed = outer.compose(inner, degree=4)

print(tuple(map(str, f.ordinary_coefficients())))
print(tuple(map(str, product.coefficients)))
print(tuple(map(str, converted.coefficients)))
print(tuple(map(str, derivative.coefficients)))
print(tuple(map(str, integral.coefficients)))
print(tuple(map(str, composed.coefficients)))
```

Output:

```
('1', '2', '3/4')
('0', '1', '12', '99', '432')
('1', '2', '3/2')
('2', '3/2')
('1/2', '1', '4', '9')
('1', '2', '5', '6', '3')
```

The conversion changes stored coordinates but preserves ordinary coefficients:

$$(1, 2, 3)_{(n!)^2} \longmapsto \left(1, 2, \frac{3}{2}\right)_{n!}.$$

Both represent $1 + 2z + \frac{3}{4}z^2$.

21.5.2 Formal reciprocal, exponential, logarithm, and power

For a requested degree D:

- `reciprocal(degree=D)` requires a nonzero constant coefficient in `FormalSeries`, or a unit constant in `FiniteNormalizedSeries`.
- `compose(inner, degree=D)` requires the inner ordinary constant coefficient to be zero.
- `exp(degree=D)` requires ordinary constant coefficient zero.
- `log(degree=D)` requires ordinary constant coefficient one.
- `FormalSeries.power(exponent, degree=D)` accepts an integer exponent. Negative exponents first form the reciprocal.

These are formal identities through a finite degree. No analytic branch of the complex logarithm or exponential is selected.

21.5.3 Positive-characteristic product

```
from komorebi_math.generating import (
    FiniteNormalizedSeries,
    PrimeFieldDomain,
    exponential_basis,
)

field = PrimeFieldDomain(5)
basis = exponential_basis()
left = FiniteNormalizedSeries(basis, field, (1, 2, 3, 4, 0, 1))
right = FiniteNormalizedSeries(basis, field, (2, 1, 0, 3, 2, 4))
product = left.multiply(right, degree=5)

product.certificate().require()
print(product.coefficients)
```

Output:

```
(2, 0, 0, 0, 2, 1)
```

The product uses binomial structure constants and does not divide by $n!$. Calling `.ordinary_coefficients()` at or beyond degree p, however, tries to divide by $p!$ in $\mathbb{F}_p$ and correctly raises `ValidationError`. Formal `exp` and `log` similarly require every integer divisor used by the recurrence to be a unit in the selected domain.

21.5.4 Resource contract

```
GeneratingBudget(
    maximum_degree: int = 100_000,
    maximum_coefficient_bits: int = 4_000_000,
    maximum_matrix_dimension: int = 4_096,
    maximum_reachable_states: int = 100_000,
    maximum_local_combinations: int = 1_000_000,
    maximum_modulus: int = 2_000_000,
    maximum_serialized_bytes: int = 67_108_864,
    maximum_recursion_depth: int = 1_000,
)
```

`FiniteNormalizedSeries` enforces `maximum_degree` and `maximum_coefficient_bits` during construction and preserves the same budget through its operations. The other fields are shared with later generating compilers. `FormalSeries` has no budget parameter.

Two limits must be understood precisely:

1. coefficient size is checked on the completed series record, so exact intermediate arithmetic may already have occurred before an oversized result is rejected
2. `maximum_serialized_bytes` is not consulted by the generic portable dump helpers in `1.0.0b4`

Choose a small explicit truncation degree before multiplication, composition, or exact rational exponentiation. A budget is a guard, not a prediction of wall-clock time.

21.5.5 Complexity and storage

Let D be the requested maximum degree. Counts below describe scalar domain operations and omit exact-integer bit complexity, which can dominate.

Operation	Current implementation scale	Stored result
construct, convert, add, subtract, Hadamard, derivative, integral, lower, project	$O(D)$	$O(D)$
basis finite certificate	$O(D^2)$ structure-constant checks	$O(D)$ cached normalizations plus one record
Cauchy multiplication	$O(D^2)$	$O(D)$
reciprocal	$O(D^2)$	$O(D)$
exponential or logarithm	$O(D^2)$	$O(D)$
integer power	$O(D^2 \log \lvert s \rvert)$ for exponent s	$O(D)$
current formal composition	$O(D^3)$	$O(D)$
residue packet or projection	$O(D)$	$O(D)$
portable save or load	linear in encoded coefficient and descriptor payload	linear in payload

The algorithms are dense finite coefficient algorithms. They do not use FFT multiplication, Newton iteration, relaxed power-series evaluation, sparse support, or GPU kernels.

21.5.6 Failure and edge table

Boundary	Behavior in `1.0.0b4`
empty coefficient iterable	canonical zero series of degree zero
negative or Boolean truncation degree	`ValueError` or `ValidationError`
basis normalization is zero at a requested degree	`ZeroDivisionError`
factorial power is not a positive integer	`ValueError`
q is not a positive integer	`ValueError`
Pochhammer α is a nonpositive integer	`ValueError`
finite normalization table is empty, does not begin with one, or contains zero	`ValueError`
finite-table basis queried beyond its table	`IndexError`
reciprocal constant is zero or a domain nonunit	`ZeroDivisionError` or `ValidationError`
composition inner constant is nonzero	`ValueError` or `ValidationError`
formal exponential constant is nonzero	`ValueError` or `ValidationError`
formal logarithm constant is not one	`ValueError` or `ValidationError`
two finite series have different domain descriptors	`ValidationError`
basis-transfer ratio has a nonunit denominator in the selected domain	`ValidationError`
degree or coefficient bits exceed a declared budget	`ResourceLimitError`
callback basis serialized by itself	`ValueError`
coefficient domain serialized by itself	`ValidationError`

There are three source-level limits worth calling out rather than hiding:

- `FormalSeries.compose(inner)` uses `inner.degree` as its default output bound. For an outer series of higher degree, even composition with $inner(z) = z$ drops the outer tail. Pass `degree=` explicitly whenever the desired bound is not exactly the inner degree. The domain-aware `FiniteNormalizedSeries.compose` instead defaults to the maximum of the two input degrees.
- `FormalSeries` and `WeightedMonomialBasis` are not frozen records. Their public attributes can be rebound after construction and thereby bypass the constructor's invariants. Treat constructed instances as read-only.
- The runtime-checkable `CoefficientDomain` protocol verifies member shape, not algebraic laws. The five built-in domains provide the tested contract. A custom domain is the caller's responsibility and has no automatic portable decoder.

The composition boundary is directly observable:

```
from komorebi_math.generating import FormalSeries, ordinary_basis

outer = FormalSeries(ordinary_basis(), (1, 2, 3, 4, 5))
z = FormalSeries(ordinary_basis(), (0, 1))

print(outer.compose(z).coefficients)
print(outer.compose(z, degree=4).coefficients)
```

Output:

```
(Fraction(1, 1), Fraction(2, 1))
(Fraction(1, 1), Fraction(2, 1), Fraction(3, 1), Fraction(4, 1), Fraction(5, 1))
```

21.5.7 What the shipped tests establish

A recorded formal-series replay covered the basis, rational-series, domain, positive-characteristic, budget, persistence, and stable-surface paths:

```
tests/test_generating_domains.py
15 passed

selected tests from tests/test_generating_foundation.py
12 passed, 56 deselected

tests/test_generating_block13.py plus tests/test_block15_stable_api.py
67 passed

python -m komorebi_math verify generating
verification passed 14/14 checks
```

The 94 passing test cases establish:

- descriptor roundtrips for built-in and finite-table bases
- explicit rejection of direct callback-basis persistence
- finite snapshot persistence for a callback-backed `FormalSeries`
- exact arithmetic and unit behavior in all five built-in domains
- weighted products matching independent ordinary Cauchy products
- same-basis exponential products in positive characteristic
- basis transfer, composition, and formal exponential-logarithm roundtrips
- degree and coefficient-bit resource failures
- portable roundtrips preserving basis, domain, coefficients, and budget
- the frozen stable API contract that includes `FormalSeries` and the two stable basis constructors
- the installed normalized-product, explicit-domain, and portable-record verification paths within the complete 14-check generating verifier

The replay does not prove an infinite normalization law, callback purity, analytic convergence, asymptotic complexity, or custom-domain algebraic laws.

Chapter 21 summary. A weighted monomial basis stores a_n against $e_n = z^n/\gamma_n$, so the ordinary coefficient is a_n/γ_n. `FormalSeries` is the stable exact-rational finite record. `FiniteNormalizedSeries` adds a frozen explicit domain, transfer certificates, and resource bounds. Products use $\gamma_n/(\gamma_k\gamma_{n-k})$, ordinary calculus rescales by adjacent normalizations, and composition is performed after exact conversion to ordinary coefficients. Use descriptor-backed bases for reusable persistence, pass an explicit composition degree, require units before division, and remember that every result is a finite formal truncation rather than an analytic infinite series.

22. Normalized generating functions

First route. If you already know a defining rule, choose a provider in Section 22.1 and reproduce one small prefix. If you have only samples, use the recognition section and retain its fit and holdout information. Both routes need an explicit choice between normalized and ordinary coefficients. When saving a reproducible result, Section 22.3.4 shows how to freeze the evaluated prefix together with its normalization.

Chapter 21 introduced the finite series

$$F(z) = \sum_{n=0}^{d} a_n \frac{z^n}{\gamma_n}, \qquad \gamma_0 = 1, \quad \gamma_n \neq 0,$$

and the distinction between the stored normalized coefficient a_n and the ordinary coefficient $c_n = a_n/\gamma_n$. The next layer adds a declarative provider interface around that finite algebra. A provider states where coefficients come from, a section isolates arithmetic lanes, a monoid series changes the index product, an adapter crosses into numerical signal processing, and a frozen record removes executable callbacks before persistence.

The implementation remains finite even when a mathematical definition uses an infinite product or a formal infinite series. Calling `function.series(d)` constructs exactly the prefix through degree d. It does not install a lazy infinite object and it does not certify any identity beyond that prefix.

> **API tier.** Every Chapter 22 symbol is present in the complete `1.0.0b4` public research manifest. None is in the beta or frozen stable manifest. `CustomFunctionSpec`, `FunctionRegistry`, `FrozenGeneratingFunction`, `GeneratingBudget`, and `freeze_custom_function` are also convenience exports from the package root. The complete surface, including recognition, sections, monoids, and FIR adapters, is `komorebi_math.generating`.

The shortest useful import is

```
from komorebi_math.generating import (
    CustomFunctionSpec,
    FunctionRegistry,
    FrozenGeneratingFunction,
    GeneratingBudget,
    algebraic_function,
    audit_section_cycle,
    compose_functions,
    custom_section,
    dirichlet_convolution,
    euler_product_function,
    freeze_custom_function,
    guess_linear_recurrence,
    rational_function,
)
```

No object in this chapter is a computer algebra expression tree. `CustomFunctionSpec` stores a Python coefficient callback, `FrozenGeneratingFunction` stores a finite data snapshot, and the closed-form guess records store bounded candidates. These three roles must not be interchanged.

22.1 Declarative generating-function objects

22.1.1 Core record and registry

The provider record has the exact constructor and public method

```
CustomFunctionSpec(
    name: str,
    basis: WeightedMonomialBasis,
    builder: CoefficientBuilder,
    source_kind: str = "custom",
    metadata: Mapping[str, object] = <factory>,
) -> None

CustomFunctionSpec.series(
    self,
    degree: int,
) -> FormalSeries
```

Its public data members are:

Member	Meaning
`name`	Human-readable provider name
`basis`	Normalized monomial basis used by the returned coefficients
`builder`	Callback receiving d and returning exactly $d + 1$ coefficients
`source_kind`	Descriptive construction label
`metadata`	User or constructor metadata, not a proof object

`series(d)` rejects a negative degree, executes the callback, checks only the returned length, and constructs a `FormalSeries`. The callback is trusted to be deterministic and mathematically correct. It is not sandboxed, memoized, or symbolically inspected.

The registry is an explicit in-memory name table:

```
FunctionRegistry() -> None

FunctionRegistry.register(
    self,
    function: CustomFunctionSpec,
) -> None

FunctionRegistry.get(
    self,
    name: str,
) -> CustomFunctionSpec

FunctionRegistry.names(
    self,
) -> tuple[str, ...]
```

Registration and lookup strip surrounding whitespace and compare lowercase names. The original `function.name` remains on the provider. A second registration under the same normalized name raises `KeyError` instead of silently replacing the first provider. `names()` returns the normalized names in sorted order.

The registry has no global singleton. Applications create and own registry instances explicitly. A registry is neither portable nor thread synchronized. Persist the selected finite functions rather than the registry itself.

22.1.2 Complete constructor ledger

The declarative constructor surface is:

```
explicit_function(
    name: str,
    basis: WeightedMonomialBasis,
    coefficients: tuple[int | Fraction, ...],
) -> CustomFunctionSpec

linear_recurrence_function(
    name: str,
    coefficients: tuple[int | Fraction, ...],
    initial: tuple[int | Fraction, ...],
    *,
    basis: WeightedMonomialBasis | None = None,
) -> CustomFunctionSpec

hypergeometric_function(
    name: str,
    initial: int | Fraction,
    ratio: Callable[[int], int | Fraction],
    *,
    basis: WeightedMonomialBasis | None = None,
) -> CustomFunctionSpec

rational_function(
    name: str,
    numerator: tuple[int | Fraction, ...],
    denominator: tuple[int | Fraction, ...],
    *,
    basis: WeightedMonomialBasis | None = None,
) -> CustomFunctionSpec

algebraic_function(
    name: str,
    polynomial_terms: Mapping[tuple[int, int], int | Fraction],
    initial_value: int | Fraction,
    *,
    basis: WeightedMonomialBasis | None = None,
) -> CustomFunctionSpec

euler_product_function(
    name: str,
    exponents: Mapping[int, int | Fraction]
        | Callable[[int], int | Fraction],
    *,
    basis: WeightedMonomialBasis | None = None,
) -> CustomFunctionSpec

factorial_power_bell_function(
    power: int,
    *,
    name: str | None = None,
) -> CustomFunctionSpec

weighted_factorial_power_bell_function(
    power: int,
    weights: tuple[int | Fraction, ...]
        | Callable[[int], int | Fraction],
    *,
    name: str | None = None,
) -> CustomFunctionSpec
```

```
compose_functions(
    name: str,
    outer: CustomFunctionSpec,
    inner: CustomFunctionSpec,
) -> CustomFunctionSpec
```

The word *coefficient* has two different meanings across these constructors. The distinction follows directly from the normalized basis law.

Constructor	Input rule	Stored output
`explicit_function`	Declared tuple	Normalized a_n directly
`linear_recurrence_function`	Recurrence on the sequence	Normalized a_n directly
`hypergeometric_function`	Ratio of consecutive terms	Normalized a_n directly
`rational_function`	Ordinary rational function $P(z)/Q(z)$	$a_n = \gamma_n c_n$
`algebraic_function`	Ordinary branch $P(z, F(z)) = 0$	$a_n = \gamma_n c_n$
`euler_product_function`	Ordinary Euler product	$a_n = \gamma_n c_n$
factorial-power Bell constructors	Factorial-power Bell recurrence	Native normalized Bell values
`compose_functions`	Ordinary formal composition	Returned in the outer basis

This table matters whenever `basis` is not ordinary. For example, `linear_recurrence_function(..., basis=exponential_basis())` applies the recurrence to the stored exponential coefficients a_n, not to $a_n/n!$. By contrast, `rational_function` first derives the ordinary coefficients of P/Q and then multiplies coefficient n by $n!$.

22.1.3 Explicit, recurrent, and hypergeometric providers

`explicit_function` copies its tuple into exact `Fraction` values. A request through degree d succeeds only when at least $d + 1$ values were declared. The constructor does not assume that omitted trailing coefficients are zero. This makes the captured boundary explicit.

For a recurrence of order r, the coefficients and seeds mean

$$a_{n+r} = \sum_{j=0}^{r-1} c_j a_{n+j}, \qquad (a_0, \dots, a_{r-1}) = \texttt{initial}.$$

The coefficient and initial tuples must be nonempty and have the same length. Generation through degree d takes $O(rd)$ exact scalar operations after the seeds have been converted to fractions.

The hypergeometric provider implements

$$a_0 = s, \qquad a_{n+1} = a_n R(n).$$

The ratio callback is evaluated once at every index from 0 through $d - 1$. A zero term remains zero unless a later callback operation itself fails. The constructor does not prove that $R(n)$ is rational as a function. Each returned value is converted to `Fraction` at execution time.

22.1.4 Rational and algebraic providers

Let

$$P(z) = \sum_{n \geq 0} p_n z^n, \qquad Q(z) = \sum_{k=0}^{q} q_k z^k, \qquad q_0 \neq 0.$$

The rational builder solves

$$c_n = \frac{1}{q_0}\left(p_n - \sum_{k=1}^{\min(n,q)} q_k c_{n-k}\right)$$

and returns $a_n = \gamma_n c_n$. Numerator and denominator tuples use ascending powers. A finite numerator is extended by zeros. A finite denominator defines the recurrence for every requested degree.

The algebraic builder receives a sparse mapping

```
{
    (z_degree, y_degree): coefficient,
    ...
}
```

and interprets it as

$$P(z,y) = \sum_{i,j} p_{ij} z^i y^j.$$

For the requested branch $y(0) = y_0$, construction requires

$$P(0,y_0) = 0, \qquad P_y(0,y_0) \neq 0.$$

The nonzero derivative is the formal implicit-function condition. Coefficients are then solved exactly, one degree at a time. The implementation recomputes truncated powers of the developing branch. With s the largest supplied y-degree, its straightforward cost is $O(sd^3)$ exact scalar operations in the worst case. Large rational numerators can make the bit cost much higher.

The constructor converts both key coordinates with `int(...)`. Callers should therefore supply genuine nonnegative integer pairs. In `1.0.0b4` a nonintegral numeric key can be silently truncated before validation. This is a source-level input-validation limitation, not a supported coercion rule.

22.1.5 Euler products and factorial-power Bell families

The Euler-product provider represents the finite prefix of

$$F(z) = \prod_{m\geq 1} (1 - z^m)^{-c_m}.$$

If a mapping is supplied, absent positive indices have exponent zero. If a callback is supplied, it is queried on positive indices only. The builder uses the logarithmic-derivative recurrence

$$\ell_k = \sum_{d\mid k} d\, c_d, \qquad n f_n = \sum_{k=1}^{n} \ell_k f_{n-k}, \qquad f_0 = 1.$$

The current divisor scan and coefficient recurrence together use $O(d^2)$ exact scalar operations. No convergence claim is needed because the result is a formal finite prefix.

For a positive integer s, `factorial_power_bell_function(s)` uses

$$\gamma_n = (n!)^s$$

and defines

$$\exp\left(\sum_{m\geq 1} \frac{z^m}{(m!)^s}\right) = \sum_{n\geq 0} B_n^{(s)} \frac{z^n}{(n!)^s}.$$

The exact recurrence is

$$B_n^{(s)} = \sum_{m=1}^{n} \binom{n-1}{m-1} \binom{n}{m}^{s-1} B_{n-m}^{(s)}.$$

The weighted constructor inserts a rational block weight w_m into every summand. A finite weight tuple uses entry zero only as an ignored placeholder and must contain entries through the largest requested block size. A callable is live and is queried as the degree grows. The unweighted path is quadratic in the degree at the recurrence level. The weighted implementation builds full Bell-polynomial rows and has cubic scalar-operation growth in the worst case.

22.1.6 Ordinary formal composition

`compose_functions(name, outer, inner)` defines

$$H(z) = F(G(z)).$$

Both providers are evaluated through the requested output degree. The inner series is converted to the outer basis, ordinary composition is performed exactly, and the result remains in the outer basis. The required formal condition is

$$G(0) = 0.$$

The current repeated-power implementation is cubic in the truncation degree. An `explicit_function` used as either operand must declare coefficients all the way through the requested degree, including explicit trailing zeros. Use a rational provider with denominator (1) when a finite polynomial should be extendable by zero coefficients.

22.1.7 Declarative workflow

This example creates rational, algebraic, Euler-product, and composed providers without constructing a symbolic expression tree:

```
from komorebi_math.generating import (
    FunctionRegistry,
    algebraic_function,
    compose_functions,
    euler_product_function,
    rational_function,
)

fibonacci = rational_function(
    "fibonacci",
    (0, 1),
    (1, -1, -1),
)
catalan = algebraic_function(
    "catalan",
    {(0, 0): 1, (0, 1): -1, (1, 2): 1},
    1,
)
partition = euler_product_function(
    "partition",
    lambda _index: 1,
)
geometric = rational_function("geometric", (1,), (1, -1))
z_plus_z2 = rational_function("z+z^2", (0, 1, 1), (1,))
composed = compose_functions(
    "1/(1-z-z^2)",
    geometric,
    z_plus_z2,
)
```

```
registry = FunctionRegistry()
registry.register(fibonacci)
registry.register(catalan)

print(registry.names())
print(tuple(int(v) for v in fibonacci.series(10).coefficients))
print(tuple(int(v) for v in catalan.series(8).coefficients))
print(tuple(int(v) for v in partition.series(10).coefficients))
print(tuple(int(v) for v in composed.series(7).coefficients))
```

Output:

```
('catalan', 'fibonacci')
(0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55)
(1, 1, 2, 5, 14, 42, 132, 429, 1430)
(1, 1, 2, 3, 5, 7, 11, 15, 22, 30, 42)
(1, 1, 2, 3, 5, 8, 13, 21)
```

The final line is Fibonacci-shifted because

$$\frac{1}{1-(z+z^2)} = 1 + z + 2z^2 + 3z^3 + 5z^4 + \cdots.$$

22.1.8 Construction failures and live-provider limits

Condition	Result in `1.0.0b4`
`series(d)` with $d < 0$	`ValueError: degree must be nonnegative`
Builder returns other than $d + 1$ entries	`ValueError`
Explicit provider is requested past its declared tuple	`ValueError: explicit function has insufficient declared coefficients`
Recurrence seed count differs from recurrence order	`ValueError`
Rational denominator is empty or has zero constant term	`ValueError`
Algebraic polynomial is empty	`ValueError`
Initial algebraic value is not on the curve	`ValueError`
Formal implicit derivative vanishes	`ValueError`
Composition inner constant term is nonzero	`ValueError`
Registry normalized name already exists	`KeyError`

Provider metadata is descriptive. It is not validated as a theorem certificate at construction. A callable ratio, exponent rule, weight rule, or custom builder can depend on mutable external state. Reproducible work should freeze the evaluated prefix described in Section 22.3.

22.2 Normalization maps and closed forms

22.2.1 The normalization-change law

Suppose one finite series is represented in two bases,

$$F(z) = \sum_{n=0}^{d} a_n \frac{z^n}{\gamma_n} = \sum_{n=0}^{d} b_n \frac{z^n}{\eta_n}.$$

Then coefficient equality gives the diagonal map

$$b_n = \frac{\eta_n}{\gamma_n} a_n.$$

`FormalSeries.convert(target_basis)` implements this law through ordinary coefficients. It changes representation, not the polynomial F. For a provider, conversion occurs after a prefix has been built:

```
source = function.series(degree)
converted = source.convert(target_basis)
assert converted.ordinary_coefficients() == source.ordinary_coefficients()
```

The constructor table in Section 22.1 determines whether the provider's input sequence is already normalized or is first interpreted as an ordinary function. There is no separate generic `normalize_function` call.

> **Module-name boundary.** The private implementation module `komorebi_math.generating.normalization` contains carry-linear prime-power kernels used by later chapters. It is not the basis-conversion mechanism described here. Use `FormalSeries.convert` for γ-to-η coefficient changes.

Recognition routines accept plain coefficient iterables. They do not receive a basis. Passing `series.coefficients` asks about the normalized sequence (a_n). Passing `series.ordinary_coefficients()` asks about the ordinary sequence (a_n/γ_n). Neither choice is inferred for the caller.

22.2.2 Recognition function signatures

The complete bounded-recognition surface is:

```
guess_linear_recurrence(
    values: Iterable[int | Fraction],
    *,
    max_order: int = 12,
    holdout: int | None = None,
) -> LinearRecurrenceGuess | None

rational_gf_from_recurrence(
    recurrence: LinearRecurrenceGuess,
    initial: Sequence[int | Fraction],
) -> tuple[tuple[Fraction, ...], tuple[Fraction, ...]]

characteristic_closed_form(
    recurrence: LinearRecurrenceGuess,
    initial: Sequence[int | Fraction],
) -> Any | None

guess_hypergeometric_ratio(
    values: Iterable[int | Fraction],
    *,
    max_numerator_degree: int = 4,
    max_denominator_degree: int = 4,
    holdout: int | None = None,
) -> HypergeometricGuess | None
```

```
guess_p_recursive(
    values: Iterable[int | Fraction],
    *,
    max_order: int = 4,
    max_degree: int = 5,
    holdout: int | None = None,
) -> PRecursiveGuess | None

guess_algebraic_gf(
    values: Iterable[int | Fraction],
    *,
    max_x_degree: int = 4,
    max_y_degree: int = 4,
    holdout: int | None = None,
) -> AlgebraicGFGuess | None

guess_quasipolynomial(
    values: Iterable[int | Fraction],
    *,
    max_period: int = 12,
    max_degree: int = 6,
    holdout: int | None = None,
) -> QuasiPolynomialGuess | None
```

Except for `guess_quasipolynomial` and `rational_gf_from_recurrence`, these workflows require the optional SymPy backend either while fitting or while constructing the symbolic rendering. The import of `komorebi_math.generating` itself does not import SymPy eagerly.

22.2.3 Candidate record ledger

All five result types are frozen slotted data classes.

```
LinearRecurrenceGuess(
    order: int,
    coefficients: tuple[Fraction, ...],
    fit_terms: int,
    holdout_terms: int,
    exact_on_prefix: bool,
) -> None

LinearRecurrenceGuess.equation(self) -> str

HypergeometricGuess(
    numerator: tuple[int, ...],
    denominator: tuple[int, ...],
    fit_relations: int,
    holdout_relations: int,
    exact_on_prefix: bool,
) -> None

HypergeometricGuess.ratio_expression(self) -> Any

PRecursiveGuess(
    order: int,
    degree: int,
    polynomials: tuple[tuple[int, ...], ...],
    fit_relations: int,
    holdout_relations: int,
    exact_on_prefix: bool,
) -> None
```

```
PRecursiveGuess.expression(self) -> Any

AlgebraicGFGuess(
    x_degree: int,
    y_degree: int,
    monomials: tuple[tuple[int, int, int], ...],
    fit_coefficients: int,
    holdout_coefficients: int,
    exact_on_prefix: bool,
) -> None

AlgebraicGFGuess.expression(self) -> Any

QuasiPolynomialGuess(
    period: int,
    degree: int,
    residue_values: tuple[tuple[Fraction, ...], ...],
    fit_terms: int,
    holdout_terms: int,
    exact_on_prefix: bool,
) -> None
```

Their mathematical payloads are:

Record	Candidate law
`LinearRecurrenceGuess`	$a_{n+r} = \sum_{j=0}^{r-1} c_j a_{n+j}$
`HypergeometricGuess`	$a_{n+1}/a_n = P(n)/Q(n)$
`PRecursiveGuess`	$\sum_{j=0}^{r} P_j(n) a_{n+j} = 0$
`AlgebraicGFGuess`	$P(x, F(x)) = 0$
`QuasiPolynomialGuess`	One Newton-form polynomial on each residue class

`monomials` stores triples (i, j, c) for $cx^i y^j$. `polynomials` stores one ascending coefficient tuple for each shift $P_j(n)$. `residue_values` stores forward-difference Newton coefficients, not sampled function values despite the field name.

22.2.4 Fit, holdout, and proof boundary

The fit portion selects a candidate. The holdout portion is then checked, and the implementation finally checks the candidate against the entire supplied prefix. Therefore `exact_on_prefix=True` means exact rational equality at all provided indices covered by the candidate law.

It does **not** mean:

- the law is unique,
- the law holds for the next coefficient,
- the supplied data came from the guessed model,
- an infinite formal identity has been proved.

An infinite claim needs independent information such as a defining recurrence, a functional equation, or a symbolic proof. The candidate record intentionally does not expose `certificate().require()`.

The constant-recurrence bridge forms an ordinary rational generating function. For

$$a_{n+r} = \sum_{j=0}^{r-1} c_j a_{n+j},$$

the denominator is

$$Q(z) = 1 - c_{r-1}z - c_{r-2}z^2 - \cdots - c_0 z^r.$$

The numerator is the truncated product $Q(z)F(z)$ through degree $r-1$. `characteristic_closed_form` separately asks SymPy to solve the recurrence with the supplied initial values. It can return `None` when SymPy has no supported form.

22.2.5 Exact recognition workflow

```
from komorebi_math.generating import (
    guess_algebraic_gf,
    guess_hypergeometric_ratio,
    guess_linear_recurrence,
    rational_gf_from_recurrence,
)

fibonacci = (0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89)
recurrence = guess_linear_recurrence(fibonacci, max_order=4)
assert recurrence is not None
numerator, denominator = rational_gf_from_recurrence(
    recurrence,
    fibonacci,
)

central_binomial = (
    1, 2, 6, 20, 70, 252, 924, 3432, 12870, 48620,
)
ratio = guess_hypergeometric_ratio(central_binomial)
assert ratio is not None

catalan = (
    1, 1, 2, 5, 14, 42, 132, 429, 1430, 4862, 16796, 58786,
)
algebraic = guess_algebraic_gf(
    catalan,
    max_x_degree=2,
    max_y_degree=3,
)
assert algebraic is not None

print(recurrence.equation())
print(tuple(int(v) for v in numerator))
print(tuple(int(v) for v in denominator))
print(ratio.numerator, ratio.denominator)
print(algebraic.monomials)
```

Output:

```
a[n+2] = (1) a[n+0] + (1) a[n+1]
(0, 1)
(1, -1, -1)
(2, 4) (1, 1)
((0, 0, 1), (0, 1, -1), (1, 2, 1))
```

The last two records encode

$$\frac{a_{n+1}}{a_n} = \frac{4n+2}{n+1}$$

and

$$1 - F(x) + xF(x)^2 = 0.$$

A quasipolynomial uses finite differences on each lane. For example, the sequence

$$a_n = \left\lfloor \frac{n}{3} \right\rfloor^2 + (n \bmod 3)$$

is recovered with period 3, degree 2, and residue tuples

$$(0, 1, 2), \qquad (1, 1, 2), \qquad (2, 1, 2).$$

These are Newton forward differences because

$$q^2 = \binom{q}{1} + 2\binom{q}{2}.$$

22.2.6 Recognition cost and failure behavior

Operation	Principal finite cost
`rational_gf_from_recurrence`	$O(r^2)$ exact arithmetic
`guess_quasipolynomial`	Repeated lane difference tables over tested periods and degrees
Constant recurrence guess	Repeated exact dense linear solves up to `max_order`
Hypergeometric guess	Exact nullspaces across numerator and denominator degree pairs
P-recursive guess	Exact nullspaces of size $(r+1)(s+1)$
Algebraic GF guess	Truncated powers plus exact nullspaces over candidate monomials
`characteristic_closed_form`	Backend-dependent symbolic recurrence solving

The symbolic searches can grow much faster than the prefix length suggests because rational matrix entries grow in bit length. The Chapter 22 guessers do not accept a `GeneratingBudget`. Bound the prefix and all `max_*` parameters before calling them.

The shipped boundary behavior is:

Condition	Result
SymPy is unavailable for a symbolic path	`BackendUnavailableError`
Prefix is shorter than the routine's minimum	`None`
Hypergeometric prefix has a zero before the final term	`None`
No model is found within the declared search box	`None`
SymPy cannot solve a recognized constant recurrence	`None` from `characteristic_closed_form`
Initial tuple is shorter than recurrence order	`ValueError` in rational GF bridge, or an indexing failure in the symbolic bridge

> **Known validation gap.** In `1.0.0b4` the recognition functions do not validate `holdout` or all `max_*` arguments as nonnegative bounded integers. A negative holdout can reach an internal indexing failure, and the result data-class constructors accept inconsistent fields when called directly. Treat constructor defaults or caller-validated positive bounds as the supported path. This does not affect the validated default workflows.

22.3 Sections, monoids, adapters, and portable records

22.3.1 Custom exponential and residue sections

For a declared basis γ, the custom exponential is

$$E_\gamma(z) = \sum_{n=0}^{d} \frac{z^n}{\gamma_n}.$$

Its normalized coefficient tuple is simply $(1, \dots, 1)$. The section with modulus m and residue r is

$$S_{m,r}^{(\gamma)}(z) = \sum_{\substack{0 \le n \le d \\ n \equiv r \pmod m}} \frac{z^n}{\gamma_n}.$$

The signed version multiplies the term $n = mq + r$ by $(-1)^q$.

The complete API is:

```
custom_exponential(
    basis: WeightedMonomialBasis,
    degree: int,
) -> FormalSeries

custom_section(
    basis: WeightedMonomialBasis,
    modulus: int,
    residue: int,
    degree: int,
    *,
    signed: bool = False,
) -> FormalSeries

root_filter_value(
    basis: WeightedMonomialBasis,
    modulus: int,
    residue: int,
    degree: int,
    z: complex,
) -> complex

audit_section_cycle(
    basis: WeightedMonomialBasis,
    *,
    modulus: int,
    degree: int,
    signed: bool = False,
    z: complex = 0.37 + 0.11j,
) -> SectionCycleAudit
```

With

$$\omega = e^{2\pi i/m},$$

the finite root filter is

$$S_{m,r}^{(\gamma)}(z) = \frac{1}{m} \sum_{j=0}^{m-1} \omega^{-rj} E_{\gamma}(\omega^{j} z).$$

`root_filter_value` evaluates the right side in complex floating point. `custom_section(...).evaluate(z)` evaluates the left side using the same finite truncation. Their small residual is numerical evidence for this finite projection, not an exact `Certificate`.

The custom lowering operator from Chapter 21 shifts normalized coefficients. It sends one unsigned section to the preceding residue section, with a wrap from residue zero to residue $m - 1$. One complete unsigned cycle returns the truncated section. A signed cycle returns its negative.

The audit record is

```
SectionCycleAudit(
    basis: str,
    modulus: int,
    degree: int,
    signed: bool,
    one_step_failures: int,
    full_cycle_failures: int,
    root_filter_residual: float,
) -> None
```

The one-step and full-cycle counts cover every residue. The root-filter residual inside `audit_section_cycle` checks the unsigned residue-zero section only, even when `signed=True`. The `signed` audit flag therefore changes the lowering-cycle checks but not the root-filter comparison.

Example:

```
from komorebi_math.generating import (
    audit_section_cycle,
    custom_section,
    factorial_power_basis,
)

basis = factorial_power_basis(2)
section = custom_section(basis, 3, 1, 10)
signed = custom_section(basis, 3, 1, 10, signed=True)
audit = audit_section_cycle(basis, modulus=3, degree=20)

print(tuple(int(v) for v in section.coefficients))
print(tuple(int(v) for v in signed.coefficients))
print(audit.one_step_failures, audit.full_cycle_failures)
print(audit.root_filter_residual < 1e-12)
```

Output:

```
(0, 1, 0, 0, 1, 0, 0, 1, 0, 0, 1)
(0, 1, 0, 0, -1, 0, 0, 1, 0, 0, -1)
0 0
True
```

`custom_section` validates $m \geq 1$, $0 \leq r < m$, and $d \geq 0$. `root_filter_value` does not repeat the modulus and residue validation in `1.0.0b4`. A zero modulus reaches a `ZeroDivisionError`. Validate the same domain before calling the numerical helper directly.

22.3.2 Finite monoid series

A monoid series replaces addition of indices by a caller-declared associative operation $\star$. For finite coefficient maps a and b,

$$(a * b)(u) = \sum_{x \star y = u} a(x) b(y).$$

The generic record and its members are:

```
FiniteMonoidSeries(
    coefficients: Mapping[Index, Fraction],
    combine: Callable[[Index, Index], Index],
    identity: Index,
    name: str = "monoid series",
) -> None

FiniteMonoidSeries.coefficient(
    self,
    index: Index,
) -> Fraction

FiniteMonoidSeries.multiply(
    self,
    other: FiniteMonoidSeries[Index],
    *,
    admissible: Callable[[Index], bool] | None = None,
) -> FiniteMonoidSeries[Index]
```

`admissible` filters combined output indices. It is the explicit finite support boundary for products that would otherwise grow beyond the desired range.

The built-in integer-index helpers are:

```
additive_series(
    values: Iterable[int | Fraction],
) -> FiniteMonoidSeries[int]

multiplicative_series(
    values: Iterable[int | Fraction],
) -> FiniteMonoidSeries[int]

dirichlet_convolution(
    left: Iterable[int | Fraction],
    right: Iterable[int | Fraction],
    *,
    count: int,
) -> tuple[Fraction, ...]

prime_valuation_packets(
    values: Iterable[int | Fraction],
    prime: int,
) -> dict[int, tuple[tuple[int, Fraction], ...]]
```

`additive_series` assigns entries to indices $0, 1, \ldots$ and uses index addition. `multiplicative_series` assigns entries to $1, 2, \ldots$ and uses index multiplication. The direct Dirichlet helper returns

$$(a * b)(n) = \sum_{d \mid n} a(d) b(n/d), \qquad 1 \le n \le N.$$

`prime_valuation_packets` writes an index as $n = p^v u$ and groups (u, a_n) by v.

```
from komorebi_math.generating import (
    additive_series,
    dirichlet_convolution,
    prime_valuation_packets,
)

ordinary = additive_series((1, 2, 3))
square = ordinary.multiply(ordinary, admissible=lambda n: n <= 4)
divisors = dirichlet_convolution(
    (1, 1, 1, 1, 1, 1),
    (1, 1, 1, 1, 1, 1),
    count=6,
)
packets = prime_valuation_packets(
    (10, 20, 30, 40, 50, 60, 70, 80),
    2,
)

print(tuple(square.coefficient(n) for n in range(5)))
print(tuple(int(v) for v in divisors))
print(tuple((v, len(packet)) for v, packet in packets.items()))
```

Output:

```
(Fraction(1, 1), Fraction(4, 1), Fraction(10, 1), Fraction(12, 1), Fraction(9, 1))
(1, 2, 2, 3, 2, 4)
((0, 4), (1, 2), (2, 1), (3, 1))
```

Two source-level boundaries are important:

- `FiniteMonoidSeries` trusts `combine` to be associative and to use the declared identity. `multiply` checks that the two identity values agree, but it does not verify that the two `combine` callables define the same operation. It always uses the left operand's callback.
- `prime_valuation_packets` checks only that its parameter is at least two. It does not perform a primality test. A composite value therefore produces a repeated-divisibility grouping, not a prime-adic valuation theorem.

The coefficient mapping is stored by reference inside a frozen data class. A mutable mapping can still be mutated externally. Use an immutable mapping discipline when the record is shared. These monoid records and callbacks do not have portable codecs.

22.3.3 Formal-series to FIR adapters

A finite ordinary polynomial

$$F(z) = \sum_{n=0}^{d} c_n z^n$$

is interpreted as the causal transfer polynomial

$$H(z) = \sum_{n=0}^{d} c_n z^{-n}.$$

The bridge converts normalized coefficients to ordinary coefficients first. Its complete API is:

```
series_to_fir_taps(
    series: FormalSeries,
    *,
    degree: int | None = None,
    dtype: Any = float,
) -> np.ndarray

series_to_fir_adapter(
    series: FormalSeries,
    *,
    degree: int | None = None,
    dtype: Any = float,
) -> FIRSeriesAdapter

fir_taps_to_series(
    taps: Any,
    *,
    basis: WeightedMonomialBasis | None = None,
    max_denominator: int | None = None,
) -> FormalSeries
```

The adapter record is:

```
FIRSeriesAdapter(
    series: FormalSeries,
    taps: np.ndarray,
    variable_substitution: str =
        "formal z maps to delay z^(-1)",
) -> None

FIRSeriesAdapter.response(
    self,
    *,
    points: int = 512,
    sample_rate: float = 1.0,
    whole: bool = False,
) -> FrequencyResponse

FIRSeriesAdapter.certificate(
    self,
    *,
    tolerance: float = 0.0,
) -> Certificate
```

The `Certificate` has `Exactness.NUMERICAL` and theorem identifier `GF-SIGNAL-FIR-BRIDGE`. It compares the converted taps against floating representations of the ordinary coefficients. A request beyond the stored series degree pads with zeros because the series is explicitly truncated to the selected degree.

The reverse adapter converts a floating value through its decimal string. `max_denominator` then optionally applies `Fraction.limit_denominator`. This is a declared rationalization boundary, not recovery of an unknown exact number.

> **Lossy-dtype boundary.** `series_to_fir_taps` accepts caller-selected NumPy dtypes. An integer dtype can truncate rational coefficients without raising. `series_to_fir_adapter(...).certificate()` detects the resulting residual, but the bare tap conversion has no certificate. Use a floating or complex dtype and require the adapter certificate when fidelity matters.

Complex taps with any nonzero imaginary part cannot be converted to `FormalSeries` because the current exact series scalar domain is rational and real. Empty, multidimensional, or nonfinite tap arrays are rejected.

The normalized coefficients and ordinary taps are visibly different in an exponential basis:

```
from komorebi_math.generating import (
    FormalSeries,
    exponential_basis,
    fir_taps_to_series,
    series_to_fir_adapter,
)

basis = exponential_basis()
source = FormalSeries(basis, (0, 1, 2, 12))
adapter = series_to_fir_adapter(source)
restored = fir_taps_to_series(
    adapter.taps,
    basis=basis,
    max_denominator=1000,
)

print(adapter.taps.tolist())
print(adapter.certificate().valid)
print(restored.coefficients)
print(adapter.response(points=16).response.shape)
```

Output:

```
[0.0, 1.0, 1.0, 2.0]
True
(Fraction(0, 1), Fraction(1, 1), Fraction(2, 1), Fraction(12, 1))
(16,)
```

The tap vector is $(a_n/n!)$, while conversion back into the exponential basis restores the original normalized tuple.

22.3.4 Frozen providers and portable records

Executable callbacks are not portable data. The finite handoff record is:

```
FrozenGeneratingFunction(
    name: str,
    basis_name: str,
    normalization: tuple[Fraction, ...],
    coefficients: tuple[Fraction, ...],
    source_kind: str,
    metadata: Mapping[str, Any] = <factory>,
) -> None

FrozenGeneratingFunction.degree: int

FrozenGeneratingFunction.series(
    self,
    degree: int | None = None,
) -> FormalSeries

freeze_custom_function(
    function: CustomFunctionSpec,
    degree: int,
    *,
    include_metadata: bool = True,
) -> FrozenGeneratingFunction

register_generating_codecs() -> None
```

The frozen record stores both the coefficient prefix and

$$(\gamma_0, \dots, \gamma_d).$$

Reconstruction therefore needs neither the original basis callback nor the function builder. Validation requires nonempty names, at least one coefficient, equal normalization and coefficient lengths, $\gamma_0 = 1$, nonzero normalizations, and portable metadata.

`dumps_portable` and `loads_portable` register the generating codecs automatically on first use. Most applications do not call `register_generating_codecs` themselves. Its public expert hook replaces the built-in registrations idempotently.

```
from komorebi_math.export import dumps_portable, loads_portable
from komorebi_math.generating import (
    algebraic_function,
    freeze_custom_function,
)

catalan = algebraic_function(
    "catalan",
    {(0, 0): 1, (0, 1): -1, (1, 2): 1},
    1,
)
frozen = freeze_custom_function(catalan, 8)
restored = loads_portable(dumps_portable(frozen))

print(restored == frozen)
print(restored.degree)
print(tuple(int(v) for v in restored.series().coefficients))
```

Output:

```
True
8
(1, 1, 2, 5, 14, 42, 132, 429, 1430)
```

The digest-checked portable envelope detects payload modification before reconstruction. It does not prove the generating rule that produced the coefficients.

A frozen record is bounded by design. `restored.series(9)` in the example raises `ValidationError`. Its reconstructed table basis also knows normalizations only through degree eight. Operations that implicitly grow beyond that range can raise `IndexError`. Truncate products and compositions to the captured degree, or freeze a wider prefix first.

22.3.5 Cost and boundary summary

Path	Time	Memory	Evidence class
Custom section	$O(d)$	$O(d)$	Exact coefficients
Root-filter value	$O(md)$	$O(d)$	Numerical complex equality
Section-cycle audit	Up to $O(m^2 d)$	$O(md)$	Finite counts and residual
Monoid product	$O(\|A\|\|B\|)$	Number of admitted output indices	Exact if callback law is correct
Direct Dirichlet prefix	$O(N^2)$ divisor scan	$O(N)$	Exact rational prefix
Series-to-tap conversion	$O(d)$	$O(d)$	Numerical certificate on adapter
Freeze or restore	$O(d)$ before JSON overhead	$O(d)$	Schema and digest validation

22.4 Resource budgets

22.4.1 Budget record and defaults

The shared generating-subsystem resource contract is:

```
GeneratingBudget(
    maximum_degree: int = 100_000,
    maximum_coefficient_bits: int = 4_000_000,
    maximum_matrix_dimension: int = 4_096,
    maximum_reachable_states: int = 100_000,
    maximum_local_combinations: int = 1_000_000,
    maximum_modulus: int = 2_000_000,
    maximum_serialized_bytes: int = 64 * 1024 * 1024,
    maximum_recursion_depth: int = 1_000,
) -> None
```

`DEFAULT_GENERATING_BUDGET` is one instance with those values. Every field must be a positive non-Boolean integer. The degree limit is positive even though degree zero is a valid request.

The complete method ledger is:

```
GeneratingBudget.require_degree(
    self,
    degree: int,
) -> int

GeneratingBudget.require_terms(
    self,
    count: int,
    *,
    label: str = "term count",
) -> int

GeneratingBudget.require_matrix_dimension(
    self,
    dimension: int,
) -> int

GeneratingBudget.require_states(
    self,
    states: int,
) -> int

GeneratingBudget.require_local_combinations(
    self,
    combinations: int,
) -> int

GeneratingBudget.require_modulus(
    self,
    modulus: int,
) -> int

GeneratingBudget.require_serialized_bytes(
    self,
    size: int,
) -> int

GeneratingBudget.require_coefficient_bits(
    self,
    bits: int,
) -> int
```

```
GeneratingBudget.max_modulus_table: int
```

`max_modulus_table` is a compatibility property returning `maximum_modulus`. Each `require_*` method returns the validated input. A malformed value raises `ValidationError`. A well-formed value beyond the configured ceiling raises `ResourceLimitError`.

There is no `require_recursion_depth` method in `1.0.0b4`. `maximum_recursion_depth` is serialized and validated as a positive field, but the Chapter 22 implementation does not enforce it.

22.4.2 Enforcement is operation-specific

A budget is effective only when the called operation accepts it or the caller invokes a guard explicitly.

Resource	Enforced examples
Degree and coefficient bits	`FiniteNormalizedSeries` construction and operations from Chapter 21
Matrix dimension and reachable states	Later carry and Cartier compilers
Local combinations and term counts	Later mask and digit compilers
Modulus	Prime-power and modular table constructors
Serialized bytes	Available as a manual guard
Recursion depth	Field only in `1.0.0b4`

The declarative providers, closed-form guessers, section helpers, monoid helpers, FIR adapters, `freeze_custom_function`, and portable dump/load calls documented in this chapter do **not** accept `budget=`. A large `CustomFunctionSpec.series(d)` request is not stopped by `DEFAULT_GENERATING_BUDGET`.

For those APIs, guard the request before execution:

```
from komorebi_math.generating import (
    GeneratingBudget,
    rational_function,
)

budget = GeneratingBudget(
    maximum_degree=8,
    maximum_coefficient_bits=64,
)
function = rational_function("geometric", (1,), (1, -1))

degree = budget.require_degree(8)
series = function.series(degree)

largest_bits = max(
    max(abs(value.numerator).bit_length(),
        value.denominator.bit_length())
    for value in series.coefficients
)
budget.require_coefficient_bits(largest_bits)
```

For serialization, measure the encoded byte payload and invoke `require_serialized_bytes` explicitly if an application requires that ceiling.

22.4.3 Typed failure example

```
from komorebi_math.exceptions import ResourceLimitError
from komorebi_math.generating import GeneratingBudget

budget = GeneratingBudget(maximum_degree=8)

print(budget.require_degree(8))

try:
    budget.require_degree(9)
except ResourceLimitError as error:
    print(type(error).__name__)
    print(str(error))
```

Output:

```
8
ResourceLimitError
degree 9 exceeds maximum_degree=8
```

The budget is immutable. Create a second record to authorize a larger finite computation. Do not mutate or replace the process-wide default.

22.4.4 Evidence and current limits

The Chapter 22 source audit covered:

Evidence	Result
`tests/test_generating_foundation.py`	Included in focused replay
`tests/test_generating_block13.py`	Included in focused replay
`tests/test_generating_domains.py`	Included in focused replay
Combined focused generating replay	**141 passed**
`examples/custom_generating_functions.py`	Passed
Declarative, recognition, section, monoid, FIR, persistence, and budget examples above	Replayed against `1.0.0b4`

The 141-test replay is broader than Chapter 22 because those source test files also exercise masks, Cartier operators, Bell reductions, and coefficient domains used in later chapters. Relevant Chapter 22 checks include basis sections, Fibonacci recognition, hypergeometric and algebraic guesses, negative low-complexity recognition results, Euler-product partitions, custom registries, algebraic and weighted builders, frozen portable round trips, FIR bridges, lazy optional-SymPy behavior, and typed budget failures.

The supported path is exact on declared finite coefficients and explicit at every conversion boundary. These limits remain in the shipped source:

1. Recognition candidates are prefix identities, not infinite proofs.
2. Symbolic recognition has no integrated `GeneratingBudget`.
3. Holdout and search-bound arguments are not fully validated.
4. Algebraic exponent keys are coerced through `int(...)`.
5. Monoid callback compatibility and associativity are trusted.
6. The direct root-filter helper does not fully validate its address.
7. FIR dtype conversion can be lossy until its certificate is checked.
8. Frozen providers cannot extend beyond their captured normalization table.
9. Recursion depth and portable byte ceilings are not automatically enforced by the Chapter 22 calls.

Chapter 22 summary. A normalized generating function has two independent declarations: the coefficient source and the basis normalization. Declarative providers build finite exact prefixes, diagonal conversion preserves ordinary coefficients, and recognition proposes bounded models without promoting them to theorems. Sections expose residue lanes, monoid records replace the index product, FIR adapters mark the exact to numerical boundary, and frozen records replace live callbacks with digest-checked finite data. Resource ceilings are explicit, but only operations that accept a budget or manually invoke a guard enforce them.

23. Masks, Cartier operators, and digit algebra

First route. Begin with the finite mask expansion in Section 23.1.1. The carry compiler in Section 23.1.2 evaluates the same kind of coefficient data through radix digits. For prime-field rational masks, continue to the Cartier compiler in Sections 23.3 to 23.4. Keep a short direct prefix as a readable comparison when inspecting a compiled plan, and record the radix and digit order with its transition matrices.

A local generating-function rule becomes finite and executable through explicit masks, transition matrices, and coefficient records. A Mahler mask describes a scale equation, carry matrices evaluate its coefficients from radix digits, Cartier sections compile rational masks over a prime field, and digit kernels expose the no-borrow algebra behind Lucas and Kummer phenomena. The implementations are finite by design. Degrees, prefix lengths, matrix dimensions, state counts, and prime-power moduli are declared before expansion.

The chapter covers six implementation modules and one explicit bridge:

Concern	Canonical implementation module
Exact masks, carry plans, Kummer layers, and coboundaries	`komorebi_math.generating.masks`
Polynomial Cartier maps, automata, and linear representations	`komorebi_math.generating.cartier`
Lucas-local kernels and finite closure audits	`komorebi_math.generating.digit_algebra`
Carry-linear valuations and digit-unit twists	`komorebi_math.generating.normalization`
Prime-power factorial and kernel compilers	`komorebi_math.generating.padic_units`
Formal-series and FIR conversion	`komorebi_math.generating.adapters`
Public research imports	`komorebi_math.generating`

All public names documented in this chapter belong to the **research** API in version `1.0.0b4`. None is exported by `komorebi_math.stable` or `komorebi_math.beta`. The complete and least ambiguous import style is

```
from komorebi_math.generating import (
    GeneratingBudget,
    compile_finite_mask_carry_plan,
    compile_rational_mask_automaton,
    mahler_mask_product,
)
```

The package root re-exports a smaller convenience subset, including `FiniteMaskCarryPlan`, `PrimePowerKernelCompiler`, `compile_finite_mask_carry_plan`, `compile_rational_mask_automaton`, `mahler_mask_inverse`, and `mahler_mask_product`. Code that needs the full system should import from `komorebi_math.generating` so that related record types and certificates remain visibly grouped.

> **Finite-claim boundary.** A successful mask certificate proves equality in a stated truncated formal ring. An automaton certificate compares a stated coefficient prefix. A digit-algebra audit exhausts a stated finite digit box. An analytic tail estimate is numerical and is not interval-rigorous. None of these finite records silently upgrades itself to an unrestricted convergence theorem or an unbounded congruence theorem.

23.1 Finite and local Mahler masks

23.1.1 Product, inverse, and functional equation

Let

$$R(z) = \sum_{j=0}^{m} r_j z^j, \qquad r_0 = 1, \qquad b \geq 2.$$

The local Mahler product is

$$\mathcal{M}_b[R](z) = \prod_{\ell \geq 0} R\left(z^{b^\ell}\right).$$

Only finitely many factors affect a finite truncation. In $\mathbb{Q}[z]/(z^{D+1})$, the returned series therefore satisfies

$$F(z) = R(z)F(z^b), \qquad R(z) = \frac{F(z)}{F(z^b)}.$$

The three exact entry points are

```
mahler_mask_product(
    mask: Iterable[int | Fraction],
    radix: int,
    degree: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> tuple[Fraction, ...]

mahler_mask_inverse(
    series: Iterable[int | Fraction],
    radix: int,
    degree: int | None = None,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> tuple[Fraction, ...]

certify_mahler_functional_equation(
    series: Iterable[int | Fraction],
    mask: Iterable[int | Fraction],
    radix: int,
    degree: int | None = None,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> Certificate
```

Coefficient tuples use ascending powers. Both the mask and series must have constant coefficient exactly one. `mahler_mask_product` returns exactly `degree + 1` rational coefficients. `mahler_mask_inverse` uses the supplied degree, or the source's final stored degree when `degree=None`. The certificate compares every coefficient through the selected degree and reports at most the first 16 failures in `diagnostics["failures"]`.

```
from fractions import Fraction

from komorebi_math.generating import (
    certify_mahler_functional_equation,
    mahler_mask_inverse,
    mahler_mask_product,
)

mask = (1, 2, -1)
```

```
series = mahler_mask_product(mask, radix=3, degree=20)
recovered = mahler_mask_inverse(series, radix=3, degree=20)
certificate = certify_mahler_functional_equation(
    series,
    mask,
    radix=3,
    degree=20,
)

assert recovered[:3] == tuple(Fraction(value) for value in mask)
assert all(value == 0 for value in recovered[3:])
certificate.require()
```

The arithmetic is exact, but the claim is finite:

$$F(z) - R(z)F(z^3) = 0 \pmod{z^{21}}.$$

Source-audit warning. In `1.0.0b4`, `mahler_mask_product` checks `radix >= 2`, but `mahler_mask_inverse` and `certify_mahler_functional_equation` do not repeat that guard. Their mathematics still requires $b \geq 2$. Callers must validate the radix before invoking either operation. `polynomial_mask_coboundary` inherits the same gap through its use of `mahler_mask_inverse`. Also, the certificate path does not apply the degree budget when `degree=None`. Supply an explicit degree in bounded or adversarial workflows. These are research-surface validation gaps, not additional supported conventions.

23.1.2 Finite carry compiler

For a finite mask, the coefficient of the infinite product can be read through a bounded carry state. If q is the incoming carry, q' the outgoing carry, and d the current radix digit, the transition entry is

$$T_d(q, q') = r_{d+bq'-q},$$

with coefficients outside $0, \ldots, m$ interpreted as zero. The compiler is

```
compile_finite_mask_carry_plan(
    mask: Iterable[int | Fraction],
    radix: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> FiniteMaskCarryPlan
```

The immutable result has the following public interface.

Member	Meaning
`radix`	b
`mask`	normalized exact coefficient tuple
`carry_bound`	largest represented carry
`matrices[d]`	exact T_d
`dimension`	`carry_bound + 1`
`evaluate(index)`	one exact coefficient
`sequence(count, *, budget=...)`	finite prefix
`certificate(count, *, budget=...)`	comparison with direct Mahler expansion

Digits are consumed **least significant first**. With a row-vector state v, one step is $v \leftarrow vT_d$, the initial vector is e_0, and the returned coefficient is the final zero-carry component.

For the binary overfull mask $R(z) = 1 + z + z^2$, the plan has carry bound two and

$$T_0 = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & 1 \end{bmatrix}, \qquad T_1 = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 0 & 1 & 0 \end{bmatrix}.$$

```python
from komorebi_math.generating import compile_finite_mask_carry_plan

plan = compile_finite_mask_carry_plan((1, 1, 1), radix=2)
plan.certificate(100).require()

# 13 has least-significant-first binary digits (1, 0, 1, 1).
assert plan.evaluate(13) == 3
assert plan.sequence(8) == (1, 1, 2, 1, 3, 2, 3, 1)
```

This prefix is Stern's diatomic sequence shifted by one index. The certificate establishes the coefficient identity for the requested prefix, not a new unbounded identity by itself.

`NormalizedMaskPlan` is an alias of `FiniteMaskCarryPlan`. It is not a second record format. Construct plans with the compiler rather than the raw dataclass constructor, because the compiler validates the unit constant, radix, matrix dimension, and transition construction.

23.1.3 Digit-local Cauchy products

`compile_digit_cauchy_product` compiles the ordinary Cauchy product of several digit-multiplicative sequences. Each input table must contain one weight per radix digit and must assign weight one to digit zero.

```
compile_digit_cauchy_product(
    digit_weights: Sequence[Sequence[int | Fraction]],
    radix: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> DigitCauchyProductPlan
```

For h factors, all b^h local digit combinations are first collected by their digit sum. The returned plan has `factor_count == dimension == h`, exact `matrices`, and the methods `evaluate(index)` and `sequence(count, *, budget)`. Unlike `FiniteMaskCarryPlan`, it has no certificate method and no registered portable codec in `1.0.0b4`. A caller that needs evidence should compare its finite prefix with a direct convolution over the same range.

23.1.4 Defect masks, coboundaries, and analytic realization

The remainder of the mask surface separates exact formal identities from one numerical realization.

Function	Finite operation
`frobenius_defect_mask(mask, prime, degree, *, budget=...)`	$R(z^p)/R(z)^p$ through degree D
`first_frobenius_lift(mask, prime, degree)`	$(\mathfrak{D}_p R - 1)/p \pmod p$, after an explicit divisibility check
`polynomial_mask_coboundary(candidate, radix, degree=None)`	$Q(z)/Q(z^b)$ for a declared polynomial unit
`solve_polynomial_coboundary(numerator, denominator, radix, degree_bound, *, budget=...)`	bounded rational solve of $B(z)Q(z) = A(z)Q(z^b)$
`certify_rational_mask_algebraic_relation(numerator, denominator, prime, degree, *, budget=...)`	$A(z)F(z)^{p-1} = B(z) \pmod{(p, z^{D+1})}$
`euler_product_collapse(radix, exponents)`	finite orbit bookkeeping for Euler factors
`analytic_mahler_product(mask, point, radix, terms)`	floating-complex finite product and conservative tail estimate

The Frobenius maps are

$$\mathfrak{D}_p R(z) = \frac{R(z^p)}{R(z)^p}, \qquad \mathfrak{L}_p R(z) = \frac{\mathfrak{D}_p R(z) - 1}{p} \pmod{p}.$$

`first_frobenius_lift` rejects a coefficient whose adjusted defect is not an integer divisible by p. It does not presume the divisibility.

`PolynomialCoboundaryResult` stores `radix`, `degree_bound`, optional `coefficients`, and an exact `residual`. Its convenience properties are `found` and `valid`. `require()` returns the coefficients only when the exact residual vanishes, and `certificate()` returns the finite exact evidence.

```
from fractions import Fraction

from komorebi_math.generating import solve_polynomial_coboundary

result = solve_polynomial_coboundary(
    numerator=(1, 2),
    denominator=(1, 0, 2),
    radix=2,
    degree_bound=4,
)

assert result.require() == (Fraction(1), Fraction(2))
```

Bounded-solver limitation. `PolynomialCoboundaryResult` distinguishes a verified returned solution from no solution found within the declared bound. The `1.0.0b4` record does **not** report rank or nullity, so it cannot expose whether a consistent bounded system was unique or underdetermined. The implementation selects zero for free variables. A finite polynomial solution is also not an unrestricted analytic factorization.

`euler_product_collapse` returns `EulerProductCollapse(radix, mask_exponents, closed_form_exponents, obstruction_orbits)`. The `collapses` property is true exactly when every radix-free orbit has zero terminal exponent sum. `require()` raises when an obstruction orbit remains. This is finite exponent bookkeeping for the supplied map. It makes no unrestricted convergence claim about an analytic Euler product.

`AnalyticMaskApproximation` stores `radix`, `point`, `terms`, `value`, `relative_tail_bound`, and `absolute_error_bound`. Its certificate has `Exactness.NUMERICAL`. It requires $|z| < 1$, but its ordinary complex floating-point product and conservative bound are not interval-rigorous. An infinite relative bound produces an invalid certificate rather than a false convergence claim.

23.2 Carry and digit operators

23.2.1 Kummer borrow layers

For prime p, Kummer's theorem identifies

$$v_p\binom{n}{k} = \text{number of base-}p\text{ borrows in } n - k.$$

The layer polynomial

$$L_{n,p}(t) = \sum_{k=0}^{n} t^{v_p\binom{n}{k}}$$

is represented by `KummerLayerDistribution(index, prime, counts)`. Its public members are

Member	Meaning
`counts[j]`	number of subindices in borrow layer j
`total`	sum of all layer counts, certified equal to `index + 1`

Member	Meaning
`count(borrows)`	one layer count, or zero outside stored support
`support_count(maximum_borrows)`	cumulative count through a layer
`certificate()`	exact exhaustion certificate

The related functions are

```
kummer_layer_distribution(index: int, prime: int) -> KummerLayerDistribution
zero_borrow_count(index: int, prime: int) -> int
one_borrow_count(index: int, prime: int) -> int

factorial_power_support_count(
    index: int,
    prime: int,
    factorial_power: int,
    modulus_exponent: int,
) -> int

factorial_power_support_indices(
    index: int,
    prime: int,
    factorial_power: int,
    modulus_exponent: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> tuple[int, ...]
```

For factorial power s modulo p^r, survival uses a **strict** boundary:

$$\binom{n}{k}^s \not\equiv 0 \pmod{p^r} \quad \iff \quad s\, v_p\binom{n}{k} < r.$$

Thus $sv = r - 1$ survives and $sv = r$ does not. The implementation converts this to

$$v_p\binom{n}{k} \le \left\lfloor \frac{r-1}{s} \right\rfloor.$$

`factorial_power_support_count` obtains the answer from the layer counts. `factorial_power_support_indices` explicitly scans $k = 0, \ldots, n$ after a term-budget check.

The two boundary cases can be executed directly. Since $v_2\binom{4}{2} = 1$ and $s = 2$, the weighted valuation is two. It survives modulo 2^3, where it equals $r - 1$, and vanishes modulo 2^2, where it equals r.

```
from komorebi_math.generating import PrimePowerKernelCompiler

surviving = PrimePowerKernelCompiler(2, 3, 2).kernel(4, 2)
vanishing = PrimePowerKernelCompiler(2, 2, 2).kernel(4, 2)

assert surviving.valuation == 2
assert surviving.residue == 4
assert surviving.survives

assert vanishing.valuation == 2
assert vanishing.residue == 0
assert not vanishing.survives
```

23.2.2 Carry-layer convolution

```
factorial_power_convolution_layers(
    left: Sequence[int],
    right: Sequence[int],
    index: int,
    prime: int,
    factorial_power: int,
    modulus_exponent: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> CarryLayerConvolution
```

The result stores `index`, `prime`, `exponent`, `factorial_power`, `modulus`, and one modular sum per surviving borrow layer. Its `residue` property adds the layers modulo p^r. The routine requires both coefficient arrays to contain indices through `index`, scans exactly `index + 1` subindices, and constructs a strict `PrimePowerKernelCompiler` for the binomial-power residue.

23.2.3 Lucas-local digit kernels

`DigitKernel` is a finite lower-triangular table. For radix b, modulus m, total digit d, and selected digit e, define

$$K(d, e) = \texttt{table[d][e]} \pmod{m}, \qquad 0 \le e \le d < b.$$

The lifted no-borrow weight is

$$K_{\text{global}}(n, k) = \prod_i K(n_i, k_i),$$

and is zero when any $k_i > n_i$. The record constructor and its methods are

```
DigitKernel(
    radix: int,
    modulus: int,
    table: tuple[tuple[int, ...], ...],
    name: str = "digit kernel",
)

kernel.local_weight(digit, subdigit) -> int
kernel.global_weight(index, subindex) -> int
kernel.lift(digit_values, index) -> int
kernel.local_multiply(left, right) -> tuple[int, ...]
kernel.global_multiply(left, right, *, count) -> tuple[int, ...]
```

The convenience constructor

```
factorial_power_digit_kernel(power: int, prime: int) -> DigitKernel
```

uses

$$K(d, e) = \binom{d}{e}^s \pmod{p}.$$

`base_digits(index, radix)` returns least-significant-first digits and represents zero as `(0,)`. `lift_digit_sequence(digit_values, *, radix, modulus, count)` applies an identity kernel to produce a finite digit-multiplicative prefix.

The finite theorem audit is

```
audit_factorial_power_digit_algebra(
    *,
    prime: int,
    power: int,
    left_digits: Iterable[int],
    right_digits: Iterable[int],
    max_digits: int = 3,
) -> DigitAlgebraAudit
```

For all $0 \leq n < p^D$, it checks the lifted Lucas weights and the closure identity

$$(a \star_s b)_n \equiv \prod_i (a \star_s b)_{n_i} \pmod{p}.$$

The record prints `tested_weights`, `weight_failures`, `tested_coefficients`, `closure_failures`, and `local_product`. It has no `.valid` property or `.require()` method in `1.0.0b4`. Validity means both failure counts are zero.

```
from komorebi_math.generating import audit_factorial_power_digit_algebra

audit = audit_factorial_power_digit_algebra(
    prime=3,
    power=2,
    left_digits=(1, 2, 1),
    right_digits=(1, 1, 2),
    max_digits=2,
)

assert audit.tested_weights == 45
assert audit.tested_coefficients == 9
assert audit.weight_failures == 0
assert audit.closure_failures == 0
assert audit.local_product == (1, 0, 2)
```

Primality guard discrepancy. The Lucas theorem used here requires a prime. `factorial_power_digit_kernel` and `audit_factorial_power_digit_algebra` currently reject values below two but do not test primality. `local_normalized_kernel` and `digit_factorized_normalized_kernel` likewise do not perform a prime test. Composite inputs can therefore return finite modular calculations that are not certified Lucas arithmetic. Validate with a strict prime-aware operation, or with the application's own primality guard, before using those research helpers in a theorem claim.

23.3 Cartier sections

The Cartier operator selects one residue class of exponents. In the exact notation retained by this guide,

$$\Lambda_r\left(\sum_n a_n z^n\right) = \sum_n a_{pn+r} z^n.$$

The implementation names the selected residue `digit` and uses $0 \leq r < p$. All polynomial coefficients are reduced modulo the selected prime and stored in ascending power order.

23.3.1 Polynomial primitives

```
polynomial_multiply_mod(
    left: Sequence[int],
    right: Sequence[int],
    modulus: int,
) -> tuple[int, ...]
```

```
polynomial_power_mod(
    polynomial: Sequence[int],
    exponent: int,
    modulus: int,
) -> tuple[int, ...]

polynomial_cartier(
    polynomial: Sequence[int],
    digit: int,
    prime: int,
) -> tuple[int, ...]

rational_mask_coefficients_mod_prime(
    numerator: Sequence[int],
    denominator: Sequence[int],
    prime: int,
    count: int,
) -> tuple[int, ...]

cartier_degree_bound(
    numerator: Sequence[int],
    denominator: Sequence[int],
    prime: int,
) -> int
```

`polynomial_multiply_mod` is a general modular primitive and only requires a modulus of at least two. `polynomial_cartier`, `rational_mask_coefficients_mod_prime`, and `cartier_degree_bound` perform an actual primality test. The rational-mask recurrence requires

$$A(0) = B(0) \neq 0 \pmod{p}.$$

It returns the unique unit-series prefix satisfying

$$B(z)F(z) = A(z)F(z^p) \quad \text{in } \mathbb{F}_p[[z]].$$

For numerator degree a and denominator degree b, the invariant degree bound is computed from

$$\Delta = \max\left(b, \left\lceil \frac{a + (p-2)b}{p-1} \right\rceil\right).$$

That is a state-polynomial degree bound. It is not the number of reachable automaton states.

23.3.2 Rational-mask algebraic certificate

In characteristic p, the finite rational-mask relation can also be tested as

$$A(z)F(z)^{p-1} = B(z) \pmod{(p, z^{D+1})}.$$

`certify_rational_mask_algebraic_relation` returns `RationalMaskAlgebraicCertificate(prime, degree, failures)`. The record exposes `valid`, `require()`, and `certificate()`. The constructor function calls `require()` internally, so a failed relation raises rather than returning an invalid record.

23.4 Congruence automata and finite snapshots

23.4.1 Reachable Cartier automata

```
compile_rational_mask_automaton(
    numerator: Sequence[int],
    denominator: Sequence[int],
    prime: int,
    *,
    minimize: bool = True,
    max_states: int = 100_000,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> CartierAutomaton

minimize_cartier_automaton(
    automaton: CartierAutomaton,
) -> CartierAutomaton
```

The compiler starts from the denominator polynomial, closes the reachable state set under every Cartier digit, and optionally minimizes the resulting output automaton by exact partition refinement. Digits are read least significant first. If

$$N = d_0 + d_1 p + \cdots + d_{L-1} p^{L-1},$$

then evaluation follows the transitions labelled $d_0, d_1, \ldots, d_{L-1}$. Its transition count is $O(\lfloor \log_p N \rfloor + 1)$.

The returned record is

```
CartierAutomaton(
    prime,
    numerator,
    denominator,
    degree_bound,
    transitions,
    outputs,
    state_numerators,
    state_members,
    start_state=0,
)
```

The compiled automaton exposes these members.

Member	Meaning
`number_states`	reachable states after optional minimization
`theoretical_state_bound`	$p^{\Delta+1}$, all possible bounded numerator vectors
`evaluate(index)`	one coefficient modulo p
`sequence(count)`	finite coefficient prefix
`certificate(count)`	finite comparison with the defining recurrence

`AutomatonCertificate` stores only `compared_terms` and a tuple of `(index, observed, expected)` failures. Its `valid` property tests whether the failure tuple is empty, and `require()` raises on the first discrepancy. Reachability, closure, state numerators, merged state members, degree bounds, and outputs belong to `CartierAutomaton`, not to its finite-prefix certificate.

> **Construction rule.** The raw automaton and linear-representation dataclasses do not perform complete `__post_init__` validation. Use the compilers for live construction. Portable decoding performs structural checks, but even a structurally valid snapshot should be replayed with a finite certificate when its mathematical provenance matters.

23.4.2 Large-index linear evaluation

An automaton enumerates the reachable nonlinear state set. A Cartier linear representation instead retains the full bounded polynomial vector space.

```
compile_cartier_linear_representation(
    numerator: Sequence[int],
    denominator: Sequence[int],
    prime: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> CartierLinearRepresentation
```

The record stores `prime`, normalized `numerator` and `denominator`, `degree_bound`, one transition matrix per digit, `start_vector`, and `output_scale`. Its `dimension` is `degree_bound + 1`. Its operational methods are `transition(vector, digit)`, `evaluate(index)`, and `sequence(count)`.

```
from komorebi_math.generating import (
    base_digits,
    compile_cartier_linear_representation,
)

index = 10**18 + 12345
representation = compile_cartier_linear_representation(
    numerator=(1, 1),
    denominator=(1, -1),
    prime=5,
)

digits = base_digits(index, 5)
value = representation.evaluate(index)

assert digits == (
    0, 4, 3, 3, 4, 3, 0, 0, 0, 0, 0, 0, 0,
    0, 0, 0, 0, 0, 4, 3, 0, 2, 4, 3, 1, 3,
)
assert representation.dimension == 2
assert value == 0
```

With row-vector convention, the ordered product is

$$v_N = v_0 T_{d_0} T_{d_1} \cdots T_{d_{L-1}}, \qquad f_N = (v_N)_0 B(0)^{-1} \pmod{p}.$$

The scalar evaluation cost is $O(L\Delta^2)$ for dense transition matrices of dimension $\Delta+1$. Compilation stores $p(\Delta+1)^2$ residues. Reachable-automaton evaluation is $O(L)$ table lookups after potentially more expensive state exploration.

23.4.3 Carry and Cartier equality

For a polynomial mask, the carry matrices and the Cartier multiplication matrices are entrywise equal on the compiler's declared state space.

```
finite_mask_carry_matrices(
    mask: Sequence[int],
    prime: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> tuple[tuple[tuple[int, ...], ...], ...]

certify_cartier_carry_equivalence(
    mask: Sequence[int],
    prime: int,
```

```
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> CartierCarryEquivalence
```

`CartierCarryEquivalence` stores `prime`, `dimension`, and failures of the form `(digit, source, target, observed, expected)`. It provides `valid` and `require()`. The finite claim is matrix equality, not a claimed conjugacy with an arbitrary external automaton.

23.4.4 Portable snapshots

The trusted portable layer registers data-only codecs for these Chapter 23 objects:

Record	Codec tag
`FiniteMaskCarryPlan`	`generating.finite_mask_carry_plan`
`CartierAutomaton`	`generating.cartier_automaton`
`CartierLinearRepresentation`	`generating.cartier_linear_representation`
`KummerLayerDistribution`	`generating.kummer_layer_distribution`
`CarryLayerConvolution`	`generating.carry_layer_convolution`

```
from komorebi_math.export import dumps_portable, loads_portable
from komorebi_math.generating import compile_rational_mask_automaton

source = compile_rational_mask_automaton((1, 1), (1, -1), 5)
payload = dumps_portable(source)
restored = loads_portable(payload)

assert restored.sequence(200) == source.sequence(200)
restored.certificate(200).require()
```

The envelope carries a SHA-256 integrity digest and rejects tampering. This is integrity and closed data reconstruction, not authenticity or authorization. `DigitKernel`, `DigitCauchyProductPlan`, prime-power compiler instances, `FIRSeriesAdapter`, and most certificate records have no registered portable codec in this release. Recompile them from validated parameters or persist a separate application-owned schema.

23.5 Signal adapters

The generating-to-signal bridge interprets a finite ordinary series

$$H(z) = \sum_{n=0}^{D} h_n z^n$$

as the causal FIR transfer polynomial

$$H(z^{-1}) = \sum_{n=0}^{D} h_n z^{-n}.$$

It does not infer an IIR system, an infinite impulse response, a minimum-phase factorization, or stability beyond the finite FIR convention.

```
series_to_fir_taps(
    series: FormalSeries,
    *,
    degree: int | None = None,
    dtype: Any = float,
) -> numpy.ndarray
```

```
series_to_fir_adapter(
    series: FormalSeries,
    *,
    degree: int | None = None,
    dtype: Any = float,
) -> FIRSeriesAdapter

fir_taps_to_series(
    taps: Any,
    *,
    basis: WeightedMonomialBasis | None = None,
    max_denominator: int | None = None,
) -> FormalSeries
```

`series_to_fir_taps` first requests ordinary coefficients from the source basis, then converts them to the selected NumPy dtype. The adapter stores the truncated `FormalSeries`, a copied one-dimensional tap array, and the explicit string `formal z maps to delay z^(-1)`. Its methods are

```
adapter.response(
    *,
    points: int = 512,
    sample_rate: float = 1.0,
    whole: bool = False,
) -> FrequencyResponse

adapter.certificate(
    *,
    tolerance: float = 0.0,
) -> Certificate
```

The certificate has `Exactness.NUMERICAL` because exact rational series coefficients have been converted to a NumPy array. It checks coefficient-to-tap agreement only.

```
from fractions import Fraction

import numpy as np

from komorebi_math.generating import (
    FormalSeries,
    fir_taps_to_series,
    ordinary_basis,
    series_to_fir_adapter,
)

source = FormalSeries(
    ordinary_basis(),
    (1, Fraction(1, 2), Fraction(-1, 4), 2),
)
adapter = series_to_fir_adapter(source)
adapter.certificate().require()

restored = fir_taps_to_series(adapter.taps, max_denominator=1000)
response = adapter.response(points=32)

assert np.allclose(adapter.taps, [1.0, 0.5, -0.25, 2.0])
assert restored.coefficients == source.coefficients
assert response.response.shape == (32,)
```

Floating taps are converted back through their decimal string representation. `max_denominator` requests a bounded rational approximation explicitly. Nonreal complex taps, nonfinite taps, empty or multidimensional arrays, and invalid denominator bounds are rejected.

23.6 Carry-linear normalization and unit twists

23.6.1 Carry-linear valuation profiles

A carry-linear normalization has valuation profile

$$\nu(n) = an + s\, v_p(n!),$$

where $a \in \mathbb{Z}$ and $s \geq 0$. Its convolution defect is

$$\begin{aligned}\nu(n) - \nu(k) - \nu(n-k) &= s\left(v_p(n!) - v_p(k!) - v_p((n-k)!)\right) \\ &= s\, v_p\binom{n}{k}.\end{aligned}$$

The linear term cancels. Carries therefore control the valuation defect.

```
CarryLinearValuation(
    prime: int,
    linear_slope: int,
    carry_weight: int,
)

profile.value(index: int) -> int
profile.defect(index: int, subindex: int) -> int

classify_carry_linear_valuation(
    valuation: Callable[[int], int],
    prime: int,
    checked_through: int,
) -> CarryLinearCertificate
```

The classifier recovers $a = \nu(1)$ and $s = \nu(p) - pa$, then checks every value and every split through `checked_through`. Its result stores `prime`, `linear_slope`, `carry_weight`, `checked_through`, and failures of the form `(index, subindex, observed, expected)`. It supplies `valid` and `require()`. The callback classification is explicitly finite even though the mathematical classification motivating it is unbounded.

```
from komorebi_math.generating import (
    CarryLinearValuation,
    classify_carry_linear_valuation,
)

profile = CarryLinearValuation(prime=3, linear_slope=2, carry_weight=5)
certificate = classify_carry_linear_valuation(profile.value, 3, 40)
certificate.require()

assert certificate.linear_slope == 2
assert certificate.carry_weight == 5
assert profile.defect(5, 2) == 0
```

23.6.2 Digit-unit twists

Let $w_0, \dots, w_{p-1}$ be nonzero residues modulo prime p, and define

$$u(n) = \prod_i w_{n_i} \pmod{p}.$$

The local twisted factorial-power kernel is

$$K_u(d, e) = \binom{d}{e}^s \frac{w_d}{w_e w_{d-e}} \pmod{p},$$

and the digit-factorized global kernel is the product of these local factors.

```
digit_unit(
    index: int,
    prime: int,
    weights: Sequence[int],
) -> int

local_normalized_kernel(
    total_digit: int,
    selected_digit: int,
    prime: int,
    factorial_power: int,
    unit_weights: Sequence[int],
) -> int

digit_factorized_normalized_kernel(
    index: int,
    subindex: int,
    prime: int,
    factorial_power: int,
    unit_weights: Sequence[int],
) -> int
```

`digit_unit` strictly tests that `prime` is prime and that every weight is a unit. The two kernel helpers validate digit range, weight-table length, and invertibility but do not independently test primality. Treat them as prime-domain helpers only after the caller has established the domain.

23.6.3 What the carry and Cartier compilers share

The same least-significant-first digit word drives three finite machines:

1. Exact rational carry matrices for a finite Mahler mask.
2. Prime-field Cartier transitions for a rational mask.
3. Prime-power valuation and unit calculations for normalized kernels.

Their shared digit order does not make their evidence interchangeable. The finite-mask plan proves rational coefficient agreement. The Cartier automaton proves modular prefix agreement. The prime-power compiler returns a valuation, unit, and residue after strict domain validation.

23.7 `generating.padic_units` and strict prime-power domain guards

23.7.1 Valuation primitives

The prime-power implementation module provides

```
factorial_valuation(index: int, prime: int) -> int
integer_valuation(value: int, prime: int) -> int
binomial_valuation(index: int, subindex: int, prime: int) -> int
borrow_count(index: int, subindex: int, prime: int) -> int
```

Each function performs an actual primality test. `factorial_valuation` uses Legendre's sum

$$v_p(n!) = \sum_{j \geq 1} \left\lfloor \frac{n}{p^j} \right\rfloor.$$

`integer_valuation` rejects zero because the record language stores finite integer valuations only. `binomial_valuation` and `borrow_count` require $0 \leq k \leq n$. Their equality is the Kummer bridge used by the layer compiler.

23.7.2 Prime-power binomial compiler

```
PrimePowerUnitCompiler(
    prime: int,
    exponent: int,
    max_modulus: int = 2_000_000,
)
```

Construction checks that `prime` is prime, `exponent` is positive, and $p^r \leq$ `max_modulus`. It builds a prefix table of the p-free factorials modulo p^r. Public operations are

```
compiler.unit_factorial(index: int) -> int
compiler.binomial_data(index: int, subindex: int) -> PrimePowerBinomial
compiler.binomial(index: int, subindex: int) -> int
```

`PrimePowerBinomial` stores `index`, `subindex`, `prime`, `exponent`, `modulus`, `valuation`, `unit`, and `residue`. Its `survives` property is exactly `valuation < exponent`.

```
from komorebi_math.generating import PrimePowerUnitCompiler

compiler = PrimePowerUnitCompiler(prime=3, exponent=4)
entry = compiler.binomial_data(20, 7)

assert compiler.modulus == 81
assert entry.valuation == 1
assert entry.unit == 1
assert entry.residue == 3
assert entry.survives
```

The prefix table costs $O(p^r)$ time and memory at construction. A query uses $O(\log_p n)$ unit-factorial iterations, plus modular exponentiation, and completed unit factorials are memoized.

23.7.3 Normalized prime-power kernels

For

$$\gamma_n = c^n (n!)^s u_n,$$

the geometric factor cancels from the normalized structure constant. The compiler evaluates

$$C_\gamma(n,k) = \binom{n}{k}^s \frac{u_n}{u_k u_{n-k}} \pmod{p^r}.$$

```
PrimePowerKernelCompiler(
    prime: int,
    exponent: int,
    factorial_power: int,
    unit_sequence: Callable[[int], int] | None = None,
    max_modulus: int = 2_000_000,
)

compiler.modulus -> int
compiler.kernel(index: int, subindex: int) -> NormalizedKernelResidue
```

`factorial_power` may be zero here. A missing `unit_sequence` means the constant unit one. Every evaluated callback value must be coprime to p. `NormalizedKernelResidue` stores `index`, `subindex`, `factorial_power`, `prime`, `exponent`, `valuation`, `unit`, and `residue`. `survives` tests the strict condition `valuation < exponent`.

```
from komorebi_math.generating import PrimePowerKernelCompiler

unit = lambda index: 1 + 3 * index
kernel = PrimePowerKernelCompiler(3, 4, 2, unit)
entry = kernel.kernel(20, 7)

assert kernel.modulus == 81
assert entry.valuation == 2
assert entry.unit == 46
assert entry.residue == 9
assert entry.survives
```

The callback is live executable state and is not portable. Persist its application-level identifier and parameters, then reconstruct it in trusted code. Do not serialize an arbitrary callback as though it were a package-owned portable record.

23.7.4 Guard and failure matrix

Request	Guard in `1.0.0b4`	Failure
nonprime `prime` in `padic_units` valuation or compiler APIs	strict trial-division primality test	`ValueError`
nonpositive prime-power exponent	strict	`ValueError`
$p^r >$ `max_modulus`	checked before prefix-table allocation	`ValueError`
zero passed to `integer_valuation`	rejected as having no finite valuation	`ValueError`
subindex outside $[0, n]$	strict	`ValueError` or zero only where explicitly documented
unit callback returns a multiple of p	checked at each kernel query	`ValueError`
nonunit Mahler constant	exact unit-series guard	`ValidationError`
radix below two in mask product or carry compiler	strict	`ValidationError`
matrix, state, term, degree, or modulus request above budget	precondition check	`ResourceLimitError`
composite passed to `factorial_power_digit_kernel`	**not detected**	finite result without a Lucas-theorem guarantee
radix below two in `mahler_mask_inverse` or its functional certificate	**not detected**	unsupported research-surface result

The resource budget relevant to this chapter defaults to degree 100,000, matrix dimension 4,096, reachable states 100,000, local combinations 1,000,000, modulus table 2,000,000, and serialized payload 64 MiB. Raising a budget makes a larger request permissible. It does not change the arithmetic domain or turn a finite audit into an unbounded theorem.

The mask and Cartier implementations check only the budget dimensions they actually allocate. In particular, the exact mask routines do not call `require_coefficient_bits`, and portable dumping does not automatically call a `GeneratingBudget` object's `require_serialized_bytes`. Exact rational coefficient growth and final payload size therefore remain caller-managed resources on these paths. The `maximum_recursion_depth` field is also not used by the iterative Chapter 23 compilers.

23.7.5 Complexity and allocation envelope

Let D be a truncation degree, $m = \deg R$, $c = \lceil m/(b-1) \rceil + 1$ the carry dimension, L a radix-digit length, h the number of digit-local factors, S a reachable automaton state count, and $q = p^r$.

Operation	Time envelope	Stored data	Active precondition
`mahler_mask_product`	worst-case $O(D^2 \log_b D)$ rational operations	$O(D)$ coefficients	degree
`mahler_mask_inverse`	worst-case $O(D^2)$ rational operations	$O(D)$ coefficients	degree
finite-mask compilation	$O(bc^2)$	$O(bc^2)$ rationals	matrix dimension
finite-mask evaluation	$O(Lc^2)$	one c-vector	validated index and compiled plan
digit Cauchy compilation	$O(b^h + bh^2)$	$O(bh^2)$ rationals	local combinations and matrix dimension
support enumeration	$O(n \log_p n)$ borrow work	up to $O(n)$ indices	term count
prime-power compiler construction	$O(q)$	$O(q)$ residues	modulus table
prime-power query	$O(\log_p n)$ iterations plus modular powers	memoized unit factorials	strict prime and unit guards
reachable Cartier compilation	bounded by S states and pS transitions	$O(pS)$ transitions plus state polynomials	degree, matrix dimension, and state guards
reachable automaton evaluation	$O(L)$ table lookups	one state index	nonnegative index
Cartier linear evaluation	$O(L(\Delta+1)^2)$	$p(\Delta+1)^2$ residues	matrix dimension

These are operation-count envelopes for the shipped dense algorithms. Exact `Fraction` cost also depends on numerator and denominator bit growth. Automaton minimization adds partition-refinement work after reachable-state compilation.

23.7.6 Evidence and reproducible checks

The shipped `1.0.0b4` evidence relevant to this chapter includes:

Executed check	Result
`tests/test_generating_foundation.py`	passed in the focused Chapter 23 replay
`tests/test_generating_block13.py`	passed in the focused Chapter 23 replay
`tests/test_generating_cartier_padic.py`	passed in the focused Chapter 23 replay
Combined focused replay	**173 passed**
`examples/mahler_cartier_compilers.py`	passed
`examples/prime_power_generating.py`	passed

The focused tests exercise exact mask inversion, finite carry plans, Cauchy products, Kummer layers, strict support boundaries, Frobenius defects, coboundaries, portable round trips, signal adapters, Cartier automata and minimization, carry/Cartier equality, large prime-power indices, unit twists, and rejection of perturbed finite profiles. A passing finite suite validates the shipped cases and guards. It does not erase the explicitly documented validation gaps above.

> **Chapter 23 summary.** Start with a unit local mask and a radix at least two. Expand it exactly only to a declared degree, or compile it into carry matrices that consume least-significant-first digits. Over a verified prime field, Cartier sections turn a rational Mahler equation into a reachable automaton or a bounded linear representation, both capable of logarithmic digit-length evaluation. Kummer layers and Lucas-local kernels expose the carry mechanism behind factorial-power support. FIR adapters make the formal coefficient-to-delay convention explicit. Carry-linear profiles and unit twists extend the normalized kernel without changing the strict survival boundary. Use registered snapshots only for supported closed records, replay finite certificates after restoration, and never infer prime mathematics from the few low-level research helpers that currently accept composites.

24. Prime-power, Bell, cyclotomic, and q-Kummer systems

First route. Use the kernel example in Section 24.1.4 to see valuation, unit, and residue together. For Bell reductions, compare the complete coefficient rows in Section 24.3 before using a residue automaton. Cyclotomic collapse and q-Kummer valuation are independent branches in Sections 24.4 to 24.5. Choose the branch matching the input object, and inspect its result-field table before interpreting a zero or an obstruction.

Four finite exact-arithmetic workflows share the same local principle: global coefficients are reduced to prime-radix valuations, unit parts, digit sums, or cyclotomic orbits before an exact residue is assembled. The implementations are finite compilers. They do not construct an infinite p-adic field, prove convergence of an infinite product, or infer a congruence from numerical agreement.

The four workflows answer different questions.

Workflow	Primary question	Returned evidence
Prime-power compiler	What is a binomial or normalized kernel modulo p^r?	valuation, unit, residue, support flag
Generalized Bell reduction	Does a factorial-power Bell row reduce to its base-p digit sum?	exact coefficient comparison and certificate
Cyclotomic collapse	Is a finite Mahler mask a cyclotomic coboundary?	closed-form exponents or explicit obstruction orbits
q-Kummer decomposition	What is the p-adic valuation of an integer Gaussian binomial?	mixed-radix branch record and support predicate

API tier and import surfaces.

The complete surface documented here is public from `komorebi_math.generating` and is covered by the research public-API manifest. It is not re-exported by `komorebi_math.stable` or `komorebi_math.beta`. Consequently, the exact signatures are checked in the current release, but they do not carry the frozen 1.x stable-surface promise.

The root namespace provides only the most common entry points:

```
from komorebi_math import (
    BellParityAutomaton,
    BellResidueAutomaton,
    PrimePowerKernelCompiler,
    generalized_bell_digit_reduction,
    q_binomial_valuation_decomposition,
)
```

Use the generating namespace for the full records, primitive valuations, cyclotomic verifiers, weighted Bell reduction, and direct q-Kummer checks:

```
from komorebi_math.generating import (
    BellDigitReduction,
    BellParityAutomaton,
    BellResidueAutomaton,
    CyclotomicCollapse,
    NormalizedKernelResidue,
    PointedSubindexCertificate,
    PrimePowerBinomial,
```

```
    PrimePowerKernelCompiler,
    PrimePowerUnitCompiler,
    QKummerDecomposition,
)
```

Only `normalized_cyclotomic_expression` and `verify_cyclotomic_coboundary` require the optional SymPy backend. The prime-power, Bell, exponent-lattice, and q-Kummer paths otherwise use the Python standard library and Komorebi Math's exact records.

> **Finite-evidence boundary.** A returned exact residue is exact for its selected p^r, index, and parameters. A finite certificate establishes the identity encoded by that certificate. Neither result is an unrestricted theorem about an unexecuted family of inputs.

24.1 Factorial-power prime-power kernels

24.1.1 Normalized structure constants

Let a weighted monomial basis have normalization

$$\gamma_n = c^n (n!)^s u_n,$$

where $s \geq 0$ is an integer and every u_n is a p-adic unit. Its product structure constant at (n, k) is

$$K_{n,k} = \frac{\gamma_n}{\gamma_k \gamma_{n-k}} = \binom{n}{k}^s \frac{u_n}{u_k u_{n-k}}.$$

The geometric factor c^n cancels. If

$$v = v_p\binom{n}{k},$$

then

$$v_p(K_{n,k}) = sv.$$

The kernel survives modulo p^r exactly when $sv < r$. The compiler keeps the valuation separate from the unit so it never attempts to invert a multiple of p.

24.1.2 Prime-power compiler signatures

The raw binomial compiler and its immutable result record are

```
PrimePowerUnitCompiler(
    prime: int,
    exponent: int,
    max_modulus: int = 2_000_000,
) -> None

PrimePowerUnitCompiler.unit_factorial(
    self,
    index: int,
) -> int

PrimePowerUnitCompiler.binomial_data(
    self,
    index: int,
    subindex: int,
) -> PrimePowerBinomial
```

```
PrimePowerUnitCompiler.binomial(
    self,
    index: int,
    subindex: int,
) -> int

PrimePowerBinomial(
    index: int,
    subindex: int,
    prime: int,
    exponent: int,
    modulus: int,
    valuation: int,
    unit: int,
    residue: int,
) -> None

PrimePowerBinomial.survives: bool
```

The normalized-kernel layer is

```
PrimePowerKernelCompiler(
    prime: int,
    exponent: int,
    factorial_power: int,
    unit_sequence: Callable[[int], int] | None = None,
    max_modulus: int = 2_000_000,
) -> None

PrimePowerKernelCompiler.modulus: int

PrimePowerKernelCompiler.kernel(
    self,
    index: int,
    subindex: int,
) -> NormalizedKernelResidue

NormalizedKernelResidue(
    index: int,
    subindex: int,
    factorial_power: int,
    prime: int,
    exponent: int,
    valuation: int,
    unit: int,
    residue: int,
) -> None

NormalizedKernelResidue.survives: bool
```

`unit_sequence=None` selects the constant sequence $u_n = 1$. A custom callback is evaluated at n, k, and $n - k$. All three returned values must be coprime to p.

The implementation module also defines

```
constant_unit_sequence(_index: int) -> int
```

as the callback that always returns one. It is not re-exported in `komorebi_math.generating.__all__`. Use `unit_sequence=None` on the supported umbrella surface.

The compiler data members are intentionally inspectable:

Compiler	Members established at construction
`PrimePowerUnitCompiler`	`prime`, `exponent`, `max_modulus`, `modulus`, `prefix_units`, `block_unit`
`PrimePowerKernelCompiler`	`prime`, `exponent`, `factorial_power`, `unit_sequence`, `max_modulus`, `binomial_compiler`

`prefix_units` is the p-free prefix table and `block_unit` is its final entry. Treat both as read-only implementation data. The unit compiler also maintains a private memoization dictionary named `_cache`.

24.1.3 Record-field interpretation

Field	Meaning
`prime`	selected prime p
`exponent`	modulus exponent r
`modulus`	p^r, present on the raw binomial record or compiler
`valuation`	$v_p\binom{n}{k}$ for `PrimePowerBinomial`, or $sv_p\binom{n}{k}$ for `NormalizedKernelResidue`
`unit`	surviving unit factor modulo p^r
`residue`	reconstructed result modulo p^r
`survives`	whether `valuation < exponent`

When the valuation is at least r, the residue is zero and the implementation stores `unit=0` as a sentinel. In that branch, `unit` is not the mathematical p-free unit of the vanished coefficient.

24.1.4 Exact kernel example

```
from dataclasses import asdict
from math import comb

from komorebi_math.generating import (
    PrimePowerKernelCompiler,
    PrimePowerUnitCompiler,
)

raw = PrimePowerUnitCompiler(3, 5).binomial_data(137, 52)
kernel = PrimePowerKernelCompiler(3, 5, 2).kernel(137, 52)

print(asdict(raw))
print(asdict(kernel))
print(kernel.residue == pow(comb(137, 52), 2, 3**5))
```

Output:

```
{'index': 137, 'subindex': 52, 'prime': 3, 'exponent': 5,
 'modulus': 243, 'valuation': 2, 'unit': 211, 'residue': 198}
{'index': 137, 'subindex': 52, 'factorial_power': 2, 'prime': 3,
 'exponent': 5, 'valuation': 4, 'unit': 52, 'residue': 81}
True
```

The same untwisted kernel can be evaluated from the command line:

```
python -m komorebi_math generating kernel \
  --index 137 --subindex 52 --prime 3 --exponent 5 --power 2
```

24.1.5 Compilation cost and resource guard

Initialization constructs a prefix-unit table of length $p^r + 1$. Its time and memory costs are therefore $O(p^r)$. A completed unit-factorial query uses $O(\log_p n)$ iterations and is memoized by `index`. A binomial query uses three unit-factorial values, one modular inverse, and the valuation calculation.

`max_modulus` guards this table directly. It is not a `GeneratingBudget` object, and the default compiler refuses $p^r > 2{,}000{,}000$. Raising the limit is an explicit memory decision.

Invalid condition	Result
`prime` is composite	`ValueError("prime must be prime")`
`exponent < 1`	`ValueError("exponent must be positive")`
`p**exponent > max_modulus`	`ValueError` before prefix allocation
`factorial_power < 0`	`ValueError`
`subindex` lies outside $[0, n]$	`ValueError`
custom unit is divisible by p	`ValueError("unit_sequence must return p-adic units")`

The primality check is deterministic trial division. It is suitable for the finite moduli targeted here, not a large-prime certification engine.

24.2 p-adic units and valuations

24.2.1 Valuation primitives

The four exact primitives are

```
factorial_valuation(
    index: int,
    prime: int,
) -> int

integer_valuation(
    value: int,
    prime: int,
) -> int

binomial_valuation(
    index: int,
    subindex: int,
    prime: int,
) -> int

borrow_count(
    index: int,
    subindex: int,
    prime: int,
) -> int
```

Legendre's formula is evaluated directly:

$$v_p(n!) = \sum_{j \geq 1} \left\lfloor \frac{n}{p^j} \right\rfloor .$$

The binomial valuation is then

$$v_p\binom{n}{k} = v_p(n!) - v_p(k!) - v_p((n-k)!).$$

Kummer's carry theorem gives the digit interpretation used by `borrow_count`:

$$v_p\binom{n}{k} = \text{number of base-}p\text{ borrows in } n - k.$$

The implementation counts borrows while subtracting `subindex` from `index`. It does not construct the potentially enormous integer $\binom{n}{k}$.

24.2.2 Unit factorials

Write

$$n! = p^{v_p(n!)} U_p(n), \qquad p \nmid U_p(n).$$

`PrimePowerUnitCompiler.unit_factorial(n)` returns $U_p(n) \bmod p^r$. The raw binomial compiler reconstructs

$$\binom{n}{k} \equiv p^{v} U_p(n) \left(U_p(k) U_p(n-k)\right)^{-1} \pmod{p^r}.$$

```
from komorebi_math.generating import (
    binomial_valuation,
    borrow_count,
    factorial_valuation,
    integer_valuation,
)

print(factorial_valuation(137, 3))
print(binomial_valuation(137, 52, 3))
print(borrow_count(137, 52, 3))
print(integer_valuation(3**4 * 10, 3))
```

Output:

```
66
2
2
4
```

24.2.3 Domain boundaries

`integer_valuation` returns only finite valuations. It rejects zero instead of returning an infinity sentinel:

```
integer_valuation(0, 3)
# ValueError: zero has no finite valuation
```

All indices must be nonnegative, every `subindex` must lie between zero and `index`, and every radix supplied to these primitives must be prime. These functions concern ordinary integers. Rational-valued valuation APIs and truncated p-adic coefficient domains are documented with the local arithmetic models in Chapter 25.

24.3 Generalized Bell digit reduction

24.3.1 Factorial-power Bell family

For a positive integer s, Komorebi Math defines the generalized Bell polynomials by

$$\exp\left(x\sum_{m\ge 1}\frac{z^m}{(m!)^s}\right)=\sum_{n\ge 0}B_n^{(s)}(x)\frac{z^n}{(n!)^s}.$$

Their exact recurrence is

$$B_n^{(s)}(x)=x\sum_{m=1}^{n}\binom{n-1}{m-1}\binom{n}{m}^{s-1}B_{n-m}^{(s)}(x).$$

Let $s_p(n)$ denote the sum of the base-p digits of n. When

$$s\ge 2,\qquad s\equiv 1 \pmod{p-1},$$

the implemented reduction compares the two coefficient rows

$$B_n^{(s)}(x)\equiv B_{s_p(n)}^{(1)}(x) \pmod{p}.$$

The comparison is coefficientwise. It is stronger than comparing only the values at $x=1$.

24.3.2 Reduction signatures and result record

```
generalized_bell_digit_reduction(
    index: int,
    prime: int,
    factorial_power: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> BellDigitReduction

weighted_bell_digit_reduction(
    index: int,
    prime: int,
    factorial_power: int,
    digit_weights: Iterable[int],
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> BellDigitReduction

BellDigitReduction(
    index: int,
    prime: int,
    factorial_power: int,
```

```
    digit_sum: int,
    high_polynomial: tuple[int, ...],
    reduced_polynomial: tuple[int, ...],
) -> None

BellDigitReduction.valid: bool
BellDigitReduction.require(self) -> None
BellDigitReduction.certificate(self) -> Certificate
```

`high_polynomial` stores the degree-n row reduced modulo p. `reduced_polynomial` stores the smaller degree-$s_p(n)$ row. The `valid` property compares them after padding the shorter tuple with zeros.

The weighted form uses an integer table c_j and sets the high-level block weight at m to $c_{s_p(m)}$. It compares that row with the ordinary factorial-power-one Bell row built from the same digit-weight table. The table must contain entries through the maximum digit sum encountered up to `index`.

24.3.3 Pointed digit identity

The Bell proof machinery exposes its pointed subindex identity separately:

```
pointed_subindex_polynomial(
    index: int,
    prime: int,
) -> tuple[int, ...]

certify_pointed_subindex_identity(
    index: int,
    prime: int,
) -> PointedSubindexCertificate

PointedSubindexCertificate(
    index: int,
    prime: int,
    left: tuple[int, ...],
    right: tuple[int, ...],
) -> None

PointedSubindexCertificate.valid: bool
PointedSubindexCertificate.require(self) -> None
PointedSubindexCertificate.certificate(self) -> Certificate
```

For positive n, the coefficient of u^j on the left groups $\binom{n-1}{m-1}$ over positive base-p digitwise subindices m with digit sum $j+1$. The certified identity is

$$\sum_{j\geq 0}\left(\sum_{\substack{m\preceq_p n,\ m>0\\ s_p(m)=j+1}}\binom{n-1}{m-1}\right)u^j\equiv(1+u)^{s_p(n)-1}\pmod p.$$

24.3.4 Bell reduction example

```
from komorebi_math.generating import (
    certify_pointed_subindex_identity,
    generalized_bell_digit_reduction,
)

pointed = certify_pointed_subindex_identity(137, 5)
reduction = generalized_bell_digit_reduction(137, 5, 9)
```

```
print(pointed.left)
print(pointed.right)
print(reduction.digit_sum)
print(reduction.reduced_polynomial)
print(reduction.valid)
```

Output:

```
(1, 4, 1, 4, 1)
(1, 4, 1, 4, 1)
5
(0, 1, 0, 0, 0, 1)
True
```

Both producer functions call `require()` before returning. A successful result has already passed its internal exact comparison. Calling `.certificate()` adapts that comparison to the common `Certificate` interface and records the theorem identifiers `NGF.POINTED_SUBINDEX` or `NGF.BELL_DIGIT_SUM_REDUCTION`.

24.3.5 Parity and residue automata

The parity special case is the three-state binary automaton

```
generalized_bell_parity(
    index: int,
    factorial_power: int,
) -> int

BellParityAutomaton(
    outputs: tuple[int, int, int] = (1, 1, 0),
) -> None

BellParityAutomaton.transition(
    self,
    state: int,
    digit: int,
) -> int

BellParityAutomaton.evaluate(
    self,
    index: int,
) -> int
```

For $s \geq 2$, the returned parity is zero exactly when

$$\operatorname{popcount}(n) \equiv 2 \pmod 3.$$

The general prime automaton uses the period bound and Touchard's recurrence:

$$P_p = \frac{p^p - 1}{p - 1},$$
$$B_{n+p} \equiv B_{n+1} + B_n \pmod p.$$

Its exact interface is

```
bell_period_bound(
    prime: int,
) -> int

BellResidueAutomaton.compile(
    prime: int,
```

```
    factorial_power: int,
    *,
    budget: GeneratingBudget = DEFAULT_GENERATING_BUDGET,
) -> BellResidueAutomaton

BellResidueAutomaton.transition(
    self,
    state: int,
    digit: int,
) -> int

BellResidueAutomaton.evaluate(
    self,
    index: int,
) -> int

BellResidueAutomaton.certificate(
    self,
    count: int,
) -> Certificate
```

The compiled fields are `prime`, `factorial_power`, `period_bound`, and `outputs`. Evaluation reads the base-p digits least significant first and adds them modulo P_p, so the terminal state is the digit sum modulo the period. The output table supplies the corresponding ordinary Bell residue.

```
from komorebi_math.generating import BellResidueAutomaton

automaton = BellResidueAutomaton.compile(3, 5)
print(automaton.period_bound)
print(automaton.outputs)
print(automaton.evaluate(137))
print(automaton.certificate(30).valid)
```

Output:

```
13
(1, 1, 2, 2, 0, 1, 2, 1, 0, 0, 1, 0, 1)
1
True
```

24.3.6 Bell resource limits and construction discipline

The period grows extremely quickly. The default budget permits 100,000 reachable states. Small-prime examples remain manageable, while a prime-seven automaton has 137,257 states and requires an explicitly larger budget:

```
from komorebi_math.generating import BellResidueAutomaton, GeneratingBudget

budget = GeneratingBudget(maximum_reachable_states=140_000)
automaton = BellResidueAutomaton.compile(7, 13, budget=budget)
assert automaton.period_bound == 137_257
```

`generalized_bell_digit_reduction` and its weighted variant enforce `budget.maximum_degree`, but the current path does not apply `maximum_coefficient_bits` to the intermediate exact Bell rows. `BellResidueAutomaton.certificate(count)` also accepts no budget argument and constructs exact generalized Bell rows through `count`. Keep certificate counts bounded by design.

Use `BellResidueAutomaton.compile`, not the dataclass constructor, to establish the prime, power, period, and output-table invariants. Likewise, the default `BellParityAutomaton()` is the theorem-carrying parity machine. Supplying custom outputs creates a different transducer.

24.4 Cyclotomic collapse

24.4.1 Finite Mahler coboundaries

Let $\Phi_m(z)$ be the m-th cyclotomic polynomial, normalized to have constant coefficient one, and let a finite mask be

$$R(z) = \prod_{m \geq 1} \Phi_m(z)^{e_m}.$$

The collapse problem asks whether there is a finite cyclotomic product

$$Q(z) = \prod_{m \geq 1} \Phi_m(z)^{q_m}$$

such that

$$R(z) = \frac{Q(z)}{Q(z^p)}.$$

Write each index uniquely as

$$m = up^j, \qquad p \nmid u.$$

`p_free_orbit` returns `(u, j)`. Within one p-power orbit, a nonzero mask exponent at level zero is the exact obstruction. When all level-zero exponents vanish, the closed-form exponent at level $j - 1$ is the negative tail sum

$$q_{up^{j-1}} = -\sum_{\ell \geq j} e_{up^\ell}.$$

24.4.2 Cyclotomic API and member ledger

```
p_free_orbit(
    index: int,
    prime: int,
) -> tuple[int, int]

cyclotomic_coboundary(
    prime: int,
    exponents: Mapping[int, int],
) -> CyclotomicCollapse

CyclotomicCollapse(
    prime: int,
    mask_exponents: tuple[tuple[int, int], ...],
    closed_form_exponents: tuple[tuple[int, int], ...],
    obstruction_orbits: tuple[int, ...],
) -> None

CyclotomicCollapse.collapses: bool
CyclotomicCollapse.require(self) -> None

verify_cyclotomic_exponent_relation(
    collapse: CyclotomicCollapse,
) -> bool

normalized_cyclotomic_expression(
    exponents: Mapping[int, int],
) -> Any
```

```
verify_cyclotomic_coboundary(
    collapse: CyclotomicCollapse,
) -> bool
```

`mask_exponents` is the sorted nonzero input. `closed_form_exponents` is the sorted finite solution. `obstruction_orbits` lists the p-free orbit labels whose level-zero exponent is nonzero. `collapses` is true exactly when that last tuple is empty.

The exponent-lattice verifier is exact and backend-free. The expression constructor and symbolic verifier import SymPy lazily and raise `BackendUnavailableError` when it is unavailable.

24.4.3 Successful collapse and explicit obstruction

```
from dataclasses import asdict

from komorebi_math.generating import (
    cyclotomic_coboundary,
    verify_cyclotomic_exponent_relation,
)

good = cyclotomic_coboundary(3, {3: 1, 9: -1})
bad = cyclotomic_coboundary(3, {1: 1, 3: -1, 10: 2})

print(asdict(good))
print(verify_cyclotomic_exponent_relation(good))
print(bad.collapses)
print(bad.obstruction_orbits)
```

Output:

```
{'prime': 3, 'mask_exponents': ((3, 1), (9, -1)),
 'closed_form_exponents': ((3, 1),), 'obstruction_orbits': ()}
True
False
(1, 10)
```

`bad.require()` raises

```
ValidationError: p-free cyclotomic obstructions: (1, 10)
```

If any orbit is obstructed, the returned `closed_form_exponents` is empty. The function does not return a partial solution for the unobstructed orbits.

24.4.4 Input and cost boundaries

For M nonzero mask entries, orbit grouping requires approximately $O(M \log_p m_{\max})$ integer divisions. The finite exponent verification is linear in the number of returned exponents. Symbolically expanding cyclotomic polynomials can be much more expensive and should be treated as a separate optional audit.

The public annotation requires an integer-to-integer mapping. The current implementation applies `int()` to every key and exponent instead of rejecting nonintegral numeric inputs. For example, `3.9` is silently converted to `3`. Validate external data as integers before calling `cyclotomic_coboundary`. This also avoids collisions between distinct external keys after coercion.

24.5 Gaussian q-Kummer valuation

24.5.1 Integer Gaussian binomials

Here q is an integer base greater than one, not a symbolic indeterminate. The elementary objects are

$$[n]_q = \frac{q^n - 1}{q - 1}, \qquad [n]_q! = \prod_{j=1}^{n} [j]_q,$$

and

$$\begin{bmatrix} n \\ k \end{bmatrix}_q = \frac{[n]_q!}{[k]_q![n-k]_q!}.$$

The direct constructors are

```
q_integer(index: int, base: int) -> int
q_factorial(index: int, base: int) -> int
gaussian_binomial(index: int, subindex: int, base: int) -> int
q_binomial_valuation_direct(
    index: int,
    subindex: int,
    base: int,
    prime: int,
) -> int
```

They construct exact Python integers and are intended for examples, bounded verification, and small direct computations. A q-integer has $\Theta(n \log q)$ bits, a q-factorial has $\Theta(n^2 \log q)$ bits, and a typical Gaussian binomial has $\Theta(k(n-k) \log q)$ bits. The decomposition below avoids constructing the Gaussian binomial itself.

24.5.2 Mixed-radix valuation formula

For $p \nmid q$, select a block length d, and write

$$n = dN + r, \qquad k = dK + s, \qquad 0 \le r, s < d.$$

Set

$$\delta = \mathbf{1}_{s>r}, \qquad C = v_p\binom{N}{K}, \qquad E = \begin{cases} v_p(N-K), & \delta = 1, \\ 0, & \delta = 0. \end{cases}$$

The implemented formula is

$$v_p\left(\begin{bmatrix} n \\ k \end{bmatrix}_q\right) = C + \delta\lambda + E,$$

with branch-specific d and λ.

Arithmetic branch	Block length d	Lift constant λ
$p \mid q$	1	0, and the complete valuation is 0
odd p, $p \nmid q$	$\mathrm{ord}_p(q)$	$v_p(q^d - 1)$, subtracting $v_p(q-1)$ when $d = 1$
$p = 2$, odd q	2	$v_2(q+1)$

The separate two-adic branch is essential. The multiplicative order modulo two alone would not encode the required parity block.

24.5.3 Exact decomposition example

```
from dataclasses import asdict

from komorebi_math.generating import (
    q_binomial_valuation_decomposition,
    q_binomial_valuation_direct,
)

record = q_binomial_valuation_decomposition(48, 22, 2, 5)

print(asdict(record))
print(q_binomial_valuation_direct(48, 22, 2, 5))
print(record.survives(exponent=2))
print(record.survives(exponent=2, power=2))
```

Output:

```
{'index': 48, 'subindex': 22, 'base': 2, 'prime': 5, 'order': 4,
 'lift_constant': 1, 'quotient_index': 12, 'quotient_subindex': 5,
 'residue_carry': 1, 'quotient_carries': 0,
 'endpoint_valuation': 0, 'valuation': 1}
1
True
False
```

The direct value is useful as an adversarial oracle at this scale. For large indices, the decomposition record is the intended path.

24.6 Congruence certificates and adversarial cases

24.6.1 Evidence capabilities

The four subsystems do not all expose the same certificate type.

Producer	Evidence operation	Exact claim
`certify_pointed_subindex_identity`	`.require()` or `.certificate()`	two finite coefficient tuples agree modulo p
`generalized_bell_digit_reduction`	`.require()` or `.certificate()`	high and digit-reduced Bell rows agree modulo p
`BellResidueAutomaton.compile`	`.certificate(count)`	compiled outputs match the first `count` exact generalized Bell rows
`cyclotomic_coboundary`	`.require()`	no level-zero orbit obstruction remains
`verify_cyclotomic_exponent_relation`	Boolean	returned exponents reconstruct the mask divisor relation
`verify_cyclotomic_coboundary`	Boolean, optional SymPy	symbolic rational-function identity holds
`PrimePowerKernelCompiler.kernel`	no certificate method	exact residue record for one query
`q_binomial_valuation_decomposition`	no certificate method	exact branch record for one query

The immutable dataclasses are transparent records, not unforgeable proof objects. Their public constructors permit a caller to fabricate inconsistent field values. Trust a record as computed evidence only when it comes from the documented producer, and recompute from its defining inputs when reading an external payload.

24.6.2 Adversarial rejection examples

```
from komorebi_math.generating import (
    BellResidueAutomaton,
    PrimePowerKernelCompiler,
    PrimePowerUnitCompiler,
    cyclotomic_coboundary,
    generalized_bell_digit_reduction,
    integer_valuation,
)

checks = (
    lambda: integer_valuation(0, 3),
    lambda: PrimePowerUnitCompiler(101, 4),
    lambda: PrimePowerKernelCompiler(
        3, 3, 2, lambda _index: 3
    ).kernel(4, 2),
    lambda: generalized_bell_digit_reduction(10, 5, 8),
    lambda: BellResidueAutomaton.compile(7, 13),
    lambda: cyclotomic_coboundary(
        3, {1: 1, 3: -1, 10: 2}
    ).require(),
)

for check in checks:
    try:
        check()
    except Exception as error:
        print(type(error).__name__, str(error))
```

Output:

```
ValueError zero has no finite valuation
ValueError modulus 104060401 exceeds max_modulus=2000000
ValueError unit_sequence must return p-adic units
ValidationError factorial_power must be at least two and congruent to one modulo prime-1
ResourceLimitError state request 137257 exceeds maximum_reachable_states=100000
ValidationError p-free cyclotomic obstructions: (1, 10)
```

These failures occur before a successful result is reported. A false `BellDigitReduction` or `PointedSubindexCertificate` created manually is rejected by `.require()`.

24.6.3 Persistence boundary

The records in this chapter do not have registered Komorebi portable codecs in version `1.0.0b4`. Passing `NormalizedKernelResidue`, `BellDigitReduction`, `PointedSubindexCertificate`, `CyclotomicCollapse`, or `QKummerDecomposition` to `dumps_portable` raises a `ValidationError` stating that the type has no portable codec.

For application-owned persistence, store a versioned primitive mapping and recompute the result on load:

```
import json
from dataclasses import asdict

from komorebi_math.generating import q_binomial_valuation_decomposition

record = q_binomial_valuation_decomposition(48, 22, 2, 5)
payload = {
    "schema": "example.q-kummer-query",
    "schema_version": 1,
    "inputs": {
        "index": record.index,
```

```
        "subindex": record.subindex,
        "base": record.base,
        "prime": record.prime,
    },
    "observed": asdict(record),
}
text = json.dumps(payload, sort_keys=True)

loaded = json.loads(text)
recomputed = q_binomial_valuation_decomposition(**loaded["inputs"])
assert asdict(recomputed) == loaded["observed"]
```

Persisting inputs plus observed output is preferable to reconstructing a dataclass directly because the producer reruns all branch and domain checks. Compiler instances should not be persisted as records: they contain prefix tables, caches, and, for custom kernels, an arbitrary callable.

24.6.4 Known limitations and current defects

Boundary	Consequence and safe practice
Research-tier surface	Pin the package version and run the strict public-API check when signatures matter.
Finite prime-power table	Choose `max_modulus` from an explicit memory budget.
Bell state explosion	Inspect `bell_period_bound(p)` before compilation and pass an intentional `GeneratingBudget`.
Bell coefficient growth	Keep exact row and certificate counts bounded. The Bell reducers do not currently enforce the coefficient-bit budget.
Optional symbolic backend	Use `verify_cyclotomic_exponent_relation` when SymPy is unavailable.
Cyclotomic input coercion	Prevalidate integer keys and exponents because nonintegers are currently truncated with `int()`.
Direct q arithmetic	Reserve `gaussian_binomial` and direct valuations for bounded checks. Integer size grows rapidly.
q-factorial boundary inconsistency	`q_factorial(0, base)` currently returns 1 without validating `base`. Validate `base > 1` before every call.
Gaussian out-of-range convention	`gaussian_binomial` returns 0 for `k < 0` or `k > n`, whereas the valuation decomposition raises. Do not mix the two failure conventions.
No portable codecs	Persist versioned inputs and recompute, rather than treating a hand-built record as evidence.

The `q_factorial(0, base)` behavior and cyclotomic numeric coercion are current implementation limitations, not mathematical conventions endorsed by this guide.

24.6.5 Executed evidence for this chapter

The focused replay below was executed against the documented `1.0.0b4` source tree:

```
tests/test_generating_cartier_padic.py
tests/test_generating_domains.py
tests/test_block13_cli_api.py

31 passed, 36 deselected
```

The installed verification commands additionally reported:

```
komorebi_math verify generating   14/14 passed
komorebi_math verify block13      146/146 passed
```

The shipped `examples/prime_power_generating.py` produced:

```
{'kernel_residue': 81, 'kernel_valuation': 4,
 'bell_digit_sum': 5, 'q_binomial_valuation': 1}
```

The generating verifier also exercises portable generating records from other chapters. That pass does not imply that the five chapter-specific record types listed above have portable codecs.

24.7 `generating.q_kummer`: Gaussian-binomial branches and valuation records

24.7.1 Complete q-Kummer callable ledger

The module-level public callables re-exported through `komorebi_math.generating` are

```
multiplicative_order_mod_prime(
    value: int,
    prime: int,
) -> int

q_integer(
    index: int,
    base: int,
) -> int

q_factorial(
    index: int,
    base: int,
) -> int

gaussian_binomial(
    index: int,
    subindex: int,
    base: int,
) -> int

q_binomial_valuation_decomposition(
    index: int,
    subindex: int,
    base: int,
    prime: int,
) -> QKummerDecomposition

q_binomial_valuation_direct(
    index: int,
    subindex: int,
    base: int,
```

```
    prime: int,
) -> int

q_binomial_support(
    index: int,
    base: int,
    prime: int,
    exponent: int,
    power: int = 1,
) -> tuple[int, ...]
```

`multiplicative_order_mod_prime` requires a prime modulus and a value coprime to it. Its simple loop tests successive powers through `prime - 1`. The implementation does not factor $p-1$ or cache orders.

24.7.2 `QKummerDecomposition` member ledger

```
QKummerDecomposition(
    index: int,
    subindex: int,
    base: int,
    prime: int,
    order: int,
    lift_constant: int,
    quotient_index: int,
    quotient_subindex: int,
    residue_carry: int,
    quotient_carries: int,
    endpoint_valuation: int,
    valuation: int,
) -> None

QKummerDecomposition.survives(
    self,
    exponent: int,
    power: int = 1,
) -> bool
```

Member	Interpretation
`index`, `subindex`	n, k
`base`, `prime`	integer Gaussian base q and valuation prime p
`order`	branch block length d
`lift_constant`	branch constant λ
`quotient_index`, `quotient_subindex`	N, K after division by d
`residue_carry`	$\delta = 1$ when the subindex residue exceeds the index residue
`quotient_carries`	$v_p\binom{N}{K}$
`endpoint_valuation`	$v_p(N-K)$ in the residue-carry branch, otherwise zero
`valuation`	complete $v_p(\begin{bmatrix} n \\ k \end{bmatrix}_q)$

`survives(r, a)` returns

$$a\, v_p\left(\begin{bmatrix} n \\ k \end{bmatrix}_q\right) < r,$$

which is equivalent to nonvanishing of $(\begin{bmatrix} n \\ k \end{bmatrix}_q)^a \bmod p^r$.

24.7.3 Support compilation

`q_binomial_support` applies the decomposition to every $k = 0, \dots, n$:

```
from komorebi_math.generating import q_binomial_support

print(q_binomial_support(12, 2, 5, exponent=1))
print(q_binomial_support(20, 3, 2, exponent=2))
```

Output:

```
(0, 4, 8, 12)
(0, 2, 4, 8, 12, 16, 18, 20)
```

The routine is exact, but it recomputes the primality and order branch for each subindex. With the present simple order search, a support sweep is roughly $O(n(p + \log_p n))$ in the coprime odd-prime branch. If many rows share `base` and `prime`, application code should budget accordingly.

24.7.4 q-Kummer failure semantics

Condition	API behavior
composite `prime`	decomposition and order helper raise `ValueError`
`base <= 1`	decomposition and `q_integer` raise `ValueError`
`subindex` outside $[0, n]$	decomposition raises, `gaussian_binomial` returns 0
direct Gaussian value is zero	direct valuation raises `ValueError`
`exponent < 1` or `power < 1`	support and `.survives()` raise `ValueError`
order helper receives a multiple of p	`ValueError("value must be coprime to prime")`

Chapter 24 summary. Prime-power compilers separate valuation from unit arithmetic and make modular support explicit. Bell reducers turn a high index into a certified digit-sum row, with finite automata available only when their state budget is acceptable. Cyclotomic collapse is an exact orbit-coboundary calculation whose obstruction is visible at level zero. q-Kummer records split every integer Gaussian-binomial valuation into one of three arithmetic branches, quotient carries, and an endpoint correction. The results are exact but research-tier, finite, and currently nonportable. Persist defining inputs and recompute them when evidence crosses a process boundary.

25. Local arithmetic models

First route. Read the scalar and precision conventions in Section 25.1. Then choose Hurwitz coefficients, Euler coordinates, Mahler coordinates, or a recurrence packet according to the representation you need. A modulus changes which values can be distinguished: the residue one modulo five, for example, is compatible with the integers one, six, and eleven. Keep the original exact data if a later calculation will need information beyond the chosen precision.

Local arithmetic is the point where an exact global object is viewed through a finite modulus, a prime field, or a bounded p-adic precision. Komorebi Math keeps those views finite. It does not construct an infinite p-adic field or claim analytic convergence from a finite residue calculation. Instead, the package supplies exact residue rings, valuations, finite Hurwitz algebra, certified Euler-coordinate truncations, Mahler transfers, residue packets, and finite congruence certificates.

The main data flow is

$$\text{exact values} \longrightarrow \text{local or residue coordinates} \longrightarrow \text{finite reconstruction or congruence certificate.}$$

The arrow is reversible only where the relevant class supplies and verifies a reconstruction map. Reduction modulo p^r, for example, discards information and is not reversed by asking for a `TruncatedPadic` object at greater precision.

25.0 Scope, API tiers, and imports

The arithmetic package has three distinct public surfaces.

Surface	Contract in `1.0.0b4`	Arithmetic content
`komorebi_math.stable`	Frozen stable signatures, semantics, and persistence	`ArithmeticPolyphase`, stable analyze/synthesize aliases, stable mixed-radix aliases, and `mahler_polyphase`
`komorebi_math`	Pre-beta additive research surface	Ten selected arithmetic names, including `HurwitzSeries`, `MahlerSeries`, `LinearRecurrence`, and `EulerLocalCoordinates`
`komorebi_math.arithmetic`	Complete implemented arithmetic namespace	Every class and function documented in this chapter

`komorebi_math.beta` exports no arithmetic symbol in this release. The ten arithmetic names in the root research manifest are `EulerLocalCoordinates`, `HurwitzSeries`, `LinearRecurrence`, `MahlerSeries`, `StandardWindow`, `TruncatedPadic`, `affine_mahler_kernel`, `fibonacci_recurrence`, `padic_valuation`, and `signed_euler_number`.

Code that needs the complete arithmetic namespace should import it explicitly:

```
from komorebi_math.arithmetic import (
    EulerLocalCoordinates,
    HurwitzSeries,
    LinearRecurrence,
    MahlerSeries,
    StandardWindow,
    TruncatedPadic,
)
```

The stable polyphase spellings are intentionally qualified:

```
from komorebi_math.stable import (
    ArithmeticPolyphase,
    arithmetic_mixed_radix_address,
    arithmetic_mixed_radix_digits,
    arithmetic_polyphase_analyze,
    arithmetic_polyphase_synthesize,
    mahler_polyphase,
)
```

The shorter `polyphase_analyze` name in `komorebi_math.arithmetic` is the same arithmetic operation, but that spelling is not part of the stable namespace. Do not confuse it with array-oriented signal polyphase analysis from `komorebi_math.signals`.

The administrative names `FEATURE_KEY`, `status()`, and `require()` report or confirm arithmetic feature availability. They do not perform arithmetic.

25.1 Scalar domains and valuations

25.1.1 Finite scalar domains

The three domain classes represent canonical integer residues:

$$\mathbb{Z}/M\mathbb{Z}, \qquad \mathbb{F}_p, \qquad \mathbb{Z}/p^r\mathbb{Z}.$$

Their exact constructors are

```
ModularRing(modulus: int) -> None
PrimeField(modulus: int) -> None
TruncatedPadic(prime: int, precision: int) -> None
```

`ModularRing` requires $M \geq 2$. `PrimeField` additionally verifies that its modulus is prime. `TruncatedPadic` requires a prime p and precision $r \geq 1$, then exposes the modulus p^r.

Type	Public member	Meaning
`ModularRing`	`normalize(value)`	Canonical residue in `0, ..., modulus - 1`
	`add(left, right)`	Residue sum
	`subtract(left, right)`	Residue difference
	`multiply(left, right)`	Residue product
	`power(base, exponent)`	Modular nonnegative power
	`is_unit(value)`	Whether the residue is invertible
	`inverse(value)`	Inverse of a unit, otherwise `ValidationError`
`PrimeField`	`prime`	Field characteristic, equal to `modulus`
	inherited ring members	Exact prime-field residue arithmetic
`TruncatedPadic`	`modulus`	p^r
	`ring`	Corresponding `ModularRing`
	`normalize(value)`	Canonical residue modulo p^r
	`is_unit(value)`	Whether $p \nmid value$ at the visible precision
	`inverse(value)`	Inverse of a local unit modulo p^r
	`valuation(value)`	Valuation of the visible nonzero residue
	`refine(additional_digits=1)`	New domain with greater declared precision
	`coarsen(precision)`	New shallower domain

The exact callable signatures behind that table are

```
ModularRing.normalize(self, value: int) -> int
ModularRing.add(self, left: int, right: int) -> int
ModularRing.subtract(self, left: int, right: int) -> int
ModularRing.multiply(self, left: int, right: int) -> int
ModularRing.power(self, base: int, exponent: int) -> int
ModularRing.is_unit(self, value: int) -> bool
ModularRing.inverse(self, value: int) -> int

PrimeField.prime: int

TruncatedPadic.modulus: int
TruncatedPadic.ring: ModularRing
TruncatedPadic.normalize(self, value: int) -> int
TruncatedPadic.is_unit(self, value: int) -> bool
TruncatedPadic.inverse(self, value: int) -> int
TruncatedPadic.valuation(self, value: int) -> int | float
TruncatedPadic.refine(
    self, additional_digits: int = 1,
) -> TruncatedPadic
TruncatedPadic.coarsen(self, precision: int) -> TruncatedPadic
```

The arithmetic methods require integer inputs and reject booleans. Negative integers are accepted where reduction makes them meaningful.

```
from komorebi_math.arithmetic import ModularRing, PrimeField, TruncatedPadic

ring = ModularRing(12)
field = PrimeField(7)
local = TruncatedPadic(3, 4)

print(ring.normalize(-1), ring.multiply(7, 5), ring.inverse(5))
print(field.inverse(3))
print(local.modulus, local.valuation(27), local.refine(2).precision)
```

Output:

```
11 11 5
5
81 3 6
```

Precision boundary. `refine()` changes the declared modulus. It does not infer missing high digits of an already reduced residue. Also, a residue that is zero modulo p^r is reported by `TruncatedPadic.valuation()` as `float("inf")`. That result cannot distinguish exact zero from an unknown integer whose valuation is at least r.

25.1.2 Valuation and combinatorial primitives

The complete function inventory is

```
digit_sum(value: int, base: int) -> int
padic_valuation(value: Rational, prime: int) -> int | float
factorial_valuation(index: int, prime: int) -> int
binomial_valuation(index: int, choose: int, prime: int) -> int
binomial_valuation_from_digits(index: int, choose: int, prime: int) -> int
falling_factorial(value: int, order: int) -> int
carmichael_exponent_prime_power(prime: int, depth: int) -> int
unit_difference_value(
    base: int, index: int, step: int, order: int,
```

```
) -> int
unit_difference_valuation(
    base: int, index: int, step: int, order: int, prime: int,
) -> int | float
verify_binomial_digit_formula(
    index: int, choose: int, prime: int,
) -> bool
exact_binomial(index: int, choose: int) -> int
```

For a rational $x = a/b \neq 0$, normalized with $b > 0$,

$$v_p(x) = v_p(a) - v_p(b), \qquad v_p(0) = +\infty.$$

The factorial and binomial identities are

$$v_p(n!) = \sum_{j \geq 1} \left\lfloor \frac{n}{p^j} \right\rfloor,$$

$$v_p\binom{n}{k} = v_p(n!) - v_p(k!) - v_p((n-k)!) = \frac{s_p(k) + s_p(n-k) - s_p(n)}{p-1}.$$

The two binomial functions implement the two exact formulas independently. The boolean verification helper compares them.

```
from fractions import Fraction

from komorebi_math.arithmetic import (
    binomial_valuation,
    binomial_valuation_from_digits,
    factorial_valuation,
    padic_valuation,
)

print(padic_valuation(Fraction(40, 27), 2))
print(padic_valuation(Fraction(40, 27), 3))
print(factorial_valuation(20, 3))
print(binomial_valuation(20, 8, 3))
print(binomial_valuation_from_digits(20, 8, 3))
```

Output:

```
3
-3
8
1
1
```

`falling_factorial(n, r)` returns zero when $r > n \geq 0$. Likewise, `exact_binomial(n, k)` returns zero outside $0 \leq k \leq n$, rather than raising. The valuation functions reject invalid binomial indices because a valuation of that sentinel zero would have different semantics. All valuation bases must be prime.

The prime-power Carmichael exponent is

$$\lambda(p^d) = \begin{cases} (p-1)p^{d-1}, & p \text{ odd}, \\ 1, & p = 2,\ d = 1, \\ 2, & p = 2,\ d = 2, \\ 2^{d-2}, & p = 2,\ d \geq 3. \end{cases}$$

For the exponential mode $f(n) = u^n$, the implementation uses the closed finite-difference identity

$$\Delta_h^r u^n = u^n (u^h - 1)^r.$$

`unit_difference_valuation` requires u to be a unit at the declared prime. The lower-level `unit_difference_value` only evaluates the integer identity and does not impose that local-unit assumption.

25.1.3 Cost model

Operation	Arithmetic work, excluding big-integer bit cost
Ring add, subtract, multiply	$O(1)$ residue operations
Modular inverse	(O(log M)) arithmetic steps for modulus (M)
Modular nonnegative power	(O(log e)) modular multiplications for exponent (e)
`digit_sum(n, p)`	$O(\log_p n)$
`factorial_valuation(n, p)`	$O(\log_p n)$
Binomial digit valuation	$O(\log_p n)$
Closed exponential difference	Dominated by exponentiation and size of the exact integer

Python integers grow with the result. A formula that takes logarithmically many multiplications can still allocate a very large integer.

25.2 Hurwitz series

25.2.1 Coefficient convention and product

A finite Hurwitz series stores exponential-generating coefficients:

$$A(z) = \sum_{n=0}^{N} a_n \frac{z^n}{n!}.$$

Its product is the binomial convolution

$$(A \star_H B)_n = \sum_{k=0}^{n} \binom{n}{k} a_k b_{n-k}.$$

The low-level signatures are

```
hurwitz_product(
    left: Iterable[Number],
    right: Iterable[Number],
    *,
    degree: int | None = None,
    modulus: int | None = None,
) -> tuple[Number, ...]

hurwitz_inverse(
    coefficients: Iterable[Number],
    degree: int,
    *,
    modulus: int | None = None,
) -> tuple[Number, ...]
```

If `degree` is omitted from `hurwitz_product`, the function returns the complete finite product through degree `len(left) + len(right) - 2`. The inverse solves

$$u_0 = a_0^{-1}, \qquad u_n = -a_0^{-1} \sum_{r=1}^{n} \binom{n}{r} a_r u_{n-r}.$$

Over the rationals, $a_0 \neq 0$ is required. In modular mode, a_0 must be a unit modulo the declared modulus.

25.2.2 `HurwitzSeries`

```
HurwitzSeries(
    coefficients: Iterable[Number],
    modulus: int | None = None,
) -> None
```

Member	Signature or result
`coefficients`	Stored finite coefficient tuple
`modulus`	`None` or residue modulus
`degree`	Highest stored coefficient index
`coefficient(index)`	Stored coefficient, or zero beyond truncation
`truncate(degree)`	New finite series through `degree`
`multiply(other, *, degree=None)`	Hurwitz product
`inverse(degree=None)`	Reciprocal through a finite degree
`evaluate_egf(value)`	Evaluation of the stored EGF polynomial
`identity(degree, *, modulus=None)`	Multiplicative identity
`exponential_mode(value, degree, *, modulus=None)`	Coefficients $value^n$

```
HurwitzSeries.coefficient(self, index: int) -> Number
HurwitzSeries.truncate(self, degree: int) -> HurwitzSeries
HurwitzSeries.multiply(
    self,
    other: HurwitzSeries,
    *,
    degree: int | None = None,
) -> HurwitzSeries
HurwitzSeries.inverse(self, degree: int | None = None) -> HurwitzSeries
HurwitzSeries.evaluate_egf(self, value: Number) -> Number
HurwitzSeries.identity(
    degree: int, *, modulus: int | None = None,
) -> HurwitzSeries
HurwitzSeries.exponential_mode(
    value: int,
    degree: int,
    *,
    modulus: int | None = None,
) -> HurwitzSeries
```

Integer and `Fraction` coefficients become exact `Fraction` objects when no modulus is present. Floating and complex coefficients remain numerical. A modular series accepts integers only and reduces each one canonically.

Exponential modes linearize addition under the Hurwitz product:

$$(a^n)_{n\geq 0} \star_H (b^n)_{n\geq 0} = ((a+b)^n)_{n\geq 0}.$$

```
from komorebi_math.arithmetic import HurwitzSeries

left = HurwitzSeries.exponential_mode(2, 6)
```

```
right = HurwitzSeries.exponential_mode(3, 6)
product = left.multiply(right, degree=6)

print(product.coefficients)
print(HurwitzSeries((1, 1)).inverse(4).coefficients)
```

Output:

```
(Fraction(1, 1), Fraction(5, 1), Fraction(25, 1), Fraction(125, 1), Fraction(625, 1), Fraction(3125, 1),
    ↪ Fraction(15625, 1))
(Fraction(1, 1), Fraction(-1, 1), Fraction(2, 1), Fraction(-6, 1), Fraction(24, 1))
```

Modular evaluation boundary. `evaluate_egf()` performs ordinary numeric division by (n!). It is not a finite-field evaluation routine. Use the stored modular coefficients and explicit finite-field operations when the intended result lies in a residue ring.

25.2.3 Finite-field subgroup selector

For prime p, positive $m \mid p-1$, and the subgroup $\mu_m \subset \mathbb{F}_p^\times$,

$$\frac{1}{m}\sum_{\omega \in \mu_m} \omega^n = \mathbf{1}_{m|n} \pmod p.$$

The corresponding interfaces are

```
subgroup_roots(prime: int, order: int) -> tuple[int, ...]
subgroup_selector(prime: int, order: int, degree: int) -> HurwitzSeries
compressed_hurwitz_inverse(
    prime: int, compression: int, count: int,
) -> tuple[int, ...]
compressed_period(prime: int, compression: int) -> int
```

`count` is the highest compressed index, so `compressed_hurwitz_inverse(p, m, count)` returns `count + 1` entries. Its recurrence is

$$u_0 = 1, \qquad u_n = -\sum_{q<n} \binom{mn}{mq} u_q \pmod p,$$

and its proved positive-tail period is

$$h = \frac{p-1}{m}.$$

```
from komorebi_math.arithmetic import subgroup_roots, subgroup_selector

print(subgroup_roots(13, 4))
print(subgroup_selector(13, 4, 12).coefficients)
```

Output:

```
(1, 5, 8, 12)
(1, 0, 0, 0, 1, 0, 0, 0, 1, 0, 0, 0, 1)
```

Subgroup enumeration scans all nonzero residues of the prime field. It is a transparent finite verifier, not a large-prime discrete-log algorithm. Hurwitz multiplication and inversion are quadratic in the requested degree.

25.3 Standard residual windows

25.3.1 Window model

```
StandardWindow(prime: int, compression: int) -> None
```

The window has congruential order mp, where `compression = m`. The uniform tail theorem requires

$$p \text{ odd prime}, \qquad m \mid p-1, \qquad h = (p-1)/m.$$

Member	Meaning
`order`	mp
`has_uniform_period`	Whether the theorem assumptions hold
`period`	Proved positive-tail period h
`reduced_inverse(degree)`	Standard inverse residues through `degree`
`exact_coefficients(address, degree)`	Exact rational address coefficients
`residues(address, degree)`	Exact coefficients reduced modulo p
`rational_generating_function()`	Finite periodic-OGF record
`minimum_period()`	Minimum divisor-period of the computed tail block
`certificate(address, periods=4)`	Address, recurrence, and tail-period check

```
StandardWindow.order: int
StandardWindow.has_uniform_period: bool
StandardWindow.period: int
StandardWindow.reduced_inverse(self, degree: int) -> tuple[int, ...]
StandardWindow.exact_coefficients(
    self, address: int, degree: int,
) -> tuple[Fraction, ...]
StandardWindow.residues(
    self, address: int, degree: int,
) -> tuple[int, ...]
StandardWindow.rational_generating_function(
    self,
) -> PeriodicGeneratingFunction
StandardWindow.minimum_period(self) -> int
StandardWindow.certificate(
    self, address: int, periods: int = 4,
) -> ComputationResult[tuple[int, ...]]
```

The convenience functions are

```
rational_mod(value: Fraction | int, prime: int) -> int
standard_window_inverse(
    prime: int, compression: int, degree: int,
) -> tuple[int, ...]
standard_window_period(prime: int, compression: int) -> int
subgroup_standard_window_inverse(
```

```
    prime: int, compression: int, degree: int,
) -> tuple[int, ...]
```

`rational_mod` requires the rational denominator to be a unit modulo p. The last function reaches the same residue coefficients through the finite Hurwitz subgroup construction.

25.3.2 Positive-tail generating function

`PeriodicGeneratingFunction` is the finite record

```
PeriodicGeneratingFunction(
    prime: int,
    period: int,
    constant: int,
    numerator: tuple[int, ...],
) -> None
```

with methods `coefficient(index)` and `first(count)`.

```
PeriodicGeneratingFunction.coefficient(self, index: int) -> int
PeriodicGeneratingFunction.first(self, count: int) -> tuple[int, ...]
```

If `numerator = (u_1, ..., u_h)`, it represents

$$U(z) = u_0 + \frac{u_1 z + u_2 z^2 + \cdots + u_h z^h}{1 - z^h} \quad \text{in } \mathbb{F}_p[[z]].$$

The exceptional constant coefficient is outside the periodic tail. A statement that the entire sequence is periodic from index zero is stronger and is not what `StandardWindow.period` proves.

```
from komorebi_math.arithmetic import StandardWindow

window = StandardWindow(prime=7, compression=2)
result = window.certificate(address=3, periods=4)
result.certificate.require()

print(window.period, window.minimum_period())
print(window.residues(address=3, degree=12))
print(window.rational_generating_function().first(13))
```

Output:

```
3 3
(1, 6, 5, 2, 6, 5, 2, 6, 5, 2, 6, 5, 2)
(1, 6, 5, 2, 6, 5, 2, 6, 5, 2, 6, 5, 2)
```

The certificate checks that the chosen address reduces to the standard inverse, verifies the defining compressed inverse recurrence, and tests the claimed period through the requested number of repetitions. It records `minimum_period` as a diagnostic. The validity flag does not assert that the theorem period is always minimal.

`StandardWindow(2, 1)` is constructible, but `period`, `rational_generating_function`, `minimum_period`, and `certificate` reject it because the uniform-period theorem requires an odd prime. A compression that does not divide $p - 1$ behaves the same way. Direct construction of `PeriodicGeneratingFunction` performs no schema validation, so normal code should obtain that record from `rational_generating_function()`.

The inverse recurrence and its certificate are quadratic in the requested degree. Since $h = (p - 1)/m$, certification can become costly when p is large and the compression is small.

25.4 Odd and dyadic Euler coordinates

25.4.1 Source sequences and kernels

The signed Euler convention is

$$\operatorname{sech} t = \sum_{n\ge 0} E_n \frac{t^n}{n!},$$

while the nonnegative zigzag numbers satisfy

$$\sec t + \tan t = \sum_{n\ge 0} A_n \frac{t^n}{n!}.$$

The source functions are

```
bernoulli_numbers(degree: int) -> tuple[Fraction, ...]
signed_euler_numbers(degree: int) -> tuple[int, ...]
signed_euler_number(index: int) -> int
euler_zigzag_numbers(degree: int) -> tuple[int, ...]
euler_zigzag_number(index: int) -> int
odd_power_sum(modulus: int, degree: int) -> int
dyadic_source(index: int) -> Fraction
dyadic_beta(index: int) -> Fraction
dyadic_kernel(index: int) -> Fraction
odd_kernel(prime: int, index: int) -> Fraction
dyadic_kernel_valuation(index: int) -> int
dyadic_row_weight(index: int, transfer_index: int) -> int
```

For even n, the local reconstruction is

$$E_n = \sum_{r=0}^{n/2} \binom{n}{2r} \kappa_{p,r} A_{p,n-2r}.$$

The dyadic source and kernel are

$$A_{2,n} = \frac{3^{n+2}-1}{4(n+1)(n+2)},$$

$$\kappa_{2,0} = 1, \qquad \kappa_{2,r} = -2^{4r}(2r-1)B_{2r} \quad (r>0),$$

and the odd-prime kernel is

$$\kappa_{p,r} = (-1)^r A_{2r+1} p^{2r}.$$

For positive r,

$$v_2(\kappa_{2,r}) = 4r - 1.$$

`odd_power_sum(q, n)` accepts any positive odd integer q. The coordinate class itself requires a prime and routes $p = 2$ to the separate dyadic chart.

25.4.2 `EulerLocalCoordinates`

```
EulerLocalCoordinates(prime: int) -> None
```

Member	Signature or result
`is_dyadic`	Whether `prime == 2`
`source(index)`	$A_{p,n}$
`kernel(index)`	$\kappa_{p,r}$
`inverse_kernel(index)`	Inverse transfer coefficient
`reconstruct(index, *, depth=None)`	Full or truncated forward reconstruction
`inverse_reconstruct_source(index)`	Recover the local source from E_n
`kernel_valuation(index)`	$v_p(\kappa_{p,r})$
`row_weight(index, transfer_index)`	Valuation of one complete row term
`formula_row_weight(index, transfer_index)`	Separated valuation formula
`sharp_modulus(depth)`	Uniform omitted-tail modulus
`truncate(index, depth)`	`EulerTruncation` record
`certificate(maximum_index=20)`	Finite forward, inverse, and row-ledger check

```
EulerLocalCoordinates.is_dyadic: bool
EulerLocalCoordinates.source(self, index: int) -> Fraction
EulerLocalCoordinates.kernel(self, index: int) -> Fraction
EulerLocalCoordinates.inverse_kernel(self, index: int) -> Fraction
EulerLocalCoordinates.reconstruct(
    self, index: int, *, depth: int | None = None,
) -> Fraction
EulerLocalCoordinates.inverse_reconstruct_source(
    self, index: int,
) -> Fraction
EulerLocalCoordinates.kernel_valuation(
    self, index: int,
) -> int | float
EulerLocalCoordinates.row_weight(
    self, index: int, transfer_index: int,
) -> int | float
EulerLocalCoordinates.formula_row_weight(
    self, index: int, transfer_index: int,
) -> int | float
EulerLocalCoordinates.sharp_modulus(self, depth: int) -> int
EulerLocalCoordinates.truncate(
    self, index: int, depth: int,
) -> EulerTruncation
EulerLocalCoordinates.certificate(
    self, maximum_index: int = 20,
) -> ComputationResult[tuple[Fraction, ...]]
```

Reconstruction accepts even nonnegative indices only. At depth d, terms with $0 \le r \le d$ are retained, subject to $r \le n/2$. If the row is not complete, the proved moduli are

$$2^{4d+3} \quad \text{and} \quad p^{2d+2}$$

for the dyadic and odd branches respectively.

The result record is

```
EulerTruncation(
    prime: int,
```

```
    index: int,
    depth: int,
    value: Fraction,
    exact_value: int,
    modulus: int | None,
    error: Fraction,
    certificate: Certificate,
) -> None
```

`modulus is None` means the full finite row was retained and equality, rather than a proper congruence, was checked.

```
from komorebi_math.arithmetic import EulerLocalCoordinates, padic_valuation

for prime in (2, 5):
    coordinates = EulerLocalCoordinates(prime)
    result = coordinates.truncate(index=20, depth=2)
    result.certificate.require()
    print(
        prime,
        result.value,
        result.modulus,
        padic_valuation(result.error, prime),
    )
```

Output:

```
2 8804179016755/231 2048 14
5 86777696087933558237525 15625 7
```

The printed error valuations exceed the required bounds (v_2(2048)=11) and (v_5(15625)=6).

25.4.3 Certification and budgets

`EulerLocalCoordinates.certificate(N)` checks every even row through N, both reconstruction directions, and every retained row valuation. Its domain is finite and explicit in `diagnostics["maximum_index"]`. It does not prove a claim for unexecuted indices.

The source functions build Bernoulli, signed Euler, and zigzag prefixes from scratch. They do not install a cross-call cache. Repeated scalar calls such as `signed_euler_number(n)` are therefore less efficient than computing one prefix with `signed_euler_numbers(N)` and reusing it. Exact rational numerator and denominator sizes also grow rapidly. Use modest `maximum_index` values for interactive certificates and raise the bound explicitly in qualification runs.

25.5 Mahler transfer and arithmetic polyphase

25.5.1 Newton-Mahler coordinates

For values $f(0), \dots, f(d)$, the finite Newton expansion is

$$f(x) = \sum_{r=0}^{d} \Delta^r f(0) \binom{x}{r}.$$

The primitive interfaces are

```
generalized_binomial(value: Number, order: int) -> Number
difference_table(
    values: Iterable[Number],
) -> tuple[tuple[Number, ...], ...]
mahler_coefficients(values: Iterable[Number]) -> tuple[Number, ...]
```

`generalized_binomial(x, r)` returns zero for a negative order. Exact integers and `Fraction` values produce exact rational results. Other numeric types use their native arithmetic.

```
MahlerSeries(coefficients: Iterable[Number]) -> None
```

Member	Signature or result
`degree`	Highest stored coefficient index
`from_values(values)`	Consecutive-prefix analysis
`evaluate(value, *, degree=None)`	Finite Newton polynomial evaluation
`first(count)`	Values at $0, \ldots, count - 1$
`difference(order=1)`	Shift coefficients by the difference order
`affine_subsequence(multiplier, shift)`	Coordinates of $f(mx + s)$
`valuation_ledger(prime)`	Exact rational coefficient valuations
`reconstruction_certificate()`	Reanalyze the defining finite prefix

```
MahlerSeries.degree: int
MahlerSeries.from_values(values: Iterable[Number]) -> MahlerSeries
MahlerSeries.evaluate(
    self, value: Number, *, degree: int | None = None,
) -> Number
MahlerSeries.first(self, count: int) -> tuple[Number, ...]
MahlerSeries.difference(self, order: int = 1) -> MahlerSeries
MahlerSeries.affine_subsequence(
    self, multiplier: int, shift: int,
) -> MahlerSeries
MahlerSeries.valuation_ledger(
    self, prime: int,
) -> tuple[int | float, ...]
MahlerSeries.reconstruction_certificate(
    self,
) -> ComputationResult[tuple[Number, ...]]
```

`from_values` preserves a coefficient slot for every input value, including trailing zero differences. `affine_subsequence` removes trailing zero coefficients after transfer.

```
from komorebi_math.arithmetic import MahlerSeries

series = MahlerSeries.from_values([n**3 + 1 for n in range(8)])
branch = series.affine_subsequence(multiplier=4, shift=3)

series.reconstruction_certificate().certificate.require()
print(series.coefficients)
print(branch.first(5))
```

Output:

```
(1, 1, 6, 6, 0, 0, 0, 0)
(Fraction(28, 1), Fraction(344, 1), Fraction(1332, 1), Fraction(3376, 1), Fraction(6860, 1))
```

The reconstruction certificate labels integer and rational input `EXACT` and other numeric types `NUMERICAL`. In the numerical branch it still compares the reanalyzed coefficient tuple directly. It is not a tolerance-based stability or conditioning certificate.

25.5.2 Affine kernel and prime-power sparsity

The transfer kernel is defined by

$$\binom{mq+s}{r} = \sum_{k} K_{m,s}(r,k)\binom{q}{k},$$

$$K_{m,s}(r,k) = \sum_{j=0}^{k} (-1)^{k-j}\binom{k}{j}\binom{mj+s}{r}.$$

Its signatures are

```
affine_mahler_kernel(
    multiplier: int,
    shift: int,
    source_degree: int,
    target_degree: int,
) -> int

affine_kernel_matrix(
    multiplier: int, shift: int, degree: int,
) -> tuple[tuple[int, ...], ...]

affine_kernel_composition_certificate(
    first_multiplier: int,
    first_shift: int,
    second_multiplier: int,
    second_shift: int,
    degree: int,
) -> Certificate
```

Prime-power specializations are exposed separately:

```

prime_power_kernel_residue(
    prime: int,
    exponent: int,
    shift: int,
    source_degree: int,
    target_degree: int,
) -> int

prime_power_kernel_certificate(
    prime: int, exponent: int, shift: int, degree: int,
) -> Certificate
```

Rows of `affine_kernel_matrix` are target degrees and columns are source degrees. Composition obeys

$$K_{m,s}K_{n,t} = K_{mn,mt+s},$$

under that stored orientation. For a prime-power multiplier,

$$K_{p^a,s}(r,k) \equiv \binom{s}{r-p^a k} \pmod{p},$$

where the binomial is zero outside its valid range.

The affine transfer of a degree-d series uses a cubic number of elementary integer operations in the current direct implementation. The exhaustive composition certificate nests additional degree loops and should be treated as a qualification operation, not a hot-path transform for very large d.

25.5.3 Scalar and matrix unit modes

```
UnitModeMahler(base: int, jump: int, residue: int = 0) -> None
```

For nonzero integer u, positive h, and $j \geq 0$,

$$u^{hx+j} = u^j \sum_{r \geq 0} (u^h - 1)^r \binom{x}{r}.$$

Member	Meaning
`increment`	$u^h - 1$
`coefficients(degree)`	$u^j(u^h-1)^r$ through the requested degree
`evaluate(value, *, degree=None)`	Exact mode or finite truncation
`valuation_slope(prime)`	$v_p(u^h - 1)$
`certificate(maximum_value, degree=None)`	Finite-range coordinate check

```
UnitModeMahler.increment: int
UnitModeMahler.coefficients(self, degree: int) -> tuple[int, ...]
UnitModeMahler.evaluate(
    self, value: int, *, degree: int | None = None,
) -> int | Fraction
UnitModeMahler.valuation_slope(self, prime: int) -> int | float
UnitModeMahler.certificate(
    self, maximum_value: int, degree: int | None = None,
) -> Certificate
```

When `degree` is omitted or at least the evaluation value, `evaluate` returns the exact integer mode directly. Otherwise it evaluates the truncated Mahler series.

> **Certificate boundary.** If `degree < maximum_value`, `UnitModeMahler.certificate` checks only through `degree` and records an unchecked assumption for the rest. Its validity flag can still be true. Set `degree >= maximum_value` when full-range validation is required and inspect `assumptions_unchecked` before promoting the result.

Matrix modes replace $u^h - 1$ by $C^h - I$:

```
matrix_mahler_coefficients(
    matrix: np.ndarray,
    jump: int,
    residue: int,
    degree: int,
) -> tuple[np.ndarray, ...]

evaluate_matrix_mahler(
    coefficients: Iterable[np.ndarray],
    value: int,
) -> np.ndarray
```

The matrix constructor requires a square matrix. It uses NumPy object arrays and exact Python scalar operations where the entries are exact. The evaluator requires a common shape but does not independently certify that its supplied coefficient arrays came from one square matrix.

25.5.4 Arithmetic polyphase

For a finite sequence $a = (a_n)_{0 \le n < L}$,

$$a \longmapsto \left((a_{mq+r})_q \right)_{r=0}^{m-1}.$$

The complete signatures are

```
ArithmeticPolyphase(
    modulus: int,
    channels: tuple[tuple[Number, ...], ...],
    length: int,
) -> None

polyphase_analyze(
    values: Iterable[Number], modulus: int,
) -> ArithmeticPolyphase

polyphase_synthesize(
    channels: Iterable[Iterable[Number]],
    length: int | None = None,
) -> tuple[Number, ...]

mahler_polyphase(
    series: MahlerSeries, modulus: int, address: int,
) -> MahlerSeries

mixed_radix_address(
    digits: Iterable[int], radices: Iterable[int],
) -> int

mixed_radix_digits(
    address: int, radices: Iterable[int],
) -> tuple[int, ...]
```

`ArithmeticPolyphase` supplies `reconstruct()`, `nested(inner_modulus)`, `refine(fine_modulus)`, and `coarsen(coarse_modulus)`. Refinement requires the fine modulus to be divisible by the current modulus. Coarsening requires a divisor. The direct constructor does not run a `__post_init__` schema check, so normal code should use `polyphase_analyze` or a trusted portable decoder.

```
ArithmeticPolyphase.reconstruct(self) -> tuple[Number, ...]
ArithmeticPolyphase.nested(
    self, inner_modulus: int,
) -> tuple[ArithmeticPolyphase, ...]
ArithmeticPolyphase.refine(
    self, fine_modulus: int,
) -> ArithmeticPolyphase
ArithmeticPolyphase.coarsen(
    self, coarse_modulus: int,
) -> ArithmeticPolyphase
```

Nested residue digits are least-significant first:

$$j = d_0 + r_0 d_1 + r_0 r_1 d_2 + \cdots .$$

```
from komorebi_math.arithmetic import (
    mixed_radix_address,
    mixed_radix_digits,
    polyphase_analyze,
)

values = tuple(range(13))
coordinates = polyphase_analyze(values, 4)
address = mixed_radix_address((2, 1, 3), (4, 3, 5))

print(coordinates.channels)
print(coordinates.reconstruct() == values)
print(address, mixed_radix_digits(address, (4, 3, 5)))
```

Output:

```
((0, 4, 8, 12), (1, 5, 9), (2, 6, 10), (3, 7, 11))
True
42 (2, 1, 3)
```

Analysis and synthesis are linear in the number of stored values plus the number of channels. Refinement and coarsening likewise rearrange finite values without approximation.

25.5.5 Portable persistence

`ArithmeticPolyphase` is the only Chapter 25 model with a registered portable object codec in `1.0.0b4`. Its tag is `arithmetic.polyphase_coordinates`, version 1. Fractions and other supported portable scalars inside its channels are encoded by the common persistence layer.

```
from fractions import Fraction

from komorebi_math.arithmetic import polyphase_analyze
from komorebi_math.export.persistence import dumps_portable, loads_portable

coordinates = polyphase_analyze(
    (Fraction(n + 1, n + 3) for n in range(9)),
    3,
)
restored = loads_portable(dumps_portable(coordinates))

assert restored == coordinates
assert restored.reconstruct() == coordinates.reconstruct()
```

`HurwitzSeries`, `StandardWindow`, `EulerLocalCoordinates`, `MahlerSeries`, and the recurrence objects do not have registered portable object codecs in this release. Persist their primitive constructor fields under an application-owned schema, then reconstruct and rerun the appropriate certificate. Do not rely on Python `repr`, pickle, or an undocumented dataclass layout as a durable public format.

25.6 Recurrence packets

25.6.1 State convention and matrix primitives

`LinearRecurrence` uses the convention

$$x_{n+d} = \sum_{i=0}^{d-1} c_i x_{n+i}, \qquad X_n = (x_n, \dots, x_{n+d-1})^T, \qquad X_{n+1} = CX_n.$$

The matrix helpers are

```
matrix_power_exact(matrix: np.ndarray, exponent: int) -> np.ndarray
matrix_power_mod(
    matrix: np.ndarray, exponent: int, modulus: int,
) -> np.ndarray
determinant_integer(matrix: np.ndarray) -> int
```

Both power functions use binary exponentiation on square object arrays. `matrix_power_mod` requires integral entries and reduces after every multiply. `determinant_integer` performs exact fraction elimination and rejects a final nonintegral determinant.

25.6.2 `LinearRecurrence`

```
LinearRecurrence(
    coefficients: Iterable[Number],
    initial: Iterable[Number],
    *,
    name: str | None = None,
) -> None
```

The coefficient and initial tuples must be nonempty numeric data of the same length. Booleans are rejected.

Member	Signature or result
`order`	Recurrence order d
`companion_matrix`	Exact object-array transition matrix
`initial_state`	$(x_0, \dots, x_{d-1})$
`term(index)`	Cached sequential evaluation
`term_mod(index, modulus)`	Modular term by binary matrix powering
`first(count)`	Prefix tuple
`state(index)`	State X_n
`jump_matrix(modulus)`	Exact C^m, where the argument is the packet stride m
`residue_packet(modulus, address)`	Validated packet factory
`period_mod(modulus, *, max_steps=None)`	Exact finite-state orbit classification
`characteristic_polynomial()`	Ascending coefficients $(-c_0, \dots, -c_{d-1}, 1)$
`jump_characteristic_polynomial(modulus)`	Exact characteristic polynomial of C^m
`certificate(count=20)`	Recurrence and state-evolution check

```
LinearRecurrence.order: int
LinearRecurrence.companion_matrix: np.ndarray
LinearRecurrence.initial_state: np.ndarray
LinearRecurrence.term(self, index: int) -> Number
LinearRecurrence.term_mod(
    self, index: int, modulus: int,
) -> int
LinearRecurrence.first(self, count: int) -> tuple[Number, ...]
```

```
LinearRecurrence.state(self, index: int) -> np.ndarray
LinearRecurrence.jump_matrix(self, modulus: int) -> np.ndarray
LinearRecurrence.residue_packet(
    self, modulus: int, address: int,
) -> RecurrencePacket
LinearRecurrence.period_mod(
    self, modulus: int, *, max_steps: int | None = None,
) -> OrbitPeriod
LinearRecurrence.characteristic_polynomial(
    self,
) -> tuple[Number, ...]
LinearRecurrence.jump_characteristic_polynomial(
    self, modulus: int,
) -> tuple[Number, ...]
LinearRecurrence.certificate(
    self, count: int = 20,
) -> ComputationResult[tuple[Number, ...]]
```

The parameter name `modulus` has two meanings in this class. In `term_mod` and `period_mod` it is an arithmetic modulus. In `jump_matrix`, `residue_packet`, and `jump_characteristic_polynomial` it is the residue-packet stride m. The latter methods compute C^m over the original scalar domain, not modulo m.

`jump_characteristic_polynomial` requires optional SymPy. Every other member in the table works without SymPy.

`fibonacci_recurrence()` and `lucas_recurrence()` construct

$$F_{n+2} = F_{n+1} + F_n, \quad (F_0, F_1) = (0, 1),$$

$$L_{n+2} = L_{n+1} + L_n, \quad (L_0, L_1) = (2, 1).$$

The complete auxiliary signatures are

```
fibonacci_recurrence() -> LinearRecurrence
lucas_recurrence() -> LinearRecurrence
second_order_trace(
    first: Number, determinant: Number, index: int,
) -> Number
second_order_jump(
    first: Number, determinant: Number, modulus: int,
) -> tuple[Number, Number]
```

For a second-order matrix with trace T and determinant D,

$$V_0 = 2, \qquad V_1 = T, \qquad V_n = TV_{n-1} - DV_{n-2},$$

and the stride-m packet has trace V_m and determinant D^m.

25.6.3 `RecurrencePacket` and modular periods

A validated residue packet obeys

$$X_{mk+r} = (C^m)^k X_r.$$

Its record signature is

```
RecurrencePacket(
    recurrence: LinearRecurrence,
    modulus: int,
```

```
    address: int,
) -> None
```

and its members are `jump_matrix`, `initial_state`, `state(packet_index)`, `term(packet_index)`, `term_mod(packet_index, modulus)`, `first(count)`, and `certificate(count=10)`.

```
RecurrencePacket.jump_matrix: np.ndarray
RecurrencePacket.initial_state: np.ndarray
RecurrencePacket.state(self, packet_index: int) -> np.ndarray
RecurrencePacket.term(self, packet_index: int) -> Number
RecurrencePacket.term_mod(
    self, packet_index: int, modulus: int,
) -> int
RecurrencePacket.first(self, count: int) -> tuple[Number, ...]
RecurrencePacket.certificate(
    self, count: int = 10,
) -> ComputationResult[tuple[Number, ...]]
```

Use `recurrence.residue_packet(m, r)` in normal code. The bare dataclass constructor does not validate that $m > 0$ and $0 \le r < m$. The factory does.

```
from komorebi_math.arithmetic import fibonacci_recurrence

fibonacci = fibonacci_recurrence()
packet = fibonacci.residue_packet(modulus=7, address=3)
packet.certificate(count=6).certificate.require()

print(packet.first(6))
print(fibonacci.term_mod(1_000_000, 1_000_003))
print(fibonacci.period_mod(32).period)
```

Output:

```
(2, 55, 1597, 46368, 1346269, 39088169)
3
48
```

`OrbitPeriod` stores `modulus`, `preperiod`, `period`, `states_checked`, `purely_periodic`, and an exact `certificate`. If the companion determinant is a unit modulo M, the transition is invertible and a valid orbit must have preperiod zero.

```
OrbitPeriod(
    modulus: int,
    preperiod: int,
    period: int,
    states_checked: int,
    purely_periodic: bool,
    certificate: Certificate,
) -> None
```

The default period-search budget is $M^d + 1$ states. Time and memory can therefore grow exponentially in recurrence order d. Set `max_steps` explicitly for untrusted or exploratory moduli. Exhausting that budget raises `ValidationError` rather than returning a guessed period.

Operation	Current direct cost, excluding scalar bit complexity
Cached `term(n)` after a cold start	$O(nd)$
`term_mod(n, M)`	$O(d^3 \log n)$ dense matrix work
Exact `jump_matrix(m)`	$O(d^3 \log m)$
Packet state at k	$O(d^3(\log m + \log k))$ because the jump matrix is rebuilt
`period_mod(M)`	Up to $O(M^d d^2)$ work and $O(M^d d)$ stored state

Operation	Current direct cost, excluding scalar bit complexity

Recurrence and packet certificates label rational data `EXACT` and other numeric data `NUMERICAL`. Numerical validation uses direct equality of computed states. It does not supply tolerances, forward-error bounds, or conditioning analysis.

25.7 Carmichael jumps, local modes, and simultaneous congruences

25.7.1 Scalar finite differences

The exact scalar difference is

$$\Delta_h^r f(n) = \sum_{k=0}^{r} (-1)^{r-k} \binom{r}{k} f(n + kh).$$

The interfaces are

```
finite_difference_value(
    function: Callable[[int], int],
    index: int,
    step: int,
    order: int,
) -> int

certify_difference_congruence(
    function: Callable[[int], int],
    index: int,
    step: int,
    order: int,
    modulus: int,
) -> DifferenceCongruence
```

Every sampled function value must be an integer and cannot be boolean. The record

```
DifferenceCongruence(
    value: int,
    modulus: int,
    certificate: Certificate,
) -> None
```

reports whether the computed difference is divisible by the requested positive modulus. It proves only that finite calculation. It does not infer a uniform theorem over other indices or orders.

25.7.2 Precision-selected unit modes

```
local_unit_jump(prime: int, depth: int) -> int

unit_mode_for_precision(
    base: int,
    prime: int,
    depth: int,
    *,
    residue: int = 0,
) -> UnitModeMahler
```

`local_unit_jump` is the prime-power Carmichael exponent from Section 25.1. `unit_mode_for_precision` additionally verifies that the base is a unit at the prime, then returns the Mahler mode with that jump.

For $h = \lambda(p^d)$,

$$u^h \equiv 1 \pmod{p^d}, \qquad v_p(\Delta_h^r u^n) \geq dr.$$

```
from komorebi_math.arithmetic import (
    certify_difference_congruence,
    local_unit_jump,
    unit_mode_for_precision,
)

mode = unit_mode_for_precision(7, prime=5, depth=2, residue=3)
record = certify_difference_congruence(
    lambda n: 7**n,
    index=2,
    step=mode.jump,
    order=3,
    modulus=5**6,
)
record.certificate.require()

print(local_unit_jump(5, 2), mode.valuation_slope(5))
print(record.value % record.modulus, record.certificate.valid)
```

Output:

```
20 3
0 True
```

The achieved valuation slope can exceed the universal lower bound. Here $v_5(7^{20}-1) = 3$, so an order-three difference gains valuation nine while the requested certificate uses only 5^6.

25.7.3 One jump for several primes

```
simultaneous_unit_difference(
    base: int,
    primes_and_depths: dict[int, int],
    *,
    index: int,
    order: int,
) -> ComputationResult[dict[int, int]]
```

For local requirements ((p_i,d_i)), the function chooses

$$h = \operatorname{lcm}_i \lambda(p_i^{d_i})$$

and evaluates the exact integer

$$u^n(u^h - 1)^r.$$

The result value maps each prime to its achieved valuation. The certificate is valid when

$$v_{p_i}(\Delta_h^r u^n) \geq d_i r$$

at every requested prime.

```
from komorebi_math.arithmetic import simultaneous_unit_difference
```

```
result = simultaneous_unit_difference(
    7,
    {2: 4, 3: 3, 5: 2},
    index=2,
    order=3,
)
result.certificate.require()

print(result.certificate.diagnostics["common_jump"])
print(result.value)
```

Output:

```
180
{2: 15, 3: 9, 5: 9}
```

Every requested prime is validated and the base must be a unit at all of them. A base divisible by even one requested prime raises `ValidationError`.

> **Recorded baseline defect.** In the audited `1.0.0b4` source, `simultaneous_unit_difference` converted each reported valuation to `int`. For $u = 1$, and also for $u = -1$ when the common jump is even, the difference is exactly zero for positive order and its valuation is $+\infty$. That baseline conversion raised `OverflowError: cannot convert float infinity to integer`. When using that baseline, handle these zero-difference modes separately or use `finite_difference_value` with `padic_valuation`, preserving `float("inf")`.

The simultaneous routine constructs the full integer $u^n(u^h - 1)^r$ and stores it in certificate diagnostics. It is exact but can consume substantial time, memory, and report space. Budget the common jump and order before using many primes or deep local precisions. It is not implemented as a modular-only valuation algorithm.

25.7.4 Failure matrix

Request	Result
Composite valuation base or field characteristic	Prime validation failure
Nonunit modular inverse	`ValidationError`
Negative factorial index or invalid valuation binomial indices	`ValidationError`
Modular Hurwitz float coefficient	`ValidationError`
Hurwitz inverse with nonunit constant	`ValidationError`
Window with $p = 2$ or $m \nmid p - 1$, followed by a period-dependent call	`ValidationError`
Odd Euler reconstruction index	`ValidationError`
Mahler valuation ledger with float or complex coefficients	`ValidationError`
Modular recurrence with nonintegral data	`ValidationError`
Recurrence orbit exceeds `max_steps`	`ValidationError`
Jump characteristic polynomial without SymPy	`BackendUnavailableError`
Local unit mode with a base divisible by the prime	`ValidationError`
Simultaneous zero-difference mode $u = \pm 1$, positive order	Recorded baseline `OverflowError` defect

25.7.5 Executed evidence

The discussion was audited against the shipped `1.0.0b4` source, not inferred from the symbolic outline alone. The focused replay covered

```
tests/test_arithmetic_domains_valuation.py
tests/test_arithmetic_hurwitz_windows.py
tests/test_arithmetic_euler.py
tests/test_arithmetic_mahler_polyphase.py
tests/test_arithmetic_recurrence.py
```

and produced

```
31 passed
```

The installed arithmetic verifier produced

```
verification passed 7/7 checks
```

Those seven checks cover Hurwitz multiplication and inversion, the standard window period, odd and dyadic Euler coordinates, Mahler transfer, recurrence packets and modular periods, the compressed inverse recurrence, and simultaneous local valuation gains. The portable `ArithmeticPolyphase` roundtrip is additionally exercised by the recorded polyphase persistence suite.

Chapter 25 summary. Use finite rings to make reduction explicit, valuation functions to measure local divisibility, Hurwitz series for exact EGF convolution, and standard windows only under their odd-prime subgroup assumptions. Euler charts provide distinct odd and dyadic kernels with finite congruence certificates. Mahler coordinates convert values and affine residue branches into exact binomial-basis coefficients. Arithmetic polyphase is the stable, portable residue layout. Recurrence packets replace a fine state step by an exact jump matrix, while modular execution avoids constructing huge recurrence integers. Carmichael jumps certify finite local gains. In the recorded baseline, the simultaneous routine constructs a potentially enormous exact difference and has the zero-difference reporting defect documented above. Every certificate is bounded by its executed indices, degree, precision, or orbit budget.

26. Exact sequence execution

First route. Select a catalog sequence or wrap a custom evaluator, then inspect a small finite prefix. If compiling, require the returned certificate before using the selected model. For a very large index, decide whether you need the full exact term or only its residue, then consult Section 26.6 for the available execution route. A lazy view still needs an explicit stopping point when you turn it into a list or report.

The sequence subsystem turns a rule $a : \mathbb{N} \to \mathcal{R}$ into a finite, inspectable execution object. It supports four distinct ideas that should not be conflated:

1. a lazy evaluator that computes and caches requested terms
2. a declared finite model, such as a recurrence or automaton
3. a compiler that selects a declared model or fits a constant recurrence to a finite prefix
4. a certificate that records exactly what was checked

The implementation is finite even when the mathematical sequence is infinite. Every certificate covers a declared model or a finite prefix. A prefix-fitted recurrence is an extrapolation model, not an automatically proved identity.

The exact workflows in this chapter use integers and `Fraction` values. The `Sequence` constructor itself accepts any Python numeric value, including floating and complex values. Its `exact` field is user-supplied metadata. It does not inspect the evaluator or prove exact scalar arithmetic.

26.1 Sequence protocol and catalog

26.1.1 API tier and import boundary

Sequence execution is part of the **research API** in `1.0.0b4`. No sequence symbol belongs to the frozen `komorebi_math.stable` or `komorebi_math.beta` manifests.

Surface	Role	Sequence coverage
`komorebi_math.sequences`	authoritative sequence namespace	all 36 exported names in this chapter
`komorebi_math`	convenient research root	the principal classes, compiler, and selected catalog constructors
`komorebi_math.beta`	frozen beta surface	none
`komorebi_math.stable`	frozen stable surface	none

The namespace export ledger is complete as follows.

Group	Exported names
feature	`FEATURE_KEY`, `status`, `require`
records and alias	`Sequence`, `AutomaticSequence`, `HolonomicRecurrence`, `CompiledSequence`, `Polynomial`
catalog	`fibonacci_sequence`, `lucas_sequence`, `signed_euler_sequence`, `euler_zigzag_sequence`, `bernoulli_sequence`, `catalan_sequence`, `bell_sequence`, `motzkin_sequence`, `partition_sequence`, `apery_sequence`, `thue_morse_sequence`, `sequence_catalog`, `get_sequence`
automatic	`base_digits`, `thue_morse_automaton`
holonomic	`evaluate_polynomial`, `motzkin_recurrence`, `apery_recurrence`
compiler	`detect_linear_recurrence`, `recurrence_generating_function`, `compile_sequence`

Group	Exported names
transforms	`binomial_transform_values`, `inverse_binomial_transform_values`, `binomial_transform`, `inverse_binomial_transform`, `finite_difference`, `partial_sums`, `cauchy_product`

`FEATURE_KEY` is the literal string `"sequences"`.

The research root exports these sequence objects directly:

```
from komorebi_math import (
    AutomaticSequence,
    CompiledSequence,
    HolonomicRecurrence,
    Sequence,
    apery_sequence,
    compile_sequence,
    fibonacci_sequence,
    get_sequence,
    motzkin_sequence,
    partition_sequence,
    thue_morse_sequence,
)
```

Use the namespace import for the complete facility:

```
from komorebi_math.sequences import (
    Sequence,
    binomial_transform,
    finite_difference,
    lucas_sequence,
    partial_sums,
)
```

> **Name-collision warning.** `komorebi_math.binomial_transform` is the dense coordinate-transform constructor from `komorebi_math.coordinates`, not the lazy sequence transform. `komorebi_math.finite_difference` is the polynomial expression primitive, not the sequence finite difference. Import both sequence functions from `komorebi_math.sequences`.

The feature probe is descriptive:

```
from komorebi_math import sequences

print(sequences.status().status.value)
sequences.require()
```

`status()` returns the registry record for the sequence feature. `require()` returns `None`. Neither function validates a particular sequence or executes a certificate.

26.1.2 `Sequence`

The concrete lazy wrapper has the signature

```
Sequence(
    evaluator: Callable[[int], Number],
    *,
    name: str = "sequence",
    exact: bool = True,
```

```
    metadata: dict[str, Any] | None = None,
) -> None
```

It models

$$a : \mathbb{N} \longrightarrow \mathcal{R}$$

with cached numeric evaluation carrying an explicit exactness flag. The evaluator is called only when an index is absent from the instance cache. Different `Sequence` instances have independent caches, even when they wrap the same function.

Member	Return	Contract
`name`	`str`	display label produced with `str(name)`
`exact`	`bool`	constructor metadata, not a proof
`metadata`	`dict[str, Any]`	shallow copy of the supplied mapping
`term(index)`	`Number`	evaluate and cache one nonnegative integer index
`first(count)`	`tuple[Number, ...]`	terms $a_0, \ldots, a_{N-1}$
`residue(modulus, address)`	`Sequence`	lazy subsequence a_{mk+r}
`modulo(modulus)`	`Sequence`	lazy integral residue $a_k \bmod M$
`map(function, *, name=None, exact=None)`	`Sequence`	lazy scalar map with explicit exactness override
`sequence[index]`	`Number`	alias for `term(index)`
`sequence[start:stop:step]`	`tuple`	finite nonnegative slice with positive step
`iter(sequence)`	iterator	unbounded lazy iteration from index zero

The two primary views are

$$\operatorname{residue}_{m,r}(a)(k) = a_{mk+r}, \qquad \operatorname{modulo}_{M}(a)(k) = a_k \bmod M.$$

`residue(m, r)` requires $m \geq 1$ and $0 \leq r < m$. `modulo(M)` requires $M \geq 2$. Both return new caching wrappers. The residue view delegates to and therefore fills the parent cache. The modular view first obtains a parent term, then requires it to be a rational scalar with denominator one.

`map` propagates the parent's exactness flag unless `exact=` is supplied. Because this is metadata propagation, the declaration below is permitted but mathematically dishonest:

```
Sequence(lambda n: 0.1 * n, exact=True)
```

Callers are responsible for choosing `exact=False` when the evaluator returns floating approximations.

26.1.3 Lazy views and finite slices

```
from komorebi_math.sequences import Sequence

squares = Sequence(lambda n: n * n, name="squares")

print(squares.first(8))
print(squares.residue(3, 1).first(6))
print(squares.modulo(5).first(8))
print(squares[2:10:2])
print(squares.map(lambda x: x + 1, name="square plus one").first(6))
```

Output:

```
(0, 1, 4, 9, 16, 25, 36, 49)
(1, 16, 49, 100, 169, 256)
(0, 1, 4, 4, 1, 0, 1, 4)
(4, 16, 36, 64)
(1, 2, 5, 10, 17, 26)
```

A slice must have a finite stop. Bounds must be nonnegative and the step must be positive. Integer indices, counts, moduli, addresses, and slice components reject booleans and floating coercions. Infinite iteration is intentionally unbounded, so consumers should apply their own limit:

```
from itertools import islice

first_twenty = tuple(islice(squares, 20))
```

26.1.4 Cache and concurrency boundary

The common wrapper has no eviction policy or built-in term budget. If U distinct indices are requested, its cache retains U numeric objects for the lifetime of the wrapper. Exact integers and rationals can grow much larger than the number of cached entries suggests.

`Sequence`, `HolonomicRecurrence`, and `LinearRecurrence` use mutable caches without a synchronization contract. Treat an instance as one execution context. Concurrent applications should use external synchronization or separate instances.

26.2 Fibonacci, Lucas, Catalan, Bell, and built-in families

26.2.1 Constructor catalog

Every catalog constructor takes no arguments and returns a fresh `Sequence`.

```
fibonacci_sequence() -> Sequence
lucas_sequence() -> Sequence
signed_euler_sequence() -> Sequence
euler_zigzag_sequence() -> Sequence
bernoulli_sequence() -> Sequence
catalan_sequence() -> Sequence
bell_sequence() -> Sequence
motzkin_sequence() -> Sequence
partition_sequence() -> Sequence
apery_sequence() -> Sequence
thue_morse_sequence() -> Sequence
```

The defining conventions are:

$$F_{n+2} = F_{n+1} + F_n, \qquad (F_0, F_1) = (0, 1),$$

$$L_{n+2} = L_{n+1} + L_n, \qquad (L_0, L_1) = (2, 1),$$

$$C_n = \frac{1}{n+1}\binom{2n}{n}, \qquad B_{n+1} = \sum_{k=0}^{n} \binom{n}{k} B_k,$$

$$n\,p(n) = \sum_{k=1}^{n} \sigma(k) p(n-k), \qquad p(0) = 1,$$

and

$$t_{2n} = t_n, \qquad t_{2n+1} = 1 - t_n, \qquad t_0 = 0.$$

The signed Euler sequence uses the coefficients of `sech`, the zigzag sequence uses the coefficients of `sec + tan`, and the Bernoulli constructor uses the convention $B_1 = -\frac{1}{2}$:

$$\operatorname{sech}(z) = \sum_{n\geq 0} E_n \frac{z^n}{n!}, \qquad \sec(z) + \tan(z) = \sum_{n\geq 0} A_n \frac{z^n}{n!},$$

$$\sum_{k=0}^{n} \binom{n+1}{k} B_k = 0 \quad (n \geq 1).$$

Motzkin and Apéry numbers are executed through the holonomic models in Section 26.4. Fibonacci and Lucas numbers carry declared constant-recurrence metadata. Thue-Morse carries a declared automatic model. The remaining catalog objects use their direct evaluator.

26.2.2 Exact prefixes

Constructor	First eight terms
`fibonacci_sequence`	`0, 1, 1, 2, 3, 5, 8, 13`
`lucas_sequence`	`2, 1, 3, 4, 7, 11, 18, 29`
`signed_euler_sequence`	`1, 0, -1, 0, 5, 0, -61, 0`
`euler_zigzag_sequence`	`1, 1, 1, 2, 5, 16, 61, 272`
`bernoulli_sequence`	`1, -1/2, 1/6, 0, -1/30, 0, 1/42, 0`
`catalan_sequence`	`1, 1, 2, 5, 14, 42, 132, 429`
`bell_sequence`	`1, 1, 2, 5, 15, 52, 203, 877`
`motzkin_sequence`	`1, 1, 2, 4, 9, 21, 51, 127`
`partition_sequence`	`1, 1, 2, 3, 5, 7, 11, 15`
`apery_sequence`	`1, 5, 73, 1445, 33001, 819005, 21460825, 584307365`
`thue_morse_sequence`	`0, 1, 1, 0, 1, 0, 0, 1`

Motzkin and Apéry terms are represented internally as `Fraction` values, even when their denominators are one. The table prints their mathematical integer values for readability.

26.2.3 Named lookup and aliases

```
sequence_catalog() -> dict[str, Sequence]
get_sequence(name: str) -> Sequence
```

`sequence_catalog()` constructs and returns a new dictionary on every call. Its keys, in insertion order, are

```
apery, bell, bernoulli, catalan, euler, fibonacci, lucas,
motzkin, partition, thue-morse, zigzag
```

`get_sequence` strips the supplied string, lowercases it, and replaces underscores by hyphens. It then applies the aliases below.

Accepted alias	Catalog key
`apery-zeta3`	`apery`
`euler-zigzag`	`zigzag`
`signed-euler`	`euler`
`thue-morse`	`thue-morse`
`thuemorse`	`thue-morse`

Accepted alias	Catalog key

An unknown name raises `KeyError` with the original spelling in the message. Aliases are lookup conveniences only. They do not add keys to `sequence_catalog()`.

```
from komorebi_math.sequences import get_sequence

for name in ("FIBONACCI", "apery_zeta3", "thuemorse"):
    sequence = get_sequence(name)
    print(name, sequence.name, sequence.first(6))
```

Output:

```
FIBONACCI Fibonacci (0, 1, 1, 2, 3, 5)
apery_zeta3 Apery (1, 5, 73, 1445, 33001, 819005)
thuemorse Thue Morse (0, 1, 1, 0, 1, 0)
```

The actual Apéry tuple contains denominator-one `Fraction` objects.

26.2.4 Catalog execution costs

The table below counts high-level arithmetic operations and omits the growing bit cost of exact integers and rationals.

Family	Current execution path	Prefix cost through $N-1$	Stored state
Fibonacci, Lucas	order-two sequential recurrence	$O(N)$	$O(N)$ cached terms
Motzkin, Apéry	order-two holonomic recurrence	$O(N)$	$O(N)$ rational terms
Thue-Morse	two-state DFAO	$O(N \log N)$ through the wrapper	$O(N)$ wrapper cache
Bell	incremental triangular recurrence	$O(N^2)$	$O(N)$
partitions	divisor sums plus convolution	$O(N^2)$	$O(N)$ values and divisor sums
signed Euler, zigzag, Bernoulli	each newly requested term rebuilds a helper prefix	up to $O(N^3)$	$O(N)$ wrapper cache
Catalan	one exact binomial coefficient per term	governed by integer binomial cost	$O(N)$ wrapper cache

The $O(N^3)$ entry describes the current wrapper behavior, not an inherent complexity of those sequences. It arises because each scalar evaluator asks an arithmetic helper to rebuild all coefficients through that index. Applications requiring very long prefixes should call the corresponding bulk arithmetic helper or implement a bounded incremental cache.

No catalog constructor accepts a term, byte, time, or digit budget. Bound the largest index before evaluation. Prefer modular recurrence execution when only a residue of a very large Fibonacci or Lucas index is required.

26.3 Automatic sequences

An automatic sequence is represented by a deterministic finite automaton with numeric output, abbreviated DFAO. For base $b \geq 2$, state set Q, transition map δ, initial state q_0, and output map τ,

$$a_n = \tau\Big(\delta^{*}\big(q_0, \operatorname{digits}_b(n)\big)\Big)\,.$$

Digits are read from most significant to least significant in this namespace. The canonical expansion of zero is the one-digit tuple `(0,)`.

This order differs from the carry and Cartier machines in Chapter 23. Before transferring a transition table or a digit-processing loop between subsystems, check the producer's convention on an index with unequal digits. The binary digits of two, for example, are read as one then zero here and as zero then one by a least-significant-first machine.

26.3.1 Functions and constructor

```
base_digits(index: int, base: int) -> tuple[int, ...]

AutomaticSequence(
    base: int,
    transitions: Iterable[Iterable[int]],
    outputs: Iterable[Number],
    *,
    initial_state: int = 0,
    name: str = "automatic sequence",
) -> None

thue_morse_automaton() -> AutomaticSequence
```

The transition table has one row per state and one column per base digit. The entry in row q, column d is $\delta(q, d)$.

Constructor condition	Failure
base is not an integer or is below two	`ValidationError`
no state rows	`ValidationError`
row length differs from the base	`DimensionError`
output count differs from state count	`DimensionError`
output is Boolean or nonnumeric	`ValidationError`
transition target lies outside the state range	`ValidationError`
initial state lies outside the state range	`ValidationError`
initial state's zero transition is not itself	`ValidationError`

The final condition enforces canonical leading-zero invariance:

$$\delta(q_0, 0) = q_0.$$

It does not require a zero loop at every other state.

26.3.2 Member reference

Field or member	Return	Contract
`base`	`int`	digit radix b
`transitions`	tuple of tuples	immutable state transition table
`outputs`	tuple	one numeric output per state
`initial_state`	`int`	initial row index
`name`	`str`	display label
`state_count`	`int`	number of table rows
`state(index)`	`int`	terminal state after the canonical base digits
`term(index)`	`Number`	output at `state(index)`

Field or member	Return	Contract
`first(count)`	`tuple`	finite prefix
`residue_model(power, address)`	`AutomaticSequence`	model for $a_{b^e n+r}$
`to_sequence()`	`Sequence`	common wrapper with certified automatic metadata
`certificate(count=256)`	`ComputationResult`	finite internal table/evaluation check

For $e \geq 0$ and $0 \leq r < b^e$, the residue model satisfies

$$\text{residue_model}(e, r)(n) = a_{b^e n+r}.$$

The fixed e low digits of the address are applied after the input digits. For `power=0`, the modulus is one and the returned model is equivalent to the original.

26.3.3 Thue-Morse transition card

The built-in binary parity automaton is

State	digit `0`	digit `1`	output
0	0	1	0
1	1	0	1

Equivalently, the labeled transition graph is

$$0 \xrightarrow{0} 0, \qquad 0 \xrightarrow{1} 1, \qquad 1 \xrightarrow{0} 1, \qquad 1 \xrightarrow{1} 0.$$

State zero represents even binary digit parity. State one represents odd parity. The transition table immediately gives

$$t_{2n} = t_n, \qquad t_{2n+1} = 1 - t_n.$$

26.3.4 Automatic execution example

```
from komorebi_math.sequences import base_digits, thue_morse_automaton

model = thue_morse_automaton()
record = model.certificate(1000)
record.certificate.require()

packets = {
    (power, address): model.residue_model(power, address)
    for power in range(5)
    for address in range(2**power)
}

for (power, address), packet in packets.items():
    modulus = 2**power
    assert packet.first(64) == tuple(
        model.term(modulus * n + address) for n in range(64)
    )

print(base_digits(13, 2))
print(model.state_count)
print(model.first(16))
```

```
print(model.residue_model(4, 7).first(20))
print(record.certificate.diagnostics)
print(len(packets))
```

Output:

```
(1, 1, 0, 1)
2
(0, 1, 1, 0, 1, 0, 0, 1, 1, 0, 0, 1, 0, 1, 1, 0)
(1, 0, 0, 1, 0, 1, 1, 0, 0, 1, 1, 0, 1, 0, 0, 1, 0, 1, 1, 0)
{'base': 2, 'states': 2, 'count': 1000}
31
```

There are (1+2+4+8+16=31) residue models below (2^5).

26.3.5 Certificate and cost boundary

The automatic certificate has theorem identifier `PSC-SEQ-AUTOMATIC` and exactness `Exactness.EXACT`. It records the base, state count, and checked prefix length. Constructor validation proves that the finite tables are well-formed. The certificate then checks finite evaluation consistency using those same tables. It does **not** prove that a separately defined infinite sequence is represented by this automaton.

> **Automatic-output exactness caveat.** The constructor accepts floating and complex numeric outputs, while `certificate()` still labels deterministic table execution `Exactness.EXACT` and `to_sequence()` sets `exact=True`. That label establishes exact lookup of the stored output object. It does not turn an approximate floating output into an exact mathematical scalar. Use integers or `Fraction` outputs for exact sequence claims.

For $n > 0$, `term(n)` performs

$$\lfloor \log_b n \rfloor + 1$$

table transitions and uses constant additional memory. Constructing one residue model applies e fixed low digits to each state, then reconstructs and validates the full transition table. Its cost is $O(|Q|(e+b))$, and its stored table and outputs occupy $O(|Q|b)$ entries. Converting it to `Sequence` adds an unbounded term cache.

26.4 Holonomic recurrences

A holonomic sequence satisfies a polynomial-coefficient recurrence

$$\sum_{j=0}^{r} P_j(n) a_{n+j} = 0.$$

Komorebi Math stores every polynomial in ascending powers and every coefficient as `Fraction`. To compute the next value it divides by $P_r(n)$, which must be nonzero at each executed index.

26.4.1 Types, functions, and constructor

```
Polynomial = tuple[Fraction, ...]

evaluate_polynomial(
    coefficients: Iterable[Rational],
    value: int,
) -> Fraction

HolonomicRecurrence(
    polynomials: Iterable[Iterable[Rational]],
    initial: Iterable[Rational],
```

```
    *,
    name: str = "holonomic recurrence",
) -> None

motzkin_recurrence() -> HolonomicRecurrence
apery_recurrence() -> HolonomicRecurrence
```

For

$$P(n) = c_0 + c_1 n + \cdots + c_d n^d,$$

the stored tuple is `(c0, c1, ..., cd)`. Trailing zeros are removed. An empty coefficient iterable is normalized to the zero polynomial `(0,)` rather than rejected. The final recurrence polynomial may not be identically zero.

26.4.2 Member reference

Field or member	Return	Contract
`polynomials`	tuple of `Polynomial`	$P_0, \ldots, P_r$ in ascending powers
`initial`	tuple of `Fraction`	exactly r seed values
`name`	`str`	display label
`order`	`int`	number of initial values and final shift
`coefficient(shift, index)`	`Fraction`	$P_{\text{shift}}(n)$
`term(index)`	`Fraction`	cached exact execution through the requested index
`first(count)`	tuple of `Fraction`	finite exact prefix
`to_sequence()`	`Sequence`	wrapper with certified holonomic metadata
`certificate(count=32)`	`ComputationResult`	exact recurrence residual check on a finite prefix

The update is

$$a_{n+r} = -\frac{1}{P_r(n)} \sum_{j=0}^{r-1} P_j(n) a_{n+j}.$$

26.4.3 Motzkin recurrence from the source tuples

The built-in Motzkin constructor uses

```
P0 = (-3, -3)
P1 = (-5, -2)
P2 = (4, 1)
initial = (1, 1)
```

Therefore its declared equation is

$$(-3 - 3n)M_n + (-5 - 2n)M_{n+1} + (n + 4)M_{n+2} = 0,$$

or equivalently

$$(n + 4)M_{n+2} = (2n + 5)M_{n+1} + 3(n + 1)M_n.$$

Using $M_0 = M_1 = 1$,

$$M_2 = 2, \quad M_3 = 4, \quad M_4 = 9, \quad M_5 = 21.$$

This equation is derived directly from the shipped ascending tuples. It avoids the indexing error that can arise when copying a recurrence stated with M_{n-1} and M_{n-2}.

26.4.4 Apéry recurrence

The Apéry model uses

$$(n+1)^3 A_n - \left(34(n+1)^3 + 51(n+1)^2 + 27(n+1) + 5\right) A_{n+1} + (n+2)^3 A_{n+2} = 0,$$

$$(A_0, A_1) = (1, 5).$$

Its ascending source tuples are

```
P0 = (1, 3, 3, 1)
P1 = (-117, -231, -153, -34)
P2 = (8, 12, 6, 1)
initial = (1, 5)
```

26.4.5 Direct holonomic example

```
from komorebi_math.sequences import apery_recurrence, motzkin_recurrence

motzkin = motzkin_recurrence()
apery = apery_recurrence()

motzkin.certificate(30).certificate.require()
apery.certificate(20).certificate.require()

print(motzkin.first(11))
print(apery.first(8))
print(motzkin.order, apery.order)
```

Output, with denominator-one `Fraction` wrappers suppressed:

```
(1, 1, 2, 4, 9, 21, 51, 127, 323, 835, 2188)
(1, 5, 73, 1445, 33001, 819005, 21460825, 584307365)
2 2
```

26.4.6 Validation and singular-leading-coefficient boundary

Construction rejects fewer than two shift polynomials, a seed count different from the order, Boolean or nonrational coefficients and seeds, and an identically zero final polynomial. A final polynomial that vanishes only at a particular nonnegative index is accepted at construction. Execution raises `ValidationError` when that index is reached.

```
from komorebi_math.sequences import HolonomicRecurrence

# a[n] + n*a[n+1] = 0 has a leading coefficient that vanishes at n = 0
singular = HolonomicRecurrence(((1,), (0, 1)), (1,))
singular.term(1)  # raises ValidationError at executed index 0
```

`certificate(count)` requires `count > order`. It computes the prefix with the same recurrence and then checks every declared residual exactly. It can raise before returning a record if the leading coefficient vanishes. A valid record proves that the computed finite prefix satisfies the declared recurrence. It does not independently identify a user-supplied external sequence.

An order-r prefix through $N-1$ takes $O(rN)$ polynomial evaluations and recurrence scalar operations after seeds, plus polynomial-evaluation cost. The implementation caches all computed terms, so storage is $O(N)$. Exact rational numerator and denominator growth can dominate both counts.

26.5 Exact compiler and strongest-model selection

The compiler does not synthesize every possible description of a sequence. It checks a fixed metadata order, then attempts one kind of finite inference. Its selection relation is

$$\begin{aligned}\text{declared constant recurrence} \succ \text{declared DFAO} \succ \text{declared holonomic model}\\ \succ \text{prefix-fitted recurrence} \succ \text{direct evaluator}.\end{aligned}$$

Here "strongest" means first in this implementation order. It does not mean that the compiler proves a globally minimal or mathematically canonical model.

26.5.1 Function signatures

```
detect_linear_recurrence(
    values: Iterable[Rational],
    *,
    max_order: int | None = None,
) -> LinearRecurrence | None

recurrence_generating_function(
    recurrence: LinearRecurrence,
) -> tuple[tuple[Fraction, ...], tuple[Fraction, ...]]

compile_sequence(
    sequence: Sequence,
    *,
    sample_count: int = 24,
    max_order: int | None = 8,
) -> CompiledSequence
```

`detect_linear_recurrence` accepts only non-Boolean integers and rationals. It requires at least three sample values. With no `max_order`, it searches through half the prefix length. With an explicit limit, it searches through the smaller of that limit and half the prefix length. Orders are tried from one upward, so the first returned recurrence has the smallest supported order under the finite linear-system procedure.

The recurrence convention is

$$a_{n+d} = \sum_{j=0}^{d-1} c_j a_{n+j}.$$

All systems are solved over `Fraction`. When the sample system is underdetermined, the implementation assigns zero to free variables and checks the resulting relation against the entire supplied prefix.

26.5.2 `CompiledSequence` record

The record signature is

```
CompiledSequence(
    sequence: Sequence,
    strategy: str,
    certificate: Certificate,
    recurrence: LinearRecurrence | None = None,
    automatic: AutomaticSequence | None = None,
```

```
    holonomic: HolonomicRecurrence | None = None,
) -> None
```

Applications normally obtain it from `compile_sequence` rather than invoke the dataclass constructor directly.

Field or member	Return	Contract
`sequence`	`Sequence`	original lazy evaluator
`strategy`	`str`	exact selected-strategy label
`certificate`	`Certificate`	finite agreement and provenance record
`recurrence`	`LinearRecurrence | None`	declared or detected constant model
`automatic`	`AutomaticSequence | None`	declared DFAO
`holonomic`	`HolonomicRecurrence | None`	declared polynomial recurrence
`term(index)`	`Number`	dispatch to selected model, else original evaluator
`first(count)`	tuple	dispatch to selected model, else original evaluator
`modulo(index, modulus)`	`int`	modular execution described in Section 26.6
`generating_function()`	pair of rational tuples	rational OGF only when `recurrence` is present

The exact strategy strings are:

```
declared linear recurrence
declared finite automaton
declared holonomic recurrence
detected linear recurrence
direct evaluator
```

26.5.3 Declared-model metadata

`compile_sequence` recognizes these metadata pairs in order:

Model key	Trust marker	Required model type
`recurrence`	`recurrence_certified`	`LinearRecurrence`
`automatic_model`	`automatic_certified`	`AutomaticSequence`
`holonomic_recurrence`	`holonomic_certified`	`HolonomicRecurrence`

For a recognized model, the compiler compares it with the source sequence on a finite prefix. The trust marker changes certificate exactness:

Prefix agrees	Trust marker is `True`	Certificate
yes	yes	valid and `Exactness.EXACT`
yes	no or absent	valid and `Exactness.CONDITIONAL` with an unchecked infinite-identity assumption
no	either	invalid

> **Require before dispatch.** An invalid declared-model certificate does not cause fallback to a weaker strategy. The returned `CompiledSequence` still dispatches `term` and `first` to the mismatching declared model. Call `compiled.certificate.require()` before using compiled execution.

The three `*_certified` values are trusted metadata, not protected credentials. Any caller can set them. Do not mark an externally supplied model certified until its infinite identity has been established independently. The built-in catalog sets the markers only for models constructed as the evaluator's defining implementation.

26.5.4 Rational ordinary generating function

For

$$a_{n+d} = \sum_{j=0}^{d-1} c_j a_{n+j},$$

write

$$Q(z) = 1 - c_{d-1}z - c_{d-2}z^2 - \cdots - c_0 z^d.$$

Then

$$F(z) = \sum_{n \geq 0} a_n z^n = \frac{P(z)}{Q(z)},$$

where the implementation computes the numerator coefficients through degree $d - 1$ from the initial values and trims trailing zeros. Both returned tuples are in ascending powers of z.

For Fibonacci,

```
from komorebi_math.sequences import compile_sequence, fibonacci_sequence

compiled = compile_sequence(fibonacci_sequence())
compiled.certificate.require()
numerator, denominator = compiled.generating_function()

print(numerator)
print(denominator)
```

Output:

```
(Fraction(0, 1), Fraction(1, 1))
(Fraction(1, 1), Fraction(-1, 1), Fraction(-1, 1))
```

Thus $F(z) = z/(1 - z - z^2)$. `generating_function()` raises `ValidationError` for automatic, holonomic, and direct strategies. For a detected recurrence it returns the OGF of the fitted model. Its truth status remains conditional.

26.5.5 Declared-model example

```
from komorebi_math.sequences import (
    apery_sequence,
    compile_sequence,
    fibonacci_sequence,
    thue_morse_sequence,
)

for sequence in (
    fibonacci_sequence(),
    thue_morse_sequence(),
```

```
    apery_sequence(),
):
    compiled = compile_sequence(sequence)
    compiled.certificate.require()
    print(sequence.name, compiled.strategy, compiled.first(12))
```

Output, with denominator-one `Fraction` wrappers in the Apéry row suppressed:

```
Fibonacci declared linear recurrence (0, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89)
Thue Morse declared finite automaton (0, 1, 1, 0, 1, 0, 0, 1, 1, 0, 0, 1)
Apery declared holonomic recurrence (1, 5, 73, 1445, 33001, 819005,
  21460825, 584307365, 16367912425, 468690849005,
  13657436403073, 403676083788125)
```

26.5.6 Detection and direct fallback

```
from fractions import Fraction
from komorebi_math.sequences import Sequence, compile_sequence

quartic = Sequence(lambda n: n**4 + 2*n + 1, name="quartic")
reciprocal = Sequence(lambda n: Fraction(1, n + 1), name="reciprocal")

for sequence in (quartic, reciprocal):
    compiled = compile_sequence(sequence)
    print(
        sequence.name,
        compiled.strategy,
        compiled.certificate.exactness.value,
    )

print(compile_sequence(quartic).recurrence.coefficients)
```

Output:

```
quartic detected linear recurrence conditional
reciprocal direct evaluator exact
(Fraction(1, 1), Fraction(-5, 1), Fraction(10, 1),
 Fraction(-10, 1), Fraction(5, 1))
```

The reciprocal evaluator receives `exact` because the source wrapper's default flag is true. That record says the direct callable is the selected execution path. It does not prove a formula for the callable.

26.5.7 Finite-prefix truth boundary

A detected relation establishes only

$$\forall n \in I_{\text{sample}} : \mathcal{R}(a, n) = 0.$$

It does not establish the same relation for every future index. The boundary is observable with a sequence that changes immediately after the default sample:

```
from komorebi_math.sequences import Sequence, compile_sequence

source = Sequence(lambda n: 0 if n < 24 else 1, name="prefix trap")
compiled = compile_sequence(source)

print(compiled.strategy)
print(compiled.certificate.exactness.value)
```

```
print(compiled.certificate.assumptions_unchecked)
print(compiled.term(24), source.term(24))
```

Output:

```
detected linear recurrence
conditional
('finite prefix detection does not prove the recurrence for all future terms',)
0 1
```

This is intended conditional behavior, not a failed exact calculation. A detected model must be tested against independent holdout terms before it is used to extrapolate a user-defined sequence.

The compiler does not infer DFAOs or polynomial-coefficient recurrences. It only consumes declared versions of those models and detects constant rational recurrences.

26.5.8 Compiler cost and resource controls

Let S be `sample_count` and D the effective `max_order`. Declared models incur finite prefix evaluation and comparison. Prefix fitting scans orders one through D and solves exact rational systems. A conservative high-level bound for the current dense elimination path is

$$O(SD^3)$$

scalar rational operations across all trial orders, with $O(SD)$ working storage at one order. Rational numerator and denominator growth can make the bit cost much larger.

`sample_count` must be at least three. An explicit `max_order` must be positive. `max_order=None` permits search through half the sample length. For untrusted input, set both values explicitly and cap the size and digit length of the sampled terms before compilation.

26.6 Modular and indexed evaluation

The subsystem exposes three related but different operations:

$$\text{indexing } a_n, \qquad \text{index packet } a_{mk+r}, \qquad \text{value reduction } a_n \bmod M.$$

An index residue and a value modulus are independent. The first chooses which terms to read. The second reduces the values after, or during, execution.

26.6.1 Indexed access ledger

Operation	Admissible arguments	Behavior
`sequence.term(n)`	integer $n \geq 0$	evaluate one term and cache it
`sequence[n]`	integer $n \geq 0$	same as `term`
`sequence[:N]`	finite $N \geq 0$	tuple $a_0, \ldots, a_{N-1}$
`sequence[i:j:k]`	nonnegative finite bounds, $k \geq 1$	tuple at Python range indices
`sequence.first(N)`	integer $N \geq 0$	first N terms
`sequence.residue(m, r)`	$m \geq 1, 0 \leq r < m$	wrapper $k \mapsto a_{mk+r}$
`automatic.residue_model(e, r)`	$e \geq 0, 0 \leq r < b^e$	new DFAO for $a_{b^e k+r}$

Booleans and floats are not accepted as integer indices. A negative index does not mean Python-style indexing from the end because an infinite sequence has no final element.

26.6.2 Modular dispatch

```
Sequence.modulo(modulus: int) -> Sequence

CompiledSequence.modulo(index: int, modulus: int) -> int
```

The lazy view validates $M \geq 2$ immediately and validates each value only when that term is requested. A rational term must have denominator one.

```
from fractions import Fraction
from komorebi_math.sequences import Sequence

rational = Sequence(lambda n: Fraction(1, n + 1))
residues = rational.modulo(5)

print(residues.term(0))
residues.term(1)  # raises ValidationError: denominator is not one
```

The first request prints `1`. The second fails lazily.

`CompiledSequence.modulo` dispatches as follows.

Selected strategy	Modular route	Index cost, ignoring bit arithmetic
declared integral `LinearRecurrence`	modular companion-matrix exponentiation	$O(d^3 \log n)$
prefix-detected `LinearRecurrence` in `1.0.0b4`	rejected because its denominator-one `Fraction` data fail the integral-type check	unavailable without reconstruction
`AutomaticSequence`	evaluate a_n, then require integral rational output and reduce	$O(\log_b n)$ transitions
`HolonomicRecurrence`	construct the exact rational term, then reduce	sequential through n
direct evaluator	invoke the exact term evaluator, then reduce	evaluator-dependent

Only the constant `LinearRecurrence` branch can avoid constructing the full integer term. It requires coefficients and seeds whose runtime types satisfy `numbers.Integral`, not merely rational values with denominator one.

> **Known `1.0.0b4` defect: detected modular recurrences.** `detect_linear_recurrence` represents every fitted coefficient and seed as a `Fraction`. `LinearRecurrence.term_mod` rejects every `Fraction`, including `Fraction(1, 1)`. Consequently `CompiledSequence.modulo` raises `ValidationError` for a prefix-detected recurrence instead of using the advertised modular matrix route. Built-in Fibonacci and Lucas models store Python integers and are unaffected.

After independent holdout validation, a caller may explicitly reconstruct an integral model when every detected denominator is one:

```
from komorebi_math.arithmetic import LinearRecurrence
from komorebi_math.sequences import Sequence, compile_sequence

source = Sequence(lambda n: n * n, name="squares")
compiled = compile_sequence(source)

# A finite holdout is useful evidence. The known square formula is the
# independent justification in this example.
assert all(compiled.term(n) == source.term(n) for n in range(24, 64))

detected = compiled.recurrence
```

```
data = (*detected.coefficients, *detected.initial)
if all(value.denominator == 1 for value in data):
    integer_model = LinearRecurrence(
        tuple(int(value) for value in detected.coefficients),
        tuple(int(value) for value in detected.initial),
        name=detected.name,
    )
    print(integer_model.term_mod(1000, 97))
```

Output is `27`. This workaround restores the modular type contract. It does not upgrade a finite prefix fit from conditional to proved.

26.6.3 Millionth Fibonacci residue

```
from komorebi_math.sequences import compile_sequence, fibonacci_sequence

compiled = compile_sequence(fibonacci_sequence())
compiled.certificate.require()

print(compiled.modulo(1_000_000, 1_000_003))
```

Output:

```
3
```

This uses logarithmic modular matrix powering. Calling `compiled.term(1_000_000)` instead follows the exact sequential recurrence and caches the enormous integers through that index.

26.6.4 Command-line evaluation

The built-in catalog is available through

```
python -m komorebi_math sequence NAME [--terms N] [--index N] [--modulus M] [--compile]
```

One indexed modular call is

```
python -m komorebi_math sequence fibonacci --index 1000000 --modulus 1000003 --compile
```

Output:

```
3
```

A finite automatic prefix is

```
python -m komorebi_math sequence thue-morse --terms 16 --compile
```

The JSON result contains the 16 values and

```
strategy: declared finite automaton
exactness: exact
```

With `--index`, the command prints one scalar. Without it, the command emits a JSON prefix. `--modulus` reduces every printed value. `--compile` reports the strategy for a prefix and explicitly selects compiled execution. A modular request also compiles internally because it needs `CompiledSequence.modulo`.

The CLI accepts only built-in names. Custom `Sequence` instances require the Python API.

26.6.5 Indexed-execution budgets

There is no global `SequenceBudget` object in `1.0.0b4`. A service boundary should validate at least:

Input	Suggested policy purpose
maximum index	caps sequential work and cache population
maximum prefix count	prevents accidental unbounded reports
maximum modulus bit length	caps modular integer arithmetic
maximum recurrence order	caps dense matrix and detection cost
maximum sample count	caps exact compiler elimination
maximum output digit count	prevents giant exact serialization
wall-clock or cancellation token	limits arbitrary user evaluators

Do not treat the logarithmic exponent count as a byte bound. Even modular matrix products allocate Python integers, while exact nonmodular terms can have a digit count proportional to the index.

26.7 Exact sequence transforms: binomial inverse, finite differences, and Cauchy products

The transform functions are exact when their input scalar arithmetic is exact. They do not coerce floating values to `Fraction`, and the finite tuple helpers do not perform a separate numeric type audit.

26.7.1 Function reference

```
binomial_transform_values(
    values: Iterable[Number],
) -> tuple[Number, ...]

inverse_binomial_transform_values(
    values: Iterable[Number],
) -> tuple[Number, ...]

binomial_transform(sequence: Sequence) -> Sequence
inverse_binomial_transform(sequence: Sequence) -> Sequence

finite_difference(
    sequence: Sequence,
    *,
    step: int = 1,
    order: int = 1,
) -> Sequence

partial_sums(sequence: Sequence) -> Sequence
cauchy_product(left: Sequence, right: Sequence) -> Sequence
```

The finite tuple helpers materialize one finite prefix. The corresponding lazy functions create a new `Sequence` and propagate the input exactness flag. The Cauchy product is exact only if both flags are true.

26.7.2 Binomial transform and inverse

For $0 \le n < N$,

$$b_n = \sum_{k=0}^{n} \binom{n}{k} a_k, \qquad a_n = \sum_{k=0}^{n} (-1)^{n-k} \binom{n}{k} b_k.$$

```
from komorebi_math.sequences import (
    binomial_transform_values,
    inverse_binomial_transform_values,
)

values = (1, 2, 4, 8, 16, 32)
transformed = binomial_transform_values(values)
restored = inverse_binomial_transform_values(transformed)

print(transformed)
print(restored)
```

Output:

```
(1, 3, 9, 27, 81, 243)
(1, 2, 4, 8, 16, 32)
```

Here the identity is the ordinary binomial theorem:

$$\sum_{k=0}^{n} \binom{n}{k} 2^k = 3^n.$$

The lazy form computes the same triangular sum at each requested index. The inverse is algebraically exact for integers, rationals, and any scalar domain supporting the required addition and multiplication laws.

26.7.3 Finite differences

For step $h \geq 0$ and order $r \geq 0$,

$$\Delta_h^r a_n = \sum_{k=0}^{r} (-1)^{r-k} \binom{r}{k} a_{n+kh}.$$

```
from komorebi_math.sequences import Sequence, finite_difference

quartic = Sequence(lambda n: n**4 + 2*n + 1, name="quartic")
fifth = finite_difference(quartic, order=5)

print(fifth.first(12))
```

Output:

```
(0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0)
```

The constructor permits zero step and zero order. Order zero is the identity. For positive order and zero step, the repeated value is multiplied by the alternating binomial sum and the result is zero in ordinary exact arithmetic. Negative step or order raises `ValidationError`.

26.7.4 Partial sums and Cauchy products

The inclusive partial-sum transform and ordinary Cauchy product are

$$s_n = \sum_{k=0}^{n} a_k, \qquad c_n = \sum_{k=0}^{n} a_k b_{n-k}.$$

The Cauchy coefficients are exactly the coefficients of ordinary generating function multiplication:

$$\left(\sum_{n\geq 0} a_n z^n\right)\left(\sum_{n\geq 0} b_n z^n\right) = \sum_{n\geq 0} c_n z^n.$$

```
from komorebi_math.sequences import Sequence, cauchy_product, partial_sums

left_values = (1, 2, 3)
right_values = (4, 5, 6)

left = Sequence(lambda n: left_values[n] if n < 3 else 0, name="left")
right = Sequence(lambda n: right_values[n] if n < 3 else 0, name="right")

product = cauchy_product(left, right)
ones = Sequence(lambda n: 1, name="ones")

print(product.first(6))
print(partial_sums(ones).first(8))
```

Output:

```
(4, 13, 28, 27, 18, 0)
(1, 2, 3, 4, 5, 6, 7, 8)
```

26.7.5 Transform cost ledger

For a requested prefix of length N and finite-difference order r, the current lazy and finite implementations have these high-level costs.

Transform	One term n	Prefix through $N-1$	Additional stored state
finite binomial or inverse	not applicable	$O(N^2)$	$O(N)$ output
lazy binomial or inverse	$O(n)$ summands	$O(N^2)$	$O(N)$ result cache
finite difference	$O(r)$ summands	$O(Nr)$	$O(N)$ result cache
partial sums	amortized $O(1)$ per next index	$O(N)$	$O(N)$ internal and wrapper caches
Cauchy product	$O(n)$ products	$O(N^2)$	$O(N)$ result cache plus input caches

These counts omit exact integer and rational bit complexity. A Cauchy or binomial transform of rapidly growing terms can become memory-bound well before the scalar-operation count is large.

26.7.6 Persistence and reproducible records

The portable codec registry in `1.0.0b4` does not register `Sequence`, `AutomaticSequence`, `HolonomicRecurrence`, `CompiledSequence`, or `LinearRecurrence`. This is intentional for `Sequence`: an arbitrary Python callable cannot be reconstructed safely from portable data. Runtime caches are also execution state, not a portable mathematical identity.

There are two supported documentation patterns.

Persist a finite report. The CLI can export a bounded built-in prefix:

```
python -m komorebi_math export sequence fibonacci --terms 100 --compile --format json --output .\fibonacci.json
    ↪  --force
```

The result preserves the printed values and strategy in a finite mathematical document. It does not serialize the evaluator or cache.

Persist a declarative model card. An application may store and validate the public constructor fields itself:

Model	Fields required for reconstruction
constant recurrence	coefficients, initial values, name
DFAO	base, transition rows, outputs, initial state, name
holonomic recurrence	ascending polynomial tuples, initial values, name
detected model	recurrence fields, sample count, sample values or digest, conditional status

Rational scalars should be encoded as numerator-denominator pairs rather than floating decimals. A reconstructed model must be passed through its constructor validation and a fresh certificate. A persisted prefix does not prove an infinite identity, and a persisted detected recurrence must retain its conditional provenance.

26.7.7 Failure and scope matrix

Situation	Observed boundary
evaluator is not callable	`Sequence` construction raises `ValidationError`
evaluator returns a nonnumeric value	first request for that term raises `ValidationError`
evaluator itself raises	its exception propagates from the lazy request
`exact=True` with floating output	accepted. Exactness remains unproved metadata
slice has no stop	`ValidationError` because the result would be infinite
modular term is nonrational or nonintegral	`ValidationError` at that requested term
malformed DFAO shape or target	constructor raises `DimensionError` or `ValidationError`
DFAO stores floating or complex outputs	deterministic lookup certificate remains `EXACT`. Scalar arithmetic is not thereby exact
holonomic leading polynomial vanishes at execution index	`ValidationError` during term generation
detected recurrence extrapolates beyond its prefix	permitted with a conditional certificate
modular evaluation of a detected recurrence	known `1.0.0b4` denominator-one `Fraction` rejection
declared model disagrees with prefix	compiler returns an invalid certificate and does not fall back
OGF requested without a constant recurrence	`ValidationError`
transform receives floating inputs	floating arithmetic is propagated. No exact coercion occurs
arbitrary sequence object is sent to portable codec	unsupported in `1.0.0b4`
unbounded iteration is consumed without a limit	execution and cache growth continue indefinitely

26.7.8 Verification and executable anchors

The canonical installed verification command is

```
python -m komorebi_math verify sequences
```

It executes five checks:

1. classical exact sequence catalog
2. binomial transform inversion
3. Thue-Morse finite automaton
4. exact holonomic sequence execution
5. declared recurrence compilation

Expected final line:

```
verification passed 5/5 checks
```

The focused source replay is

```
python -m pytest -q tests/test_sequences_execution.py tests/test_sequences_models.py
```

The current chapter audit obtains

```
13 passed
```

The two shipped examples are

```
python examples/sequence_compiler.py
python examples/automatic_holonomic.py
```

Both execute successfully. They cover all three declared compiler strategies, the Thue-Morse residue automaton, and the Apéry holonomic prefix.

A separate boundary probe reproduced the detected-recurrence modular defect: an integer square prefix compiled to denominator-one `Fraction` recurrence data, after which `compiled.modulo(100, 7)` raised the documented integral-data `ValidationError`. Reconstructing the same coefficients and seeds as Python integers returned the expected residue.

The independent source anchors are

```
src/komorebi_math/sequences/base.py
src/komorebi_math/sequences/catalog.py
src/komorebi_math/sequences/automatic.py
src/komorebi_math/sequences/holonomic.py
src/komorebi_math/sequences/compiler.py
src/komorebi_math/sequences/transforms.py
src/komorebi_math/arithmetic/recurrence.py
src/komorebi_math/verify/sequences.py
tests/test_sequences_execution.py
tests/test_sequences_models.py
examples/sequence_compiler.py
examples/automatic_holonomic.py
```

Chapter 26 summary. `Sequence` is a cached lazy numeric wrapper whose exactness flag is a declaration. Built-in constant recurrences, DFAOs, and holonomic recurrences provide stronger executable models. The compiler uses a fixed declared-model order, then fits only a constant rational recurrence to a bounded prefix. Declared built-ins can carry exact certificates, while inferred recurrences remain conditional. Only constant recurrences receive logarithmic modular acceleration. Every transform remains exact only when its scalar inputs are exact, every infinite iterator needs an external budget, and portable artifacts should store bounded reports or declarative model fields rather than Python callables and runtime caches.

27. Cyclic analytic systems

First route. Start with finite packet reconstruction in Section 27.1. For exact coefficient work, continue to the reciprocal, Appell, and logarithmic sections. For numerical zeros, go to Section 27.4 and read the certificate interpretation in Section 27.5 before drawing a conclusion. The combined workflow in Section 27.7 shows how exact symbolic checks and numerical diagnostics can be retained together without merging their claim classes.

The `komorebi_math.analytic` namespace turns a finite cyclic decomposition into an executable analytic calculus. It begins with the exact decomposition of a coefficient sequence into residue classes, builds entire transfer and signed section families, and then derives reciprocal, Appell, theta, logarithmic, and zero-diagnostic constructions. The implementation separates two levels of claim strength:

- Finite coefficient identities can be exact over `Fraction` and SymPy.
- Root locations, residuals, truncated products, and truncated zeta sums are numerical or conditional records.

This distinction is central to the API. A successful zero certificate says that the requested representatives are ordered and have small residuals. It does not assert that every zero has been found or prove a global zero-counting theorem.

The 43 exported names in `komorebi_math.analytic` belong to the research public surface. None is re-exported by `komorebi_math.beta` or `komorebi_math.stable` in version `1.0.0b4`. Pin the package version when these signatures form part of an application contract.

27.1 Cyclic packets and sections

27.1.1 Namespace and mathematical conventions

The public analytic layer is exported from

```
from komorebi_math import analytic
```

or directly from the subpackage:

```
from komorebi_math.analytic import cyclic_packets, signed_section
```

Let $N \geq 1$ be the cyclic order and let

$$f(z) = \sum_{m \geq 0} a_m z^m.$$

For $j \in \{0, \dots, N-1\}$, the j-th residue projection is

$$\Pi_j f(z) = \sum_{q \geq 0} a_{Nq+j} z^{Nq+j}.$$

Write the primitive root of unity as

$$\omega_N = e^{2\pi i/N},$$

the same projection has the root-of-unity form

$$\Pi_j f(z) = \frac{1}{N} \sum_{\ell=0}^{N-1} \omega_N^{-j\ell} f(\omega_N^{\ell} z).$$

The orthogonality relation

$$\frac{1}{N}\sum_{\ell=0}^{N-1}\omega_N^{(m-j)\ell}=\begin{cases}1, & m\equiv j \pmod N,\\ 0, & m\not\equiv j \pmod N\end{cases}$$

explains why the functional and coefficient definitions agree. The complete family reconstructs the original series:

$$f=\sum_{j=0}^{N-1}\Pi_j f.$$

In the finite array API, `cyclic_project_coefficients` retains the positions in one residue class and fills all other positions with zeros. `cyclic_packets` returns every residue packet, and `cyclic_reconstruct` sums equally shaped packets.

```
import numpy as np

from komorebi_math.analytic import (
    cyclic_packets,
    cyclic_projection_certificate,
    cyclic_reconstruct,
)

coefficients = np.arange(10)
packets = cyclic_packets(coefficients, order=3)

assert np.array_equal(
    cyclic_reconstruct(packets),
    coefficients,
)

checked = cyclic_projection_certificate(coefficients, order=3)
checked.certificate.require()
```

The certificate is a `ComputationResult`. Its `.value` is the tuple of packets. Its `.certificate` records the finite reconstruction residual. The result is classified as `Exactness.EXACT`, although the stored residual is represented as a floating norm for compatibility with the common certificate interface.

27.1.2 Packet products

If

$$f=\sum_{a=0}^{N-1}f_a,\qquad g=\sum_{b=0}^{N-1}g_b,$$

where the support of f_a lies in residue a and the support of g_b lies in residue b, then the product packet of residue c is

$$(fg)_c=\sum_{a+b\equiv c \pmod N} f_a g_b.$$

`cyclic_product_packets(left, right)` realizes this cyclic convolution of ordinary coefficient convolutions. Both families must have the same nonzero order and every packet must be one dimensional. The output length is chosen from the longest packet in each input family.

```
left = np.array([1.0, 2.0, 3.0, 4.0])
right = np.array([2.0, -1.0, 5.0])

product_packets = cyclic_product_packets(
    cyclic_packets(left, 3),
    cyclic_packets(right, 3),
```

```
)

assert np.allclose(
    sum(product_packets),
    np.convolve(left, right),
)
```

This is a finite coefficient operation. It does not inspect convergence radii or analytically continue an infinite series.

27.1.3 Transfer and signed sections

The transfer sections are

$$E_{N,j}(z;s)=\sum_{q\ge 0}\frac{(sz)^{Nq+j}}{(Nq+j)!},\qquad 0\le j<N,$$

and the signed sections are

$$S_{N,j}(z)=\sum_{q\ge 0}(-1)^q\frac{z^{Nq+j}}{(Nq+j)!}.$$

They are evaluated by `transfer_section` and `signed_section`. Their complete coordinate vectors are returned by `transfer_sections` and `signed_sections`. The series evaluator stops when the new term satisfies its relative tolerance. Failure to converge within `max_terms` raises `ArithmeticError`.

For order two,

$$E_{2,0}(z;1)=\cosh z,\qquad E_{2,1}(z;1)=\sinh z,$$

and

$$S_{2,0}(z)=\cos z,\qquad S_{2,1}(z)=\sin z.$$

The distinguished signed denominator is

$$D_N(z)=S_{N,0}(z)=\sum_{q\ge 0}(-1)^q\frac{z^{Nq}}{(Nq)!}.$$

The public functions

```
denominator
denominator_root_sum
denominator_derivative
```

evaluate D_N, its finite exponential root representation, and an arbitrary nonnegative derivative order. If

$$\eta_k=e^{(2k+1)\pi i/N},\qquad 0\le k<N,$$

then

$$D_N(z)=\frac{1}{N}\sum_{k=0}^{N-1}e^{\eta_k z}$$

and

$$D_N^{(r)}(z) = \frac{1}{N} \sum_{k=0}^{N-1} \eta_k^r e^{\eta_k z}.$$

`section_certificate` compares the directly summed section vector with the appropriate finite root representation. It reports numerical exactness because both paths use finite-precision complex arithmetic.

27.1.4 Companion realizations and addition

`transfer_shift_matrix(N, scale)` returns the cyclic shift with positive wrap. `signed_shift_matrix(N)` returns the signed shift J_N satisfying

$$J_N^N = -I_N.$$

The first column of the matrix exponential of the shift is the corresponding section vector. `CyclicSectionFamily` packages this realization:

```
from komorebi_math.analytic import CyclicSectionFamily

family = CyclicSectionFamily(
    order=4,
    family="signed",
    scale=1.0,
)

values = family.vector(0.2)
fundamental = family.fundamental_matrix(0.2)

assert np.allclose(fundamental[:, 0], values)
```

Its public members are:

Member	Meaning
`order`	positive cyclic order
`family`	either `"transfer"` or `"signed"`
`scale`	complex scale. The caller must supply a finite value
`evaluate(residue, z)`	evaluate one residue section
`vector(z)`	evaluate all residue sections
`fundamental_matrix(z)`	exponentiate the companion realization

SciPy's `expm` is used when available. Otherwise the package falls back to its internal matrix-exponential implementation.

Because the fundamental matrices form a one-parameter group, section coordinates obey a finite addition law. `cyclic_addition(left, right, signed=...)` performs that law. Both input tuples must have one common nonzero length. In the signed family, products that wrap around the cyclic boundary acquire a minus sign.

27.2 Appell and reciprocal families

27.2.1 Reciprocal coefficients

For a numeric parameter r, define the normalized reciprocal coefficients $P_{N,m}(r)$ through

$$D_N(z)^{-r} = \sum_{m \geq 0} P_{N,m}(r) \frac{z^{Nm}}{(Nm)!}.$$

`reciprocal_coefficients(order, parameter, degree)` returns the finite tuple

$$(P_{N,0}(r), \dots, P_{N,d}(r)).$$

Integer and `Fraction` parameters preserve exact rational arithmetic. Other numeric inputs are converted to complex arithmetic.

```
from fractions import Fraction

from komorebi_math.analytic import reciprocal_coefficients

values = reciprocal_coefficients(
    order=2,
    parameter=Fraction(1),
    degree=5,
)

assert values == (
    Fraction(1),
    Fraction(1),
    Fraction(5),
    Fraction(61),
    Fraction(1385),
    Fraction(50521),
)
```

The order-two, parameter-one sequence is the even-index secant-number family in the normalization used here.

The parameter law is a binomial convolution:

$$P_{N,m}(r+s) = \sum_{q=0}^{m} \binom{Nm}{Nq} P_{N,q}(r) P_{N,m-q}(s).$$

`reciprocal_semigroup_certificate` evaluates both sides through the requested degree. When all participating values are rational and the residual is zero, the certificate is exact. Otherwise it is numerical and uses the supplied tolerance.

`reciprocal_polynomial(order, degree)` returns $P_{N,m}(r)$ as an exact SymPy polynomial in the symbol `r`. It requires the optional SymPy dependency. `reciprocal_value(order, z, parameter)` evaluates the principal branch of $D_N(z)^{-r}$ and raises `ZeroDivisionError` when the denominator vanishes.

27.2.2 Congruential reciprocals

For residue j, introduce the normalized positive section

$$\Phi_{N,j}(w) = \sum_{m \geq 0} \frac{j!}{(Nm+j)!} w^m.$$

Its parameterized inverse is expanded as

$$\Phi_{N,j}(w)^{-r} = \sum_{m \geq 0} C_{N,j,m}(r) \frac{w^m}{(Nm)!}.$$

The finite coefficient tuple is produced by `congruential_reciprocal_coefficients`. The convenience function `congruential_inverse` fixes $r = 1$.

For the parameter-one inverse, the lower-triangular relation is

$$\sum_{q=0}^{m} \binom{Nm + j}{Nq} C_{N,j,q}(1) = \delta_{m0}.$$

The parameter law has the same residue-spaced binomial form:

$$C_{N,j,m}(r + s) = \sum_{q=0}^{m} \binom{Nm}{Nq} C_{N,j,q}(r) C_{N,j,m-q}(s).$$

These functions validate the order, residue, degree, and numeric parameter. Boolean values are not accepted as integer orders, residues, or degrees.

27.2.3 Congruential Appell polynomials

The Appell family attached to the congruential reciprocal coefficients is

$$A^{(r)}_{N,j,m}(x) = \sum_{q=0}^{\lfloor m/N \rfloor} \binom{m}{Nq} C_{N,j,q}(r) x^{m-Nq}.$$

`appell_polynomial` evaluates one polynomial. `appell_coefficients` returns all monomial coefficients in ascending power order, including explicit zeros. `appell_polynomial_symbolic` returns a SymPy expression in `x`.

The family satisfies the Appell derivative law

$$\frac{d}{dx} A^{(r)}_{N,j,m}(x) = m A^{(r)}_{N,j,m-1}(x).$$

```
from komorebi_math.analytic import (
    appell_coefficients,
    appell_polynomial,
)

degree = 8
coefficients = appell_coefficients(3, 1, 2, degree)
x = 0.31

direct = sum(
    coefficient * x**power
    for power, coefficient in enumerate(coefficients)
)

assert abs(
    direct - appell_polynomial(3, 1, 2, degree, x)
) < 1e-12
```

For symbolic checking:

```python
import sympy as sp

from komorebi_math.analytic import appell_polynomial_symbolic

x = sp.Symbol("x")
p5 = appell_polynomial_symbolic(2, 0, 1, 5)
p4 = appell_polynomial_symbolic(2, 0, 1, 4)

assert sp.simplify(sp.diff(p5, x) - 5 * p4) == 0
```

Current validation gap. The numerical Appell functions reach the shared residue validator and reject addresses outside $0 \le j < N$. In version `1.0.0b4`, `appell_polynomial_symbolic` does not call that validator and can accept a residue at least as large as the order. Validate `order` and `residue` explicitly before calling the symbolic helper.

27.2.4 Theta polynomials

`theta_polynomial(order, degree, parameter)` evaluates one transfer theta polynomial. Integer and rational parameters use exact arithmetic. `theta_polynomial_symbolic(order, degree)` returns the exact SymPy polynomial in the symbol `u`.

In the implemented normalization, every positive-degree theta polynomial vanishes at $u = 0$:

$$\Theta_{N,m}(0) = 0, \qquad m \ge 1.$$

For even order it also vanishes at $u = -1$:

$$\Theta_{N,m}(-1) = 0, \qquad N \equiv 0 \pmod 2, \qquad m \ge 1.$$

These are exact coefficient identities, not approximate sampling statements.

27.3 Logarithmic derivatives and coefficient recurrences

27.3.1 Reduced logarithmic coefficients

Set $w = z^N$ and write

$$\widehat{D}_N(w) = \sum_{m \ge 0} (-1)^m \frac{w^m}{(Nm)!}.$$

The exact logarithmic coefficients $\kappa_{N,m}$ are defined by

$$-\log \widehat{D}_N(w) = \sum_{m \ge 1} \kappa_{N,m} \frac{w^m}{m}.$$

`logarithmic_coefficients(order, degree)` returns

$$(\kappa_{N,0}, \kappa_{N,1}, \dots, \kappa_{N,d}),$$

where index zero is the unused zero entry. The implementation uses exact `Fraction` arithmetic.

If

$$\widehat{D}_N(w) = 1 + \sum_{m \ge 1} a_m w^m,$$

coefficient comparison in

$$\widehat{D}'_N(w) = -\widehat{D}_N(w) \sum_{m \geq 1} \kappa_{N,m} w^{m-1}$$

gives the recurrence

$$\kappa_{N,m} = -m a_m - \sum_{q=1}^{m-1} a_q \kappa_{N,m-q}.$$

This recurrence is the shared engine behind the reciprocal, congruential, and theta constructions.

27.3.2 Transfer tangent

The transfer tangent is the logarithmic derivative

$$T_N(z) = -\frac{D'_N(z)}{D_N(z)}.$$

`transfer_tangent(order, z)` evaluates this quotient away from zeros of D_N. Its ordinary coefficient dictionary is returned by `transfer_tangent_coefficients(order, degree)`:

$$T_N(z) = \sum_{m \geq 0} N \kappa_{N,m+1} z^{Nm+N-1}.$$

Only the nonzero residue-spaced exponents appear in the returned dictionary. The keys are ordinary monomial exponents, not compressed series indices.

```
from komorebi_math.analytic import (
    logarithmic_coefficients,
    transfer_tangent,
    transfer_tangent_coefficients,
)

kappa = logarithmic_coefficients(3, 5)
coefficients = transfer_tangent_coefficients(3, 4)

assert coefficients[2] == 3 * kappa[1]
assert coefficients[5] == 3 * kappa[2]

z = 0.1
truncated = sum(
    3 * kappa[index + 1] * z ** (3 * index + 2)
    for index in range(5)
)

assert abs(truncated - transfer_tangent(3, z)) < 1e-10
```

The last assertion is an approximation because the finite series is truncated. The coefficients used to form it are exact.

27.4 Positive zero strings and numerical zero certificates

27.4.1 Distinguished denominator wrapper

`CyclicDenominator(order)` stores one validated cyclic order and exposes:

Member	Result
`__call__(z)`	$D_N(z)$
`derivative(z, derivative_order=1)`	$D_N^{(r)}(z)$
`positive_zeros(count, start=0)`	a `ZeroStringResult`
`zero_count(radius, reduced=False)`	leading count asymptotic

Positive-zero routines require $N \geq 2$. The leading seed for zero index $m \geq 0$ is

$$x_{N,m}^{(0)} = \frac{\pi(m + \frac{1}{2})}{\sin(\pi/N)}.$$

`asymptotic_positive_zero(order, index)` returns this model. For $N = 2$ and $N = 4$, the seed is already the exact positive representative in the implemented families. Other orders are refined by an exponentially scaled Newton iteration.

`count`, `start`, and `tolerance` receive explicit domain checks. In version `1.0.0b4`, `max_iterations` does not. Pass a positive integer explicitly. For orders two and four the exact-seed branch does not consume that argument. For other orders, a nonpositive iteration limit skips refinement and normally yields a failed residual certificate.

27.4.2 `ZeroStringResult`

`positive_zero_string` has the signature

```
positive_zero_string(
    order: int,
    count: int,
    *,
    start: int = 0,
    tolerance: float = 1e-12,
    max_iterations: int = 64,
) -> ZeroStringResult
```

and returns the immutable record

```
ZeroStringResult(
    order: int,
    indices: tuple[int, ...],
    zeros: tuple[float, ...],
    residuals: tuple[float, ...],
    asymptotic_seeds: tuple[float, ...],
    certificate: Certificate,
) -> None

ZeroStringResult.rotational_orbits(
    self,
) -> tuple[tuple[complex, ...], ...]
```

The certificate is numerical. It checks:

1. Positive asymptotic seeds were constructed.
2. The requested representatives are strictly ordered.
3. The maximum scaled function residual is at most twenty times the requested tolerance.

It explicitly leaves unchecked the exhaustion of zeros outside the computed range.

Each positive representative has a rotational orbit

$$\mathcal{O}(x_m) = \{x_m \omega_N^k : 0 \le k < N\}.$$

`ZeroStringResult.rotational_orbits()` materializes these finite tuples.

```python
from komorebi_math.analytic import positive_zero_string

zeros = positive_zero_string(4, count=4)
zeros.certificate.require()

assert zeros.indices == (0, 1, 2, 3)
assert len(zeros.rotational_orbits()) == 4
assert all(len(orbit) == 4 for orbit in zeros.rotational_orbits())
```

27.4.3 Finite Hadamard and coefficient diagnostics

Given positive representatives $x_0, \dots, x_{M-1}$, the finite reduced Hadamard product is

$$H_{N,M}(z) = \prod_{m=0}^{M-1} \left(1 - \frac{z^N}{x_m^N}\right).$$

`hadamard_partial_product` evaluates this expression and requires every representative to be strictly positive. It is a finite approximation to the denominator, not a complete infinite product certificate.

`reciprocal_coefficient_from_zeros` uses finitely many orbits to approximate one reciprocal coefficient:

$$\widetilde{P}_{N,m} = (Nm)! \sum_{x \in X_M} \frac{-N x^{-Nm-1}}{D_N'(x)}.$$

Increasing the finite zero set may improve the diagnostic, but the function does not attach a global truncation bound.

27.4.4 Count and zeta diagnostics

The leading count models are

$$N_N(R) \sim \frac{N \sin(\pi/N)}{\pi} R$$

for the full rotational family, and

$$N_N^{\mathrm{red}}(R) \sim \frac{\sin(\pi/N)}{\pi} R^{1/N}$$

for the reduced convention implemented by `zero_count_asymptotic(..., reduced=True)`.

`reduced_zero_zeta(order, exponent, terms=64, use_computed_zeros=True)` has two explicit modes:

Mode	Value	Certificate
computed zeros	finite sum of x_m^{-Ns}	numerical
asymptotic model	scaled Hurwitz-zeta leading model	conditional

In computed-zero mode,

$$Z_{N,M}(s) = \sum_{m=0}^{M-1} x_m^{-Ns}.$$

The certificate records the maximum zero residual and a tail-scale diagnostic, but it lists the omitted zeta tail as unchecked. In model mode, the function returns

$$\left(\frac{\pi}{\sin(\pi/N)}\right)^{-Ns} \zeta(Ns, \tfrac{1}{2}),$$

classifies it as conditional, and explicitly omits the entire correction term. That mode requires `mpmath` through the scientific dependency profile.

The API accepts an arbitrary complex exponent. It does not enforce the half-plane in which an infinite zero sum would converge, and the model has the Hurwitz-zeta pole when $Ns = 1$. Treat computed mode as a finite sum and model mode as analytic continuation of a conditional leading expression.

27.5 Exact coefficient claims versus numerical root claims

27.5.1 Claim-strength matrix

The table below gives the practical interpretation boundary for this chapter.

Operation	Arithmetic model	Strongest local claim
cyclic coefficient split and reconstruction	finite NumPy arrays	exact structural identity
rational reciprocal coefficients	`Fraction`	exact finite coefficients
reciprocal parameter convolution	rational or complex	exact when rational. Otherwise numerical
symbolic reciprocal/Appell/theta polynomial	SymPy	exact symbolic identity
section root-sum comparison	complex floating point	numerical residual
positive zero string	scaled Newton iteration	ordered requested roots with residuals
finite Hadamard product	complex floating point	finite diagnostic only
reciprocal coefficient from zeros	finite zero truncation	approximation without global tail bound
reduced zero zeta from roots	finite sum	numerical truncation
Hurwitz-zeta model	asymptotic model	conditional leading term

An exact coefficient result does not upgrade a separately computed zero list to an exact or exhaustive list. Conversely, a numerical zero certificate does not weaken an exact rational coefficient identity computed independently.

27.5.2 Certificate reading discipline

For any returned `ComputationResult`, inspect both layers:

```
result = reduced_zero_zeta(3, 1.25, terms=24)

print(result.value)
print(result.certificate.exactness)
print(result.certificate.assumptions_checked)
print(result.certificate.assumptions_unchecked)
print(result.certificate.diagnostics)
```

Calling `result.certificate.require()` means only that the encoded validation conditions passed. It does not erase `assumptions_unchecked` or promote a numerical result to exactness.

27.5.3 Nonclaims

The analytic namespace does not claim:

- Exhaustive enumeration of every zero of D_N.
- A proof of the global zero asymptotic from numerical samples.
- A certified tail bound for every finite Hadamard or zeta truncation.
- Automatic branch reconciliation across zeros for complex reciprocal powers.
- Arbitrary-precision interval isolation of complex zeros.
- Symbolic execution without the optional SymPy dependency.

These are deliberate boundaries, not silent omissions.

27.6 Internal finite-series helpers used by public analytic constructions

The module `komorebi_math.analytic._series` is internal. Its leading underscore is the compatibility warning: applications should call the public analytic functions rather than import these helpers directly. They are documented here to make the recurrence chain auditable, not to enlarge the supported public surface.

Internal helper	Role
`validate_order`	reject nonintegral or too-small orders
`validate_degree`	reject negative or nonintegral truncation degrees
`multiply_series`	truncated ordinary Cauchy product
`inverse_series`	triangular reciprocal with nonzero constant term
`logarithmic_coefficients`	coefficients of $-\log A(w)$ when $A(0) = 1$
`power_series_from_log`	exponentiate a finite logarithmic record
`signed_denominator_coefficients`	exact or floating coefficients of D_N
`positive_section_coefficients`	normalized congruential section coefficients

For two truncated series

$$A(w) = \sum_{m=0}^{d} a_m w^m, \qquad B(w) = \sum_{m=0}^{d} b_m w^m,$$

the multiplication helper returns

$$[w^n](AB) = \sum_{q=0}^{n} a_q b_{n-q}, \qquad 0 \le n \le d.$$

If $a_0 \neq 0$, the inverse recurrence is

$$b_0 = a_0^{-1}, \qquad b_n = -a_0^{-1} \sum_{q=1}^{n} a_q b_{n-q}.$$

If

$$-\log A(w) = \sum_{n \geq 1} \kappa_n \frac{w^n}{n},$$

then `power_series_from_log` constructs the coefficients c_n of

$$C(w) = \exp\left(r \sum_{n \geq 1} \kappa_n \frac{w^n}{n} \right)$$

using

$$c_0 = 1, \qquad c_n = \frac{r}{n} \sum_{q=1}^{n} \kappa_q c_{n-q}.$$

The public reciprocal functions multiply these normalized coefficients by $(Nn)!$ at the boundary. Keeping the normalized internal series separate from the exposed factorial-power coefficients prevents accidental mixing of ordinary and exponential conventions.

27.7 End-to-end symbolic and numerical workflow

This bounded example exercises the chapter's two claim layers without conflating them.

```
from fractions import Fraction

import sympy as sp

from komorebi_math.analytic import (
    CyclicDenominator,
    appell_polynomial_symbolic,
    cyclic_projection_certificate,
    reciprocal_coefficients,
    reciprocal_semigroup_certificate,
    theta_polynomial_symbolic,
)

# Exact finite packet reconstruction.
projection = cyclic_projection_certificate(range(15), order=4)
projection.certificate.require()

# Exact rational reciprocal coefficients.
secant = reciprocal_coefficients(2, Fraction(1), degree=5)
assert secant[:4] == (
    Fraction(1),
    Fraction(1),
    Fraction(5),
    Fraction(61),
)

# Exact finite semigroup identity.
semigroup = reciprocal_semigroup_certificate(
    4,
    Fraction(2, 3),
    Fraction(5, 4),
    degree=6,
```

```
)
semigroup.certificate.require()

# Exact symbolic Appell derivative identity.
x = sp.Symbol("x")
p5 = appell_polynomial_symbolic(2, 0, 1, 5)
p4 = appell_polynomial_symbolic(2, 0, 1, 4)
assert sp.simplify(sp.diff(p5, x) - 5 * p4) == 0

# Exact symbolic theta factors.
u = sp.Symbol("u")
theta = theta_polynomial_symbolic(4, 3)
assert sp.simplify(theta.subs(u, 0)) == 0
assert sp.simplify(theta.subs(u, -1)) == 0

# Numerical zero representatives with an explicit certificate.
zeros = CyclicDenominator(4).positive_zeros(4)
zeros.certificate.require()
assert zeros.certificate.exactness.value == "numerical"
```

The symbolic assertions are literal algebraic equalities. The last assertion checks the zero result's declared claim class. It does not turn its coordinates into exact symbolic numbers.

27.8 Error model and troubleshooting

The following table records behavior in the audited reference baseline. It does not assert that a defect persists in a later package release.

Symptom	Cause	Remedy
`ValidationError` for order	zero, negative, Boolean, or nonintegral order	pass a positive integer. Zero routines require at least two
`ValidationError` for residue	address is outside `0 <= residue < order`	reduce or validate the residue explicitly
`ValidationError` for degree	negative, Boolean, or nonintegral degree	use a nonnegative integer truncation
`ValidationError` for parameter	object is not numeric	use `int`, `Fraction`, float, or complex
`BackendUnavailableError`	SymPy or mpmath-dependent path requested without dependency	install the matching optional dependency profile
`ZeroDivisionError`	reciprocal or tangent evaluated at a denominator zero	choose a point off the zero set or use a limiting analysis
`ArithmeticError`	section series exceeded `max_terms`	increase the limit or review point magnitude and tolerance
failed zero certificate	Newton residual or ordering check exceeded tolerance	inspect seeds and residuals. Do not discard the failure
unexpected complex dtype	packet product promotes to a common complex-compatible dtype	compare values, not an assumed input dtype
symbolic Appell accepts an out-of-range residue	recorded symbolic helper omits the shared residue guard	prevalidate `0 <= residue < order`
nonfinite section scale propagates	`CyclicSectionFamily` validates the family and order, not scale finiteness	require finite real and imaginary parts before construction
invalid `max_iterations` gives `TypeError` or a failed certificate	recorded zero solver does not validate this argument	pass a positive integer

For large $|z|$, the public section sum is mathematically entire but may still be numerically awkward in fixed precision. A section certificate compares two finite-precision realizations. It is not an interval-arithmetic enclosure. `reciprocal_value` and `transfer_tangent` detect an exactly zero computed denominator, not proximity to a pole. Inspect $|D_N(z)|$ when conditioning matters.

27.9 Public API reference

27.9.1 Cyclic projection

Callable	Return	Contract
`cyclic_project_coefficients(coefficients, order, residue)`	`np.ndarray`	retain one residue class
`cyclic_packets(coefficients, order)`	tuple of arrays	produce complete residue family
`cyclic_reconstruct(packets)`	`np.ndarray`	sum equally shaped packets
`cyclic_project_value(function, z, order, residue)`	`complex`	root-of-unity projection
`cyclic_product_packets(left, right)`	tuple of arrays	cyclic convolution of packet products
`cyclic_projection_certificate(coefficients, order, tolerance=...)`	`ComputationResult`	validate finite reconstruction

27.9.2 Sections and companions

Callable	Return	Contract
`transfer_section(order, residue, z, ...)`	`complex`	one positive-wrap entire section
`signed_section(order, residue, z, ...)`	`complex`	one negative-wrap entire section
`transfer_sections(order, z, scale=...)`	tuple	complete transfer vector
`signed_sections(order, z)`	tuple	complete signed vector
`denominator(order, z)`	`complex`	evaluate D_N
`denominator_root_sum(order, z)`	`complex`	finite exponential representation
`denominator_derivative(order, z, derivative_order=1)`	`complex`	arbitrary nonnegative derivative
`transfer_shift_matrix(order, scale=1)`	`np.ndarray`	positive cyclic companion
`signed_shift_matrix(order)`	`np.ndarray`	companion with $J^N = -I$
`cyclic_addition(left, right, signed=...)`	tuple	coordinate addition law
`section_certificate(order, z, family=..., tolerance=...)`	`ComputationResult`	root-sum comparison
`CyclicSectionFamily(...)`	record	family wrapper and fundamental matrix

27.9.3 Reciprocal, Appell, and theta functions

Callable	Return	Contract
`logarithmic_coefficients(order, degree)`	tuple of `Fraction`	exact reduced log coefficients
`reciprocal_coefficients(order, parameter, degree)`	numeric tuple	factorial-power reciprocal coefficients
`reciprocal_polynomial(order, degree)`	SymPy expression	polynomial in reciprocal parameter
`reciprocal_value(order, z, parameter=1)`	`complex`	principal reciprocal branch
`transfer_tangent(order, z)`	`complex`	$-D_N'/D_N$

Callable	Return	Contract
`transfer_tangent_coefficients(order, degree)`	dictionary	ordinary monomial coefficients
`reciprocal_semigroup_certificate(...)`	`ComputationResult`	finite parameter-convolution check
`congruential_reciprocal_coefficients(...)`	numeric tuple	normalized section reciprocal
`congruential_inverse(order, residue, degree)`	numeric tuple	parameter-one inverse
`appell_polynomial(...)`	number	evaluate one Appell polynomial
`appell_coefficients(...)`	numeric tuple	ascending monomial coefficients
`appell_polynomial_symbolic(...)`	SymPy expression	exact polynomial in `x`
`theta_polynomial(order, degree, parameter)`	number	evaluate one theta polynomial
`theta_polynomial_symbolic(order, degree)`	SymPy expression	exact polynomial in `u`

27.9.4 Zero diagnostics

Callable	Return	Contract
`asymptotic_positive_zero(order, index)`	`float`	leading seed model
`positive_zero_string(order, count, ...)`	`ZeroStringResult`	requested numerical representatives
`hadamard_partial_product(order, z, positive_zeros)`	`complex`	finite reduced product
`reciprocal_coefficient_from_zeros(...)`	`complex`	finite-orbit coefficient diagnostic
`zero_count_asymptotic(order, radius, reduced=False)`	`float`	leading count model
`reduced_zero_zeta(order, exponent, ...)`	`ComputationResult`	finite or conditional zeta diagnostic
`CyclicDenominator(order)`	record	denominator evaluation and zero facade
`ZeroStringResult.rotational_orbits()`	tuple of tuples	complete finite cyclic orbit per representative

The namespace also exports `status()` and `require()` for feature discovery. They report the implementation status. They are not mathematical validators.

27.10 Validation evidence

The chapter was checked against the implementation sources

```
src/komorebi_math/analytic/__init__.py
src/komorebi_math/analytic/_series.py
src/komorebi_math/analytic/appell.py
src/komorebi_math/analytic/cyclic.py
src/komorebi_math/analytic/reciprocal.py
src/komorebi_math/analytic/sections.py
src/komorebi_math/analytic/zeros.py
```

and the focused test modules

```
tests/test_analytic_cyclic_reciprocal.py
tests/test_analytic_appell_zeros.py
```

The focused replay completed with

```
19 passed
```

The shipped example `examples/cyclic_analytic.py` also completed successfully. Those executions cover finite packet reconstruction, root-of-unity projection, packet products, section identities, companion matrices, exact reciprocal and Appell formulas, symbolic theta factors, positive-zero special cases, rotational orbits, finite Hadamard diagnostics, reciprocal coefficients from zeros, count models, zeta claim classes, and invalid inputs.

Chapter 27 summary. Cyclic residue projection is an exact finite decomposition. Transfer and signed sections turn it into a finite companion calculus. Rational and symbolic reciprocal/Appell/theta constructions retain exact coefficient arithmetic. Logarithmic coefficients drive the shared recurrences. Positive zero strings, finite Hadamard products, and zeta sums remain explicitly numerical or conditional. Always read the certificate's unchecked assumptions before extending a finite diagnostic into a global analytic claim.

Part VI. Structured numerical computation and signal processing

This part has two entry points. Chapters 28 through 30 document `komorebi_math.algorithms`: packet intermediate representations, structured and low-rank operators, Krylov methods, precision allocation, finite compilation, scheduling, discovery, and optional device execution. Chapters 31 through 36A document the signal-processing tools in `komorebi_math.signals`. Use the namespace named in the relevant chapter when importing its public objects.

The claim labels are: **E** exact finite algebra or combinatorics. **N** a finite numerical result checked at a stated tolerance. **H** a heuristic or data-dependent rule. **M** a declared work, storage, or traffic model. **C** means conditional on the stated hypotheses, and **O** identifies an optional-backend statement. A certificate reports the checks and assumptions recorded by its producer. In particular, a successful finite execution is not a proof of an untested global operator hypothesis.

The API and behavioral statements in this part are grounded in the source modules named in each section. The verification ledger at the end records the tests and examples executed for the recorded reference baseline.

For the algorithms namespace, the controls are `FEATURE_KEY = "algorithms"`, `status() -> FeatureSpec`, which returns the registered feature specification, and `require() -> None`, the implemented-namespace compatibility no-op. Evidence: `src/komorebi_math/algorithms/__init__.py`.

Choose a starting point. Matrix and operator work begins in Chapter 28. Sampled-signal work can begin directly in Chapter 31 after the array and certificate conventions of Part II. The two routes meet in explicit finite operators, but readers need not study every compiler and scheduling API before filtering a signal.

Your task	Start here	Check before interpreting the result
Apply a matrix through named coordinate blocks	Chapters 28 and 29	Source/target layout and any omitted blocks
Solve or plan a finite operator computation	Chapter 30	Solver assumptions, residual, and the declared cost model
Frame a signal or inspect its spectrum	Chapters 31 and 32	Window, hop, padding, frequency scale, and reconstruction interval
Filter or change a sample rate	Chapters 33 and 34	Boundary convention, output length, and continuation state
Decompose or denoise with wavelets	Chapter 35	Transform depth, pruning, and the meaning of the risk certificate
Preserve or estimate jumps	Chapters 36 and 36A	Supplied packet information and unchecked recovery assumptions

In the operator chapters, *RHS* means right-hand side: one vector or several vectors arranged as matrix columns. A *residual* measures the discrepancy in a stated comparison. A *bound* limits a quantity under stated hypotheses. A small residual, a small bound, and a low operation count answer different questions.

28. Packet intermediate representation

A packet layout decomposes a finite coordinate space into named contiguous pieces. `PacketIR` then represents an operator by blocks between those pieces. An address is always `(target, source)`: block `(t, s)` maps source packet `s` to target packet `t`.

Before constructing a layout. Write down the input vector length, the output vector length, and the packet sizes on each side. Source sizes must partition the input, and target sizes must partition the output. A block's row count belongs to its target packet; its column count belongs to its source packet. Keeping this small shape record beside the code makes transposed addresses and mismatched layouts easier to diagnose.

28.1 Layouts, blocks, and `PacketIR`

For

$$X = \bigoplus_{s=0}^{p-1} X_s, \qquad n_s = \dim X_s > 0, \qquad n = \sum_s n_s,$$

`PacketLayout` stores `sizes=(n_0,...,n_{p-1})`. Its offsets and packet intervals are

$$o_0 = 0, \qquad o_{s+1} = o_s + n_s, \qquad I_s = [o_s, o_{s+1}).$$

`names=None` is normalized to `("0", ..., str(p-1))`. Supplied names are stringified, must match the packet count, and must be nonempty and unique. Sizes must be positive integer-index values. Booleans and numeric lookalikes such as `1.5` are rejected.

`PacketLayout` reference

```
PacketLayout(
    sizes: tuple[int, ...],
    names: tuple[str, ...] | None = None,
) -> PacketLayout
```

Member	Exact signature or value	Meaning
`sizes`	`tuple[int, ...]`	Normalized positive packet sizes
`names`	`tuple[str, ...]`	Explicit or generated packet names
`offsets`	`tuple[int, ...]`	`(o_0,...,o_p)`
`slices`	`tuple[slice, ...]`	Contiguous packet coordinate slices
`dimension`	`int`	`sum(sizes)`
`stored_coordinate_count`	property returning `int`	Equal to `dimension`
`equal`	`equal(packet_count: int, packet_size: int, *, prefix: str = "p") -> PacketLayout`	Equal-size named layout
`from_packet_system`	`from_packet_system(packet_system: Any) -> PacketLayout`	Uses `packet_dimensions()` and `names`
`index`	`index(packet: int | str) -> int`	Resolve an integer index or string name
`packet_slice`	`packet_slice(packet: int | str) -> slice`	Resolve `I_s`
`packet_size`	`packet_size(packet: int | str) -> int`	Resolve `n_s`

Member	Exact signature or value	Meaning
`split`	`split(value: Any, *, copy: bool = False) -> tuple[np.ndarray, ...]`	Split a vector or two-dimensional RHS by leading dimension
`merge`	`merge(packets: Sequence[Any]) -> np.ndarray`	Concatenate like-rank packet arrays
`crossed`	`crossed(other: PacketLayout, *, separator: str = "⊗") -> PacketLayout`	Tensor-product packet layout in left-major order
`permutation`	`permutation(order: Sequence[int]) -> np.ndarray`	Coordinate indices for a packet permutation

`split(..., copy=False)` returns views where NumPy slicing permits. `merge` requires all packets to be vectors or all to be matrices. Matrix packets must have a common RHS-column count. For layouts `X` and `Y`, `X.crossed(Y)` has sizes `n_s m_t` and names `X_s⊗Y_t` in nested left-then-right order. **E**

For source layout `X` and target layout `Y`, the stored blocks are

$$A_{ts} = Q_t A P_s \in \mathbb{K}^{m_t \times n_s}, \qquad (t, s) \in \Sigma(A).$$

`PacketIR` reference

```
PacketIR(
    source_layout: PacketLayout,
    target_layout: PacketLayout,
    blocks: Mapping[tuple[int, int], StructuredOperator | Any],
    metadata: Mapping[str, Any] = {},
) -> PacketIR
```

Member	Exact signature or value	Meaning
`square`	`square(layout, blocks, *, metadata=None) -> PacketIR`	Use one layout for source and target
`from_dense`	`from_dense(matrix, source_layout, target_layout=None, *, atol=0.0, rtol=0.0, keep_zeros=False) -> PacketIR`	Compile dense packet blocks by norm threshold
`shape`	property `tuple[int, int]`	`(target.dimension, source.dimension)`
`dtype`	property `np.dtype`	Result type of stored blocks. `float` for empty support
`support`	property `frozenset[tuple[int, int]]`	Stored block addresses
`stored_entries`	property `int`	Sum of each block's `storage_entries()`
`flop_count`	`flop_count(rhs: int = 1) -> int`	Sum of active block models
`block`	`block(target: int | str, source: int | str) -> StructuredOperator | None`	Stored block or `None`
`materialize`	`materialize() -> np.ndarray`	Dense matrix with blocks at packet slices
`apply`	`apply(value: Any) -> np.ndarray`	Apply to a vector or matrix RHS
`adjoint`	`adjoint() -> PacketIR`	Swap layouts and addresses and adjoint each block
`compose`	`compose(right: PacketIR, *, atol: float = 0.0) -> PacketIR`	`self` after `right`
`power`	`power(exponent: int, *, atol: float = 0.0) -> PacketIR`	Nonnegative square power by binary exponentiation
`tensor`	`tensor(other: PacketIR) -> PacketIR`	Blockwise Kronecker product

Member	Exact signature or value	Meaning
`diagonal_part`	`diagonal_part() -> PacketIR`	Retain `(s,s)` blocks of a common square layout
`certificate`	`certificate(*, tolerance: float = 1e-10) -> Certificate`	Compare application to materialization on the identity RHS

The application law is

$$y_t = \sum_{s:(t,s)\in\Sigma(A)} A_{ts}x_s, \qquad y = \mathrm{merge}_Y(y_0, \dots, y_{q-1}).$$

Vector input produces vector output. An `n x r` RHS produces an `m x r` output. `blocks` and `metadata` are copied into read-only mapping proxies at construction. Dense arrays supplied as blocks are wrapped by `DenseOperator`. The certificate computes

$$r_{\mathrm{IR}} = \|A(I_n) - \mathrm{materialize}(A)\|_F$$

because `np.linalg.norm` is called without an `ord`. It is valid when `r_IR <= tolerance`. Its exactness is `NUMERICAL`. **N**

Evidence: `src/komorebi_math/algorithms/layout.py`, `src/komorebi_math/algorithms/ir.py`, and `tests/test_algorithms_layout_ir.py`.

28.2 Dense-to-packet compilation

`PacketIR.from_dense` checks the full dense shape, computes

$$\theta = \tau_{\mathrm{abs}} + \tau_{\mathrm{rel}}\|A\|_2,$$

and stores a packet block exactly when

$$\|A[I_t, I_s]\|_2 > \theta.$$

The comparison is strict: a block exactly on the threshold is omitted. `keep_zeros=True` stores every packet rectangle regardless of norm. The method copies each retained dense block and records `{"support_threshold": theta}` in the IR metadata. Thresholding is numerical. Omission does not prove that a block is algebraically zero. **N/H**

Composition first materializes each contributing structured block, forms

$$C_{ts} = \sum_u A_{tu}B_{us},$$

then retains `C_ts` unless `atol > 0` and `||C_ts||_2 <= atol`. Consequently, the output blocks of `compose` are dense even if the inputs had more specialized block types. With `atol=0`, a reached block is stored even when different paths cancel to the zero matrix. This is intentional: structural reachability and a numerically nonzero block are different facts.

Runnable example (shipped as `examples/packet_ir.py`):

```
import numpy as np
from komorebi_math.algorithms import PacketIR, PacketLayout, packet_cost_estimate

layout = PacketLayout((2, 1), ("bulk", "edge"))
matrix = np.array([[2., 1., 0.],
                   [0., 3., 0.],
                   [4., 0., 5.]])
operator = PacketIR.from_dense(matrix, layout)
```

```
x = np.array([1., 2., 3.])
y = operator.apply(x)
operator.certificate().require()
cost = packet_cost_estimate(layout, layout, operator.support)

print("support", sorted(operator.support))
print("result", y)
print("stored entries", operator.stored_entries)
print("modeled flops", cost.flops)
```

Observed output in the audited environment:

```
support [(0, 0), (1, 0), (1, 1)]
result [ 4.  6. 19.]
stored entries 7
modeled flops 14
```

Evidence: `src/komorebi_math/algorithms/ir.py` and `examples/packet_ir.py`.

28.3 Support propagation

The support module treats addresses as a directed relation, still in `(target, source)` order. Relation composition is

$$L \circ R = \{(t, s) : \exists u \ (t, u) \in L \wedge (u, s) \in R\}.$$

All relation-returning public support functions return immutable `frozenset` relations.

Public API	Exact signature	Contract
`support_product`	`support_product(left: Iterable[Address], right: Iterable[Address]) -> frozenset[Address]`	Relation product `left` after `right`
`support_power`	`support_power(support, exponent: int) -> frozenset[Address]`	Repeated relation product
`support_polynomial`	`support_polynomial(support, coefficients, *, vertex_count: int) -> frozenset[Address]`	Union of supports for nonzero polynomial coefficients
`transitive_closure`	`transitive_closure(vertex_count, support, *, include_identity=True) -> frozenset[Address]`	Finite reachability relation
`inverse_support_if_acyclic`	`inverse_support_if_acyclic(vertex_count, support) -> frozenset[Address]`	Closure inclusion for an acyclic unit-diagonal inverse
`schur_fill_support`	`schur_fill_support(retained, hidden, support) -> frozenset[Address]`	Direct retained edges plus retained-hidden-retained paths
`topological_levels`	`topological_levels(vertex_count, support) -> tuple[tuple[int, ...], ...]`	Sorted executable DAG layers
`longest_path_vertices`	`longest_path_vertices(vertex_count, support) -> int`	Maximum vertex count on a directed path

`support_power(S, 0)` has no ambient vertex count. It returns identity edges only for vertices occurring in `S`, so the zero power of empty support is empty. By contrast, `support_polynomial(..., vertex_count=q)` inserts all `(v,v)` for `0 <= v < q` when the constant coefficient is nonzero, and `PacketIR.power(0)` builds the full packet identity.

For a polynomial `p(A)=sum_k c_k A^k`, the computed relation is an upper inclusion:

$$\Sigma(p(A)) \subseteq \bigcup_{k:c_k\neq 0} \Sigma(A)^k.$$

The inclusion can be strict because sums of block paths can cancel. For a strict acyclic graph on `q` vertices,

$$(I-N)^{-1} = I + N + \cdots + N^{q-1}, \qquad \Sigma((I-N)^{-1}) \subseteq \Sigma(N)^*.$$

The constructor is

```
SupportGraph(vertex_count: int, support: Iterable[Address])
```

`SupportGraph` exposes `targets(source)`, `sources(target)`, `reachable(sources)`, the property `is_acyclic`, and `closure(*, include_identity=True)`. Self-loops are ignored when testing acyclicity and building topological levels. Strict directed cycles are rejected.

Evidence: `src/komorebi_math/algorithms/support.py`, `tests/test_algorithms_support.py`, and the exhaustive four-vertex closure and random Schur-fill groups in `verification/block3_deep_audit.py`.

28.4 Complexity and memory models

For dense active packet blocks, batch size `r`, and scalar size `b` bytes, the declared models are

$$F_{\text{packet}} = 2r \sum_{(t,s)\in\Sigma} m_t n_s, \qquad S_{\text{packet}} = \sum_{(t,s)\in\Sigma} m_t n_s,$$

$$B_{\text{stream}} = b \sum_{(t,s)\in\Sigma} \left(m_t n_s + n_s r + 2 m_t r\right).$$

The traffic formula is a one-pass, no-cache-reuse model. It is not peak memory and does not include Python objects, address maps, executor setup, FFT work buffers, or dense materialization. Arithmetic intensity and the elementary roofline lower bound are

$$I = F/B, \qquad T_{\min} = \max(F/P_{\max}, B/W_{\max}).$$

These are **E/M** under the stated model, not observed runtime claims.

Public API	Exact signature
`dense_apply_flops`	`dense_apply_flops(rows: int, columns: int | None = None, rhs: int = 1) -> int`
`packet_apply_flops`	`packet_apply_flops(source_layout, target_layout, support, rhs: int = 1) -> int`
`packet_dense_storage_entries`	`packet_dense_storage_entries(source_layout, target_layout, support) -> int`
`block_diagonal_low_rank_storage_entries`	`block_diagonal_low_rank_storage_entries(layout, rank: int) -> int`
`block_diagonal_low_rank_flops`	`block_diagonal_low_rank_flops(layout, rank: int, rhs: int = 1) -> int`
`packet_streaming_bytes`	`packet_streaming_bytes(source_layout, target_layout, support, *, rhs: int = 1, itemsize: int = 8) -> int`
`arithmetic_intensity`	`arithmetic_intensity(flops: float, bytes_moved: float) -> float`
`roofline_time_lower_bound`	`roofline_time_lower_bound(flops, bytes_moved, peak_flops_per_second, bandwidth_bytes_per_second) -> float`

Public API	Exact signature
`packet_cost_estimate`	`packet_cost_estimate(source_layout, target_layout, support, *, rhs=1, itemsize=8, peak_flops_per_second=None, bandwidth_bytes_per_second=None) -> CostEstimate`

`CostEstimate` has fields `flops`, `storage_entries`, `streaming_bytes`, `arithmetic_intensity`, `roofline_seconds`, and `metadata`. Its metadata records `rhs`, `itemsize`, and `active_blocks`. Duplicate addresses are normalized. Both device rates must be supplied together. Rates must be finite and positive.

Evidence: `src/komorebi_math/algorithms/complexity.py` and `tests/test_algorithms_complexity_benchmarks.py`.

28.5 Benchmark contracts and observational timing discipline

Timing scopes are `TimingScope.KERNEL`, `DEVICE_RESIDENT`, and `END_TO_END`. A comparison contract is

$$\mathfrak{B} = (\text{case signature}, \text{output contract}, \text{timing scope}, \text{backend}).$$

`BenchmarkContract.create(case_signature, output_contract, timing_scope, backend)` stringifies and sorts signature keys. Collisions after string conversion are rejected. `matches(other, *, allow_backend_difference=True)` requires the same case signature, output contract, and timing scope. Backend equality is optional by that explicit flag.

Type/function	Exact signature or fields
`BenchmarkResult`	`contract`, `samples_seconds`, `median_seconds`, `minimum_seconds`, `maximum_seconds`, `value`
`BenchmarkComparison`	`baseline`, `candidate`, `speedup`
`benchmark_callable`	`benchmark_callable(function, contract, *, warmups=2, repeats=7, synchronize=None) -> BenchmarkResult`
`compare_benchmarks`	`compare_benchmarks(baseline, candidate, *, allow_backend_difference=True) -> BenchmarkComparison`

The benchmark helper runs untimed warmups, synchronizes after each warmup when a callback is supplied, and surrounds every timed call with synchronization. It reports the median and uses

$$\text{speedup} = \tilde{t}_{\text{baseline}} / \tilde{t}_{\text{candidate}}.$$

If the candidate median is nonpositive, the reported speedup is infinity. Timings remain environment-bound observations (**H/O**). The helper does not make them portable performance guarantees.

Evidence: `src/komorebi_math/algorithms/benchmarks.py` and `tests/test_algorithms_complexity_benchmarks.py`.

29. Structured and low-rank operators

Every concrete structured operator accepts vector and two-dimensional RHS input, preserves vector-versus-matrix rank, and supplies `shape`, `dtype`, `apply`, `materialize`, `adjoint`, `storage_entries`, and `flop_count`. `StructuredOperator.solve(value)` is the default dense square solve. `certificate_residual(value, result)` returns `||apply(value)-result||` after normalizing both arguments as RHS matrices.

29.1 Dense, identity, diagonal, block-diagonal

Constructor	Representation	Stored entries	Modeled apply flops for `r` RHS
`DenseOperator(matrix)`	Explicit `m x n` matrix	`mn`	`2mnr`
`IdentityOperator(dimension, scalar=1.0)`	`scalar * I_n`	`1`	`nr`
`DiagonalOperator(diagonal)`	`diag(d)`	`n`	`nr`
`BlockDiagonalOperator(blocks, names=None)`	Direct sum of square structured blocks	Sum of block storage	Sum of block flop models

`DenseOperator` requires a two-dimensional array and copies it. `IdentityOperator` requires a positive integer dimension. `solve` raises `np.linalg.LinAlgError` when `scalar == 0`. `DiagonalOperator` requires a nonempty vector and rejects solve when any diagonal entry equals zero. `BlockDiagonalOperator` requires at least one square block, creates a `PacketLayout` from their sizes, and exposes `block(packet)` by index or name. Its apply and solve paths split the RHS, execute each block, and merge the results. **E/N**, depending on the scalar dtype and called NumPy operation.

The exact public constructor and common method signatures are:

```
DenseOperator(matrix: np.ndarray)
IdentityOperator(dimension: int, scalar: complex = 1.0)
DiagonalOperator(diagonal: np.ndarray)
BlockDiagonalOperator(
    blocks: tuple[StructuredOperator | np.ndarray, ...],
    names: tuple[str, ...] | None = None,
)

operator.apply(value: Any) -> np.ndarray
operator.materialize() -> np.ndarray
operator.adjoint() -> StructuredOperator
operator.storage_entries() -> int
operator.flop_count(rhs: int = 1) -> int
operator.solve(value: Any) -> np.ndarray
```

`as_structured_operator(value)` returns an existing `StructuredOperator` unchanged or wraps `np.asarray(value)` in `DenseOperator`.

Evidence: `src/komorebi_math/algorithms/structured.py` and `tests/test_algorithms_structured.py`.

29.2 Toeplitz, circulant, Kronecker, Walsh-Hadamard

`CirculantOperator(first_column)` uses

$$C_{ij} = c_{(i-j) \bmod n}, \qquad Cx = \mathcal{F}_n^{-1}(\mathcal{F}_n(c) \odot \mathcal{F}_n(x)).$$

It stores `n` scalars and declares `10*n*ceil(log2(max(2,n)))*r` flops. Real operands are passed through `np.real_if_close` after the inverse FFT.

`ToeplitzOperator(first_column, first_row)` may be rectangular. Its corner entries are checked by NumPy `allclose`, not exact equality. Application uses a circulant embedding of length `m+n`. Storage is `m+n-1`, while the modeled work is `10*(m+n)*ceil(log2(max(2,m+n)))*r`. The implementation's one-element zero gap explains why the FFT length is `m+n`, not the minimal `m+n-1`.

For `KroneckerOperator(left, right)` with `left in K^(a x b)` and `right in K^(c x d)`, Fortran-order reshaping implements

$$(L \otimes R)\,\mathrm{vec}_F(X) = \mathrm{vec}_F(RXL^{\mathsf{T}}), \qquad X \in \mathbb{K}^{d \times b}.$$

It stores `ab+cd` factor entries and models, per RHS,

$$2cdb + 2cba$$

operations using the source variable convention `2*c*d*b + 2*c*b*a`.

`WalshHadamardOperator(dimension, normalized=False, dtype_value=float)` requires a positive power-of-two dimension. Its butterfly is

$$(u, v) \mapsto (u + v, u - v).$$

The unnormalized transform satisfies `H^-1 = H/n`. The normalized transform is self-inverse. The source model reports zero stored entries and `n*log2(n)*r` butterfly operations. Normalization promotes an exact integer working dtype to an inexact dtype before division.

Constructor	Shape	Notable members
`CirculantOperator(first_column)`	`(n,n)`	`first_column`
`ToeplitzOperator(first_column, first_row)`	`(len(column), len(row))`	both boundary vectors
`KroneckerOperator(left, right)`	`(a*c,b*d)`	both matrix factors
`WalshHadamardOperator(dimension, normalized=False, dtype_value=float)`	`(n,n)`	`dimension`, `normalized`, `dtype_value`

All four implement the common structured-operator methods listed in 29.1. The FFT and dense NumPy paths are numerical. The representation identities and declared operation counts are exact within their explicit finite models.

Evidence: `src/komorebi_math/algorithms/structured.py`, `tests/test_algorithms_structured.py`, and the `structured_operators` group in `verification/block3_deep_audit.py`.

29.3 Low-rank factors and recompression

$$A \approx UV^*, \qquad \|A - UV^*\| \le \varepsilon.$$

`LowRankOperator(left, right)` represents

$$A = UV^*, \qquad U \in \mathbb{K}^{m\times k}, \quad V \in \mathbb{K}^{n\times k}, \quad \operatorname{rank}(A) \le k.$$

The factors must be matrices with equal column counts. `k=0` is allowed. Application is `U @ (V.conj().T @ x)`, storage is `k(m+n)`, and modeled work is `2kr(m+n)`. `rank_bound`, `shape`, and `dtype` are properties.

The recompression APIs are

```
recompress_core(left, core, right, rank, *, tolerance=1e-10)
    -> RecompressionResult
recompress_factors(left, right, rank, *, tolerance=1e-10)
    -> RecompressionResult
```

For `A=L C R*`, reduced QR and a small SVD give

$$L = Q_L R_L, \quad R = Q_R R_R, \quad R_L C R_R^* = U\Sigma V^*,$$

$$\widetilde{U} = Q_L U_k \Sigma_k^{1/2}, \qquad \widetilde{V} = Q_R V_k \Sigma_k^{1/2}.$$

`RecompressionResult` contains `operator`, `singular_values`, `retained_rank`, `spectral_error`, `frobenius_error`, and `certificate`, plus `left`, `right`, and `materialize()`. In exact arithmetic the tail values are

$$\|A - \widetilde{U}\widetilde{V}^*\|_2 = \sigma_{k+1}, \qquad \|A - \widetilde{U}\widetilde{V}^*\|_F = \left(\sum_{j>k} \sigma_j^2\right)^{1/2}.$$

The returned factors and tails are NumPy numerical realizations. The certificate has `Exactness.NUMERICAL` and checks the actual spectral residual against `spectral_error + tolerance*max(1, ||A||_2)`. Empty factors return a valid rank-zero correction. **N**

Evidence: `src/komorebi_math/algorithms/low_rank.py`, `tests/test_algorithms_low_rank.py`, and the `low_rank` group in `verification/block3_deep_audit.py`.

29.4 Product-chain error accumulation

`BlockDiagonalLowRankOperator(diagonal, correction)` represents

$$A = D + UV^*, \qquad D = \bigoplus_s D_s.$$

The correction must match the square diagonal shape. The complete member surface is:

Member	Exact signature or value
constructor	`BlockDiagonalLowRankOperator(diagonal: BlockDiagonalOperator, correction: LowRankOperator)`
`from_factors`	`from_factors(diagonal, left, right) -> BlockDiagonalLowRankOperator`
properties	`shape`, `dtype`, `rank_bound`
execution	`apply(value)`, `materialize()`, `adjoint()`
models	`storage_entries()`, `flop_count(rhs=1)`
solve	`solve(value) -> np.ndarray`
product	`exact_product(right) -> BlockDiagonalLowRankOperator`
recompression	`recompress(rank, *, tolerance=1e-10) -> tuple[BlockDiagonalLowRankOperator, RecompressionResult]`

For dense square diagonal blocks of sizes `n_s`, its declared representation models are

$$S = \sum_s n_s^2 + 2nk, \qquad F = 2r \sum_s n_s^2 + 4nkr.$$

The object methods instead sum the actual structured block storage and flop models, so these closed forms apply only when each diagonal block is dense.

The Woodbury solve is

$$(D + UV^*)^{-1}b = D^{-1}b - D^{-1}U(I + V^*D^{-1}U)^{-1}V^*D^{-1}b.$$

Each diagonal block and the small middle matrix must be solvable. NumPy `LinAlgError` is allowed to propagate when either condition fails. `exact_product` constructs an unrecompressed BDLR representation before any requested recompression.

For factor lists in application order, `product_chain_error_bound(exact_factors, approximate_factors)` implements the telescoping spectral-norm bound

$$\left\|\widetilde{A}_{q-1}\cdots\widetilde{A}_0 - A_{q-1}\cdots A_0\right\|_2 \le \sum_{j=0}^{q-1}\left(\prod_{i>j}\|\widetilde{A}_i\|_2\right)\|\widetilde{A}_j - A_j\|_2\left(\prod_{i<j}\|A_i\|_2\right).$$

`accumulated_recompression_bound(operator_norms, local_errors, *, initial_error=0.0)` implements the recurrence

$$E_j \le \|A_j\|E_{j-1} + e_j.$$

Both helpers validate dimensions or finite nonnegative scalar inputs. They return bounds, not measured errors.

For a first recompression experiment, keep the original factors, compare the reconstructed operator with that reference, and read the reported retained rank together with the spectral and Frobenius errors. The two error fields summarize different norms; choose the one used by the downstream estimate. When several approximations are composed, use the product-chain bound rather than treating the largest single-step error as the error of the whole chain.

Runnable shipped example (`examples/low_rank_recompression.py`) produced:

```
solve residual 0.0
product rank bound 4
compressed rank 2
compression spectral error 0.0002447567526018822
```

The final number is seed- and NumPy-environment-specific numerical output, not a universal error constant.

Evidence: `src/komorebi_math/algorithms/low_rank.py`, `src/komorebi_math/algorithms/complexity.py`, and `examples/low_rank_recompression.py`.

29.5 Restricted structure discovery

Structure discovery is limited by design to a caller-supplied packet layout. It does not infer a universal representation.

```
discover_packet_support(
    matrix: Any,
    layout: PacketLayout,
    *,
    absolute_tolerance: float = 0.0,
    relative_tolerance: float = 1e-12,
) -> SupportDiscoveryResult
```

It computes

$$\theta = \tau_a + \tau_r \|A\|_2, \qquad \widehat{\Sigma} = \{(t,s) : \|A_{ts}\|_2 > \theta\}.$$

`SupportDiscoveryResult` contains `packet_ir`, every `block_norms` value, `threshold`, and a heuristic `certificate`. The certificate is always marked valid after successful input validation, has `Exactness.HEURISTIC`, reports `||A-materialize(packet_ir)||_2`, and leaves the application-level negligibility of discarded blocks unchecked. A block at the threshold is discarded, so support can change discontinuously under small perturbations. **H/N**

```
discover_block_diagonal_low_rank(
    matrix: Any,
    layout: PacketLayout,
    rank: int,
    *,
    tolerance: float = 1e-10,
) -> BDLRDiscoveryResult
```

This routine fixes the packet diagonal `D`, forms `R=A-D`, and truncates the NumPy SVD of `R` to the requested rank. `BDLRDiscoveryResult` contains `operator`, `singular_values`, `spectral_error`, `frobenius_error`, and a numerical `certificate`. The rank-constrained SVD theorem applies to the fixed residual and fixed layout. The floating realization is **N**, not exact symbolic structure discovery.

Evidence: `src/komorebi_math/algorithms/discovery.py`, `tests/test_algorithms_discovery_gpu.py`, and the `discovery` group in `verification/block3_deep_audit.py`.

30. Krylov, precision, compilation, and scheduling

The Krylov routines accept matrix-free callables. They check the dimensions and scalar pairings encountered during the run, but they cannot infer global linearity, Hermitian symmetry, or positive definiteness from finitely many generated directions.

30.1 Krylov subspaces and conjugate gradients

For nonzero `b in K^n`,

$$\mathcal{K}_k(A, b) = \operatorname{span}\{b, Ab, \dots, A^{k-1}b\}.$$

```
krylov_basis(
    apply: Callable[[np.ndarray], np.ndarray],
    start: Any,
    steps: int,
    *,
    tolerance: float = 1e-12,
) -> KrylovBasisResult
```

Modified Gram-Schmidt returns `KrylovBasisResult(basis, dimension, breakdown, certificate)`. `steps` must lie in `[1, n]`. A start norm at or below tolerance is rejected. Breakdown occurs when a generated vector has norm at or below tolerance after orthogonalization. The certificate checks

$$\|Q^*Q - I\|_F \le 100\,\texttt{tolerance}.$$

The conjugate-gradient API is

```
conjugate_gradient(
    apply,
    right_hand_side,
    *,
    precondition=None,
    initial=None,
    relative_tolerance=1e-10,
    absolute_tolerance=0.0,
    max_iterations=None,
    curvature_tolerance=1e-14,
) -> ConjugateGradientResult
```

It declares `Ax=b` with `A=A*>0` and, when supplied, a positive-definite preconditioner action. The stopping threshold is

$$\tau_{\text{stop}} = \max(\tau_{\text{abs}}, \tau_{\text{rel}}\|b\|_2).$$

With `z_k=M^{-1}r_k`, it uses

$$\alpha_k = \frac{r_k^* z_k}{p_k^* A p_k}, \quad x_{k+1} = x_k + \alpha_k p_k, \quad r_{k+1} = r_k - \alpha_k A p_k,$$

$$\beta_k = \frac{r_{k+1}^* z_{k+1}}{r_k^* z_k}, \qquad p_{k+1} = z_{k+1} + \beta_k p_k.$$

If `max_iterations=None`, the limit is `10*n`. Generated pairings must be real to the configured curvature scale and positive above the numerical floor. Violations raise `AssumptionError`. `ConjugateGradientResult` contains `solution`, `residual_norms`, `iterations`, `converged`, and `certificate`. The certificate compares a freshly evaluated final residual with the stop threshold, also reports the recursive residual, and explicitly leaves global Hermitian positive definiteness unchecked. Reaching the iteration limit returns a nonvalid, nonconverged result rather than raising. **N/C**

A returned solution array is therefore only the start of the decision. Inspect `converged`, the fresh final residual, and the certificate before using it. If the iteration cap was reached, first check the operator and preconditioner assumptions and the requested tolerance. Increasing the cap does not repair a violated positive-definiteness hypothesis.

Evidence: `src/komorebi_math/algorithms/krylov.py` and `tests/test_algorithms_krylov.py`.

30.2 Block Jacobi certificates

`lanczos_tridiagonal(apply, dimension, steps, *, start=None, seed=0, tolerance=1e-12)` performs fully reorthogonalized finite Lanczos iteration. It returns `LanczosResult(tridiagonal, basis, alpha, beta, breakdown, certificate)`. The certificate checks

$$r_{\text{orth}} = \|Q^*Q - I\|_F, \qquad r_{\text{tri}} = \|Q^*AQ - T\|_F,$$

against `1000*tolerance`. A materially complex `q* A q` raises `AssumptionError`. Eigenvalues of the returned `T` are Ritz values. The API does not certify global eigenvalue accuracy. **N/C**

For a square matrix and packet layout, define

$$D = \text{blockdiag}(A), \qquad E = D^{-1/2}(A - D)D^{-1/2}, \qquad \eta = \|E\|_2.$$

If `A` is Hermitian, every packet-diagonal block is positive definite, and `eta < 1`, then

$$\kappa(D^{-1/2}AD^{-1/2}) \le \frac{1+\eta}{1-\eta}.$$

API	Exact signature or fields
`block_jacobi_certificate`	`block_jacobi_certificate(matrix, layout, *, tolerance=1e-10) -> BlockJacobiCertificate`
`BlockJacobiCertificate`	`diagonal`, `normalized_coupling`, `eta`, `condition_bound`, `certificate`
`block_jacobi_preconditioner`	`block_jacobi_preconditioner(diagonal: BlockDiagonalOperator) -> Callable`
`preconditioned_condition_bound`	`preconditioned_condition_bound(eta: float) -> float`
`power_perturbation_bound`	`power_perturbation_bound(left_norm, right_norm, difference_norm, exponent) -> float`

The constructor raises when Hermitian residual exceeds tolerance or a packet block has minimum eigenvalue at or below tolerance. If `eta >= 1`, it does not raise: it returns `condition_bound=None` and a nonvalid certificate that records the missing coupling hypothesis. The preconditioner callable applies the exact packet-block solves represented by `diagonal`.

The power helper returns zero for exponent zero and otherwise

$$\|A^k - B^k\| \le k \max(\|A\|, \|B\|)^{k-1} \|A - B\|.$$

Runnable shipped example (`examples/structured_krylov.py`) produced:

```
iterations 4
residual 9.930136612989092e-16
```

Evidence: `src/komorebi_math/algorithms/krylov.py`, `examples/structured_krylov.py`, and the `krylov` group in `verification/block3_deep_audit.py`.

30.3 Continuous and discrete precision allocation

For sensitivities `s_i>0`, logarithmic costs `c_i>0`, and total error budget `T>0`, the continuous model is

$$\min_{\varepsilon_i > 0} \sum_i c_i \log(1/\varepsilon_i) \quad \text{subject to} \quad \sum_i s_i \varepsilon_i \le T.$$

`optimal_precision_tolerances(sensitivities, costs, total_tolerance)` returns

$$\varepsilon_i^* = \frac{T c_i}{s_i \sum_j c_j}.$$

`clipped_precision_allocation(sensitivities, costs, total_tolerance, maxima)` enforces `0 < epsilon_i <= maxima_i` through

$$\varepsilon_i(\lambda) = \min\left(u_i, \frac{c_i}{\lambda s_i}\right),$$

using bracketing followed by 240 bisection steps. When the supplied total tolerance is at least `dot(sensitivities, maxima)`, it returns `maxima.copy()`. These are floating numerical realizations of the declared allocation model.

For finite precision choices:

```
DTypeChoice(name: str, cost: float, error_units: int, dtype: str | None = None)
assign_discrete_precisions(
    options: Sequence[Sequence[DTypeChoice]],
    budget: int,
) -> PrecisionAssignment | None
```

The dynamic program solves exactly, for its finite additive integer model,

$$\min_{d_i \in \mathcal{D}_i} \sum_i c_{i,d_i} \quad \text{subject to} \quad \sum_i e_{i,d_i} \le B.$$

It returns `None` when infeasible. `PrecisionAssignment` contains `names`, `total_cost`, `error_units`, and an exact certificate. Ties are resolved by the tuple ordering `(total_cost, error_units, names)`.

Additional precision APIs are:

API	Exact signature	Result
`packet_error_bound`	`packet_error_bound(perturbation_norms, source_packet_norms) -> float`	`sum_i error_i*source_norm_i` using `math.fsum`
`precision_certificate`	`precision_certificate(perturbation_norms, source_packet_norms, observed_error, *, tolerance=1e-10) -> Certificate`	Checks observed error against bound plus tolerance
`quantize_array`	`quantize_array(value, dtype) -> np.ndarray`	NumPy cast with complex-partner preservation

API	Exact signature	Result
`quantize_by_packet`	`quantize_by_packet(values, dtypes) -> tuple[np.ndarray, ...]`	One cast per packet
`quantization_error`	`quantization_error(value, dtype, *, norm_order=2) -> float`	Norm of cast error

Complex input cast toward `float16` or `float32` becomes `complex64`. Complex input cast toward `float64` becomes `complex128`. Other target dtypes are left to NumPy's dtype behavior. This prevents silently discarding the imaginary part for the named real floating targets.

The shipped precision/scheduling example produced:

```
precision choices ('low64', 'high32')
total cost 4.0
schedule makespan 5.0
critical path ('analyze', 'high', 'synthesize')
```

Evidence: `src/komorebi_math/algorithms/precision.py`, `tests/test_algorithms_precision.py`, `examples/precision_schedule.py`, and the `precision` group in `verification/block3_deep_audit.py`.

30.4 Exact finite tree compilation

At a node `v`, the compiler compares a keep option `(c_v,e_v)` with split overhead `s_v` plus its children. The public immutable records are:

```
TreeNode(
    name: str,
    keep_cost: float,
    keep_error: float,
    split_cost: float = 0.0,
    children: tuple[TreeNode, ...] = (),
)

TreePlan(
    cost: float,
    error: float,
    leaves: tuple[str, ...],
    decisions: tuple[tuple[str, str], ...],
    objective: float | None = None,
    quantized_error: int | None = None,
    certificate: Certificate | None = None,
)
```

`TreeNode.terminal` is a property and `names()` recursively lists the topology. Names must be nonempty and unique throughout the tree. All model values must be finite and nonnegative. `TreePlan.decision(node)` returns `"keep"`, `"split"`, or `None`.

`compile_tree_lagrangian(root, penalty)` implements

$$J_v^{\text{keep}} = c_v + \lambda e_v, \qquad J_v^{\text{split}} = s_v + \sum_{u \in \text{ch}(v)} J_u^*, \qquad J_v^* = \min(J_v^{\text{keep}}, J_v^{\text{split}}).$$

It returns the exact minimizer of the supplied finite additive floating-value model. Tie order is `(objective, cost, error, leaves)`.

`compile_tree_budget(root, budget, *, error_unit=1.0)` quantizes every selected leaf independently,

$$q_v = \lceil e_v/u - 10^{-14} \rceil, \qquad \sum_{v \in L} q_v \le B,$$

and returns the minimum-cost feasible plan or `None`. The small `1e-14` offset is part of the source behavior at representational boundaries. This compiler does not round the final real error sum once.

Evidence: `src/komorebi_math/algorithms/compiler.py` and `tests/test_algorithms_compiler.py`.

30.5 Pareto frontiers and task scheduling

`pareto_frontier(root, *, tolerance=0.0, max_plans=100000)` enumerates nondominated `(cost,error)` plans. Zero tolerance gives the exact frontier of the supplied Python floating values. Positive tolerance changes dominance and tie semantics. `max_plans` guards the Cartesian product count at each split and raises `ValidationError` before an oversized combination is materialized.

The remaining tree utilities are:

API	Exact signature or fields
`combine_tree_objectives`	`combine_tree_objectives(roots, weights) -> TreeNode`
`DecisionMargin`	`node`, `keep_objective`, `split_objective`, `margin`, `chosen`
`decision_margins`	`decision_margins(root, penalty) -> tuple[DecisionMargin, ...]`
`replace_tree_nodes`	`replace_tree_nodes(root, updates) -> TreeNode`

Objective trees must have identical names and child counts at every node, and weights must be finite, nonnegative, and have positive total. Updates may name only existing nodes and fields `keep_cost`, `keep_error`, and `split_cost`.

The shipped compiler example produced:

```
Lagrangian leaves ('left', 'right')
budget leaves ('left', 'right')
Pareto points [(9.0, 0.0, ('root',)), (7.5, 0.30000000000000004, ('left', 'right')), (5.2, 0.8999999999999999,
    ↪ ('left', 'right_low', 'right_high'))]
```

The printed decimal tails are ordinary binary floating-point representations.

For scheduling, `Task(name, duration=1.0, dependencies=(), shape_key=None)` declares a finite task DAG. Names and dependency names must be nonempty strings. Dependencies must be unique and cannot include the task itself. Durations must be finite and nonnegative. Shape keys must be hashable.

Scheduling API	Exact signature or fields
`ScheduledTask`	`name`, `start`, `finish`, `level`
`TaskSchedule`	`tasks`, `makespan`, `critical_path`, `levels`. Method `by_name()`
`schedule_unlimited`	`schedule_unlimited(tasks: Sequence[Task]) -> TaskSchedule`
`shape_classes`	`shape_classes(tasks: Iterable[Task]) -> dict[Hashable | None, tuple[str, ...]]`
`batched_launch_count`	`batched_launch_count(tasks, *, batching_available=True) -> int`
`verify_schedule`	`verify_schedule(tasks, schedule, *, tolerance=1e-12) -> bool`
`amortization_threshold`	`amortization_threshold(setup_time, baseline_time, candidate_time) -> int | None`
`BreakEvenResult`	`setup_time`, `baseline_time`, `candidate_time`, `reuse_count`, `asymptotic_gain`
`break_even_analysis`	`break_even_analysis(setup_time, baseline_time, candidate_time) -> BreakEvenResult`

Scheduling API	Exact signature or fields

Under unlimited concurrency,

$$t_v^{\text{start}} = \max_{u \to v} t_u^{\text{finish}}, \qquad t_v^{\text{finish}} = t_v^{\text{start}} + d_v.$$

The makespan is the weighted critical-path length for the declared durations. This schedule is exact for that model. It does not model worker limits, launch contention, transfers, or resource occupancy. Shape batching reports the ideal launch count `number of distinct shape_key values` only when batching is available. Otherwise it reports the number of tasks. **E/M**

For setup `S`, baseline per-use time `b`, and candidate per-use time `c`, the strictly profitable reuse count is

$$q_{\min} = \left\lfloor \frac{S}{b - c} \right\rfloor + 1$$

when `b>c`, bounded below by one. If `b<=c`, there is no finite threshold and the result is `None`.

Evidence: `src/komorebi_math/algorithms/compiler.py`, `src/komorebi_math/algorithms/scheduling.py`, `examples/packet_compiler.py`, `examples/precision_schedule.py`, and the `compiler` and `scheduling` groups in `verification/block3_deep_audit.py`.

30.6 NumPy and optional CuPy execution

```
NumpyPacketExecutor(packet_ir: PacketIR)
CupyPacketExecutor(packet_ir: PacketIR)
packet_executor(packet_ir: PacketIR, backend: str = "numpy")
    -> NumpyPacketExecutor | CupyPacketExecutor
cupy_available() -> bool
```

`NumpyPacketExecutor.apply(value)` returns `DeviceExecutionResult(value, backend="numpy", returned_to_host=True, certificate=...)` and delegates to `PacketIR.apply`.

`CupyPacketExecutor` imports CuPy only when constructed and materializes and transfers every stored block once during construction. Its method

```
apply(value, *, return_host: bool = True, input_on_device: bool = False)
    -> DeviceExecutionResult
```

distinguishes input transfer from execution and output transfer. With `return_host=False`, the value remains a CuPy array. `synchronize()` calls the null CUDA stream's synchronization method.

`cupy_available()` checks module discoverability with `find_spec`. It does not prove import success, a working CUDA runtime, a visible device, execution correctness, or performance. `packet_executor` accepts backend names case-insensitively for `numpy` and `cupy`. Other names raise `ValidationError`. There is no silent CPU fallback for a requested CuPy executor. **O**

The recorded audit environment reported `cupy_available() == False`, so it verified the unavailable-backend boundary but did not execute a GPU kernel. Separately, the repository's committed CUDA qualification report records a prior Windows qualification with a 4/4 CUDA gate on an RTX 3070 Ti Laptop GPU and CuPy 14.1.1. That historical environment record is not a timing claim for the recorded audit host.

Evidence: `src/komorebi_math/algorithms/gpu.py`, `tests/test_algorithms_discovery_gpu.py`, `docs/GPU_VALIDATION.md`, and `release/BLOCK17_RELEASE_REPORT.md`.

30.7 Restricted structure discovery, discovery certificates, and false-positive controls

Discovery output must be read in this order:

1. The caller fixes the packet layout.
2. The routine computes finite block norms or a residual SVD.
3. The certificate reports the observed residual and its exactness class.
4. The caller decides whether the threshold or rank is meaningful for the application.

`discover_packet_support` uses a strict norm threshold and labels its certificate `HEURISTIC`. It does not call discarded blocks exact zeros. `discover_block_diagonal_low_rank` certifies a numerical SVD truncation only after fixing the block diagonal. Neither routine searches over layouts, identifies an unknown algebraic family, or protects a near-threshold decision from changing under perturbation. These limitations are the false-positive controls: the API exposes norms, thresholds, residuals, and unchecked assumptions rather than upgrading observed smallness to structure.

The certificate/member tables and exact signatures are in 29.5.

Evidence: `src/komorebi_math/algorithms/discovery.py`, `docs/BLOCK_3_RELEASE.md`, and `tests/test_algorithms_discovery_gpu.py`.

30.8 GPU runtime status, device execution, and hardware qualification

For this algorithms surface, runtime status has several distinct levels:

Level	What establishes it	What it does not establish
Module discoverable	`cupy_available()`	Import success or CUDA usability
Executor constructed	CuPy import plus block transfers complete	Synchronized timing or CPU parity
Device call returned	`CupyPacketExecutor.apply` returns	Timing validity. Its certificate leaves synchronization unchecked
Qualified hardware run	External gate checks runtime, device, synchronized execution, and parity	Performance portability to another host

Use a matched `BenchmarkContract` and pass `executor.synchronize` to `benchmark_callable` before presenting device timing. Compare CPU and GPU values before comparing their medians, and do not compare kernel-only timing with end-to-end timing. The source executor certificate is an execution record, not a hardware qualification record.

Failure and boundary checklist for Chapters 28 through 30

Boundary	Source behavior
Empty layout, nonpositive/noninteger sizes, duplicate names	`ValidationError` or `DimensionError`
Wrong packet leading dimension or mixed RHS ranks	`DimensionError`
Malformed/out-of-range IR address or wrong block shape	`ValidationError` / `DimensionError`
Negative or nonfinite thresholds/tolerances	`ValidationError`
Incompatible composition layouts. Nonsquare power	`DimensionError`
Negative/noninteger exponent or RHS count	`ValidationError`
Singular structured solve	NumPy `LinAlgError`
Toeplitz corner outside NumPy `allclose`	`ValidationError`
Non-power-of-two Walsh dimension	`ValidationError`
Low-rank factor/core mismatch or noncomposable product chain	`DimensionError`
Cyclic inverse/topological request or invalid graph partition	`ValidationError`
Zero Krylov start or invalid step count	`ValidationError`
Generated non-Hermitian/negative CG or Lanczos pairing	`AssumptionError`

Boundary	Source behavior
Block Jacobi `eta >= 1`	Returned nonvalid certificate, not an exception
Empty discrete option list or invalid dtype/budget	`ValidationError`
Infeasible discrete assignment or tree budget	`None`
Duplicate tree/task names, unknown updates/dependencies, DAG cycle	`ValidationError`
Pareto combination count above `max_plans`	`ValidationError`
Unknown executor backend	`ValidationError`
CuPy not installed	`BackendUnavailableError` on CuPy executor construction

Evidence: the validation branches in all thirteen `src/komorebi_math/algorithms/*.py` public modules and the ten focused test modules listed below.

30.9 Verification evidence and known defects

All commands below were run from the recovered reference repository with `PYTHONPATH=src` and the available `.venv-guide` Python environment.

Executed item	Observed result
Focused tests: `test_algorithms_layout_ir.py`, `support.py`, `complexity_benchmarks.py`, `structured.py`, `low_rank.py`, `krylov.py`, `precision.py`, `compiler.py`, `scheduling.py`, `discovery_gpu.py`	`79 passed in 1.22s`
`verification/block3_deep_audit.py`	`25,958` checks, `0` failures
`examples/packet_ir.py`	Completed. Output reproduced in 28.2
`examples/low_rank_recompression.py`	Completed. Output reproduced in 29.4
`examples/structured_krylov.py`	Completed. Output reproduced in 30.2
`examples/precision_schedule.py`	Completed. Output reproduced in 30.3
`examples/packet_compiler.py`	Completed. Output reproduced in 30.5
Local CuPy probe	`cupy_available() == False`. No device execution performed

The deep audit independently covered 1,000 PacketIR checks, 270 structured operator checks, 820 low-rank checks, 5,596 support checks, 792 Krylov checks, 7,787 precision checks, 3,633 compiler checks, 4,560 scheduling checks, and 1,500 discovery checks. Those counts come from the observed JSON printed by the verifier. They are not inferred from test collection.

No implementation failure was observed in the focused tests, examples, or deep audit. The recorded audit identified the following documentation and runtime boundaries:

- `docs/API_INVENTORY.md` lists `PacketBlock` under the algorithms layout/IR surface, but the current `algorithms.__all__` and source modules export no `PacketBlock`. Use `PacketIR` blocks as `StructuredOperator` instances.
- CuPy is absent on the recorded audit host. The local run therefore provides no new GPU correctness or performance evidence, even though a separate committed CUDA qualification report records prior qualified hardware execution.
- Threshold discovery, finite-direction CG/Lanczos checks, roofline numbers, ideal batching, and benchmark medians retain the heuristic, conditional, modeled, or observational boundaries stated above. These are contract limitations, not promoted theorem claims.

Chapters 28 through 30 summary. `PacketLayout` and `PacketIR` make packet coordinates, block addresses, execution, support, storage, and arithmetic explicit. Structured primitives and low-rank factors avoid unnecessary dense storage while retaining a materialized reference path. Krylov certificates validate generated numerical evidence without inferring global hypotheses. Precision and tree compilers are exact only for their declared finite models. Schedules and roofline estimates are resource models. Discovery remains fixed-layout and threshold-aware. GPU claims require an actually qualified runtime and matched timing scope.

31. Signal conventions, windows, and framing

Komorebi Math's signal layer is a finite-array API. In this chapter, a signal is a nonempty one-dimensional NumPy-compatible array

$$x = (x_0, \dots, x_{N-1}) \in \mathbb{K}^N, \qquad \mathbb{K} \in \{\mathbb{R}, \mathbb{C}\},$$

and time is always axis 0. Framed arrays use axis 0 for frame number and axis 1 for the sample within a frame. The routines in Chapters 31 and 32 are exported from `komorebi_math.signals`. Their implementation modules are `signals.windows`, `signals.time_frequency`, `signals.spectral`, and `signals.streaming`.

The word *finite* defines the scope of these operations. Window overlap is evaluated on a finite residue system, framing has explicit left and right padding, and inverse STFT checks only the represented finite interval. None of these operations establishes stationarity, an infinite-dimensional frame theorem, stochastic consistency, or real-time performance.

Signal-processing vocabulary. A frame is a short slice of the signal; the hop is the number of samples between successive frame starts. A window weights the samples within a frame. STFT means short-time Fourier transform, and PSD means power spectral density. COLA means constant overlap-add and NOLA means nonzero overlap-add; their precise tests are given in Section 31.2.3. Keep sample counts distinct from physical time and frequency: the sample rate is what converts between those units.

For a first reconstruction, keep the original signal and the full returned transform record. Reuse its window and framing metadata in synthesis, then compare with the retained original. Changing padding or discarding metadata can change the finite problem even when the coefficient array looks familiar.

31.1 Array, axis, dtype, boundary, and signal-first conventions

This signal research surface follows these rules:

- One-dimensional DSP functions have no `axis` argument. A multidimensional array is rejected where the implementation validates dimensionality.
- Signal-first operations elsewhere in the signal package take the signal before the kernel. The Chapter 31 framing and Chapter 32 Fourier operations have no kernel argument.
- `frame_signal` and `stft` call `np.asarray` but do not reject nonfinite samples. `periodogram`, `welch_psd`, `cross_spectrum`, `parseval_certificate`, and streaming STFT do reject nonfinite input. There is no package-wide finiteness rule.
- Named windows are floating arrays. Explicit array windows are copied with their existing dtype. Framing preserves the signal dtype. Overlap-add uses `np.result_type(frames.dtype, window.dtype)`.
- NumPy's FFT implementation determines transform precision. Fourier coefficients are complex. Frequency and time coordinates are floating arrays. Spectrogram and power-spectrum ordinates are stored as floating arrays. Cross power and H1 transfer may be complex, while coherence is floating.
- `overlap_add` and `istft` call `np.real_if_close(..., tol=1000)` after computation. Consequently, a complex result with only roundoff-sized imaginary parts may be returned as real. This is dtype simplification, not a reconstruction certificate.
- Boundary mode is mathematical input. `"zeros"` pads by zero, `"edge"` repeats endpoints, `"reflect"` mirrors without repeating the edge sample, and `"none"` forbids any required padding.
- Real input defaults to one-sided Fourier output. Complex input defaults to two-sided output and is rejected if one-sided output is explicitly requested.

The public type aliases relevant to these conventions are:

Alias	Declared values
`WindowName`	`"boxcar"`, `"rectangular"`, `"hann"`, `"hamming"`, `"blackman"`, `"bartlett"`, `"kaiser"`, `"tukey"`
`WindowSpec`	`WindowName | str | tuple[str, float] | np.ndarray`
`BoundaryMode`	`"zeros" | "reflect" | "edge" | "none"`

Runtime name normalization also recognizes `rect`, `rectangle`, and `ones` as boxcar, `hanning` as Hann, and `triang` and `triangle` as Bartlett. Case is ignored, surrounding whitespace is stripped, and underscores are changed to hyphens.

The only required runtime dependency for these APIs is NumPy (`numpy>=1.26`). The package requires Python 3.11 or newer. SciPy is not used by the implementation. It is optional and appears only in the independent convention-matched reference audit.

31.2 Deterministic windows and window metrics

31.2.1 Deterministic window construction

```
get_window(
    window: WindowSpec,
    length: int,
    *,
    periodic: bool = True,
) -> np.ndarray
```

`get_window` implements theorem record `KM-DSP-D01`, *Finite deterministic analysis window*. `length` must be a positive integer and a Boolean is not accepted as an integer.

For a symmetric window of requested length $N > 1$, let $j = 0, \dots, N-1$, $D = N - 1$, and $u_j = 2j/D - 1$. The named windows are

$$
\begin{aligned}
w_j^{\text{boxcar}} &= 1, \\
w_j^{\text{Hann}} &= \tfrac{1}{2} - \tfrac{1}{2}\cos(2\pi j/D), \\
w_j^{\text{Hamming}} &= 0.54 - 0.46\cos(2\pi j/D), \\
w_j^{\text{Blackman}} &= 0.42 - 0.5\cos(2\pi j/D) + 0.08\cos(4\pi j/D), \\
w_j^{\text{Bartlett}} &= \frac{2}{D}\left(\frac{D}{2} - \left|j - \frac{D}{2}\right|\right), \\
w_j^{\text{Kaiser}}(\beta) &= \frac{I_0\left(\beta\sqrt{1 - u_j^2}\right)}{I_0(\beta)}.
\end{aligned}
$$

For $0 < \alpha < 1$, the Tukey window is

$$
w_j^{\text{Tukey}}(\alpha) = \begin{cases}
\frac{1}{2}\left[1 + \cos\left(\pi\left(\frac{2j}{\alpha D} - 1\right)\right)\right], & j < \alpha D/2, \\
1, & \alpha D/2 \le j \le D(1 - \alpha/2), \\
\frac{1}{2}\left[1 + \cos\left(\pi\left(\frac{2j}{\alpha D} - \frac{2}{\alpha} + 1\right)\right)\right], & j > D(1 - \alpha/2).
\end{cases}
$$

The endpoint cases are exact branches: $\alpha \le 0$ produces boxcar, and $\alpha \ge 1$ produces Hann. The runtime validator restricts Tukey tuples to $0 \le \alpha \le 1$ and Kaiser tuples to finite $\beta \ge 0$. A bare `"kaiser"` uses $\beta = 14$. A bare `"tukey"` uses $\alpha = 0.5$. Only Kaiser and Tukey accept parameter tuples.

With `periodic=True`, the implementation evaluates the corresponding symmetric formula at length $N+1$, then discards its last sample. Thus the cosine denominator is N, not $N-1$. With `periodic=False`, it directly evaluates the symmetric length-N formula. Every named family returns `[1.0]` at $N=1$.

An explicit array is not regenerated: it must already be one-dimensional, have exactly `length` entries, and contain finite values. `get_window` returns a copy.

Cost. Named construction and explicit-window validation take $\Theta(N)$ time and $\Theta(N)$ output storage.

31.2.2 Gain and equivalent-noise-bandwidth metrics

```
window_metrics(window: Any, *, sample_rate: float = 1.0) -> WindowMetrics
```

For a nonempty finite window $w \in \mathbb{K}^N$, define

$$W_0 = \sum_{n=0}^{N-1} w_n, \qquad G_c = \frac{|W_0|}{N}, \qquad G_p = \frac{1}{N}\sum_{n=0}^{N-1} |w_n|^2.$$

The equivalent noise bandwidth is

$$\mathrm{ENBW}_{\mathrm{bins}} = \frac{N \sum_n |w_n|^2}{|W_0|^2}, \qquad \mathrm{ENBW}_{\mathrm{Hz}} = \frac{f_s}{N}\,\mathrm{ENBW}_{\mathrm{bins}}\,.$$

The implementation rejects a coherent sum satisfying

$$|W_0| \le \epsilon_{64} N,$$

not merely an exactly zero sum. `sample_rate` must be positive and finite. This numerical diagnostic is provenance record `KM-DSP-T01`.

`WindowMetrics` is a frozen, slotted record:

Member	Type	Meaning
`length`	`int`	N
`coherent_gain`	`float`	G_c
`power_gain`	`float`	G_p
`equivalent_noise_bandwidth_bins`	`float`	ENBW in DFT bins
`equivalent_noise_bandwidth_hz`	`float`	ENBW in hertz at the declared sample rate

Cost. One pass over the window, $\Theta(N)$ time and $O(1)$ auxiliary scalar storage apart from NumPy temporaries.

31.2.3 Overlap profiles and COLA/NOLA diagnostics

The public calls are:

```
overlap_profile(
    window: Any,
    hop_length: int,
    *,
    squared: bool = True,
) -> np.ndarray

overlap_add_certificate(
    window: Any,
    hop_length: int,
    *,
    squared: bool = True,
    require_constant: bool = False,
    tolerance: float = 1e-12,
) -> Certificate

canonical_dual_window(
    window: Any,
    hop_length: int,
    *,
    tolerance: float = 1e-12,
) -> ComputationResult[np.ndarray]
```

For $1 \leq H \leq N$, the residue profile has length H. `squared=True` computes

$$p_r^{(2)} = \sum_{\substack{0 \leq n < N \\ n \equiv r \pmod{H}}} |w_n|^2, \qquad r = 0, \dots, H-1,$$

whereas `squared=False` computes

$$p_r^{(1)} = \sum_{\substack{0 \leq n < N \\ n \equiv r \pmod{H}}} w_n.$$

The certificate sets

$$p_{\min} = \min_r |p_r|, \quad \delta = \max_r |p_r - p_0|, \quad s = \max\left(1, \max_r |p_r|\right).$$

Its nonzero-overlap condition is the strict inequality $p_{\min} > \tau s$. Its constant-overlap condition is $\delta \leq \tau s$. The certificate is valid when nonzero overlap holds and, if `require_constant=True`, constant overlap also holds. The diagnostic condition number is

$$\kappa_{\text{overlap}} = \frac{\max_r |p_r|}{p_{\min}},$$

or infinity when the nonzero test fails.

This one function can express the usual diagnostics:

- ordinary COLA: `squared=False, require_constant=True`.
- Same-window squared COLA: `squared=True, require_constant=True`.
- NOLA only: `squared=True, require_constant=False`.

The certificate is numerical, has theorem ID `KM-DSP-C01`, records `overlap_spread` and `minimum_overlap`, and leaves `finite-record boundary coverage` unchecked. Its residue calculation describes a uniform infinite shift lattice away from a finite record's edges. It does not prove that a particular finite framing covers every requested sample.

When $p_r^{(2)}$ passes the nonzero test, the canonical synthesis window is

$$\widetilde{w}_n = \frac{\overline{w_n}}{p^{(2)}_{n \bmod H}}.$$

The implementation then independently evaluates

$$q_r = \sum_{n \equiv r \pmod{H}} w_n \widetilde{w}_n$$

and accepts the result only if

$$\max_r |q_r - 1| \le \tau \max\left(1, \max_r |q_r|\right).$$

`canonical_dual_window` returns a `ComputationResult[np.ndarray]`, not a bare array. If the squared profile vanishes, its value is a zero array, the residual `dual_overlap` is infinity, and the certificate is invalid. Call `.require()` only when failure should become `ValidationError`. The result's numerical certificate is `KM-DSP-T02`. It too leaves finite-record boundary coverage unchecked.

Cost. Each profile and each dual calculation is $\Theta(N+H)$ time. A profile uses $\Theta(H)$ result storage. A dual additionally uses $\Theta(N)$ output storage.

31.3 Frames and overlap-add

31.3.1 Deterministic finite framing

```
frame_signal(
    signal: Any,
    frame_length: int,
    hop_length: int | None = None,
    *,
    center: bool = False,
    pad_end: bool = False,
    boundary: BoundaryMode = "zeros",
) -> FrameBatch
```

Let the original signal length be N, frame length L, and hop H, with $1 \le H \le L$. The default hop is $H = L$. Centering first assigns

$$p_L = p_R = \lfloor L/2 \rfloor;$$

without centering, both are zero. Let $B = N + p_L + p_R$. If $B < L$, `pad_end=False` raises `DimensionError`. With `pad_end=True`, the right pad is increased until $B = L$.

For $B \ge L$, the number of frames is

$$M = \begin{cases} 1 + \left\lfloor \dfrac{B-L}{H} \right\rfloor, & \texttt{pad_end} = \texttt{False}, \\ \max\left(1, 1 + \left\lceil \dfrac{B-L}{H} \right\rceil\right), & \texttt{pad_end} = \texttt{True}. \end{cases}$$

In the second branch, the right pad is extended by exactly

$$((M-1)H + L) - B$$

so the final frame is complete. Frame starts are

$$s_m = mH, \qquad m = 0, \dots, M-1,$$

and the returned array is

$$F_{m,n} = x^{\mathrm{pad}}_{s_m+n}, \qquad F \in \mathbb{K}^{M\times L}.$$

`pad_end=False` discards an incomplete terminal tail. `pad_end=True` adds only enough right padding to include the final complete frame. `boundary="none"` is valid only when these rules request no actual padding. Reflect padding requires at least two source samples.

`FrameBatch` is a frozen, slotted record:

Member	Shape/type	Meaning
`frames`	`(M, L)` ndarray	copied frame data. Axis 0 is frame, axis 1 is local time
`starts`	`(M,)` integer ndarray	padded-array starts mH
`original_length`	`int`	N
`frame_length`	`int`	L
`hop_length`	`int`	H
`pad_left`, `pad_right`	`int`	actual finite padding
`boundary`	`BoundaryMode`	recorded boundary selection
`frame_count`	property	M
`padded_length`	property	$N + p_L + p_R$
`covered_length`	property	$(M-1)H + L$
`certificate()`	method	exact layout certificate `KM-DSP-D02`

The layout certificate checks that `frames` is two-dimensional with second dimension L, that `starts == arange(M) * H`, and that covered length does not exceed padded length. It records `uncovered_tail = padded_length - covered_length`. It certifies indexing and shape, not equality with a separately retained source signal.

Cost. The implementation materializes every frame with slicing and `np.stack`: $\Theta(ML)$ time and $\Theta(ML)$ result storage. Overlap means samples are copied into more than one row.

31.3.2 Raw overlap-add

```
overlap_add(
    frames: Any,
    hop_length: int,
    *,
    synthesis_window: Any | None = None,
    length: int | None = None,
) -> np.ndarray
```

For nonempty `frames` of shape (M, L), and a synthesis window v of length L,

$$y[n] = \sum_{m=0}^{M-1} F_{m,n-mH} v_{n-mH},$$

where only local indices $0 \le n - mH < L$ contribute. If `synthesis_window=None`, $v \equiv 1$. The represented output length is

$$R = (M-1)H + L.$$

`length` must be a positive integer no greater than R and, when supplied, returns the prefix `y[:length]`.

This primitive performs no overlap normalization. Overlapped samples are sums, so `overlap_add(frame_signal(x, L, H).frames, H)` is generally not x when $H < L$. Normalized analysis/synthesis belongs to `istft` in Chapter 32.

Cost. $\Theta(ML)$ time and $\Theta(R)$ output storage.

31.4 Canonical dual windows

The canonical-dual construction in Section 31.2.3 is the bridge from an infinite-lattice overlap diagnostic to a synthesis window:

$$\widetilde{w}_n = \frac{\overline{w_n}}{p^{(2)}_{n \bmod H}}, \qquad p^{(2)}_r = \sum_{n \equiv r \pmod H} |w_n|^2.$$

Its certificate checks the unit cross-profile and leaves finite-record boundary coverage unchecked. It therefore complements, but does not replace, the local-denominator check performed by `istft` on the actual finite reconstruction interval.

31.5 Complete Chapter 31 API and result reference

Public symbol	Exact call or role	Return
`WindowName`	literal alias	type alias
`WindowSpec`	named, parameterized, or explicit window	type alias
`WindowMetrics`	frozen record constructor	metric record
`get_window`	`get_window(window, length, *, periodic=True)`	`(N,)` ndarray
`window_metrics`	`window_metrics(window, *, sample_rate=1.0)`	`WindowMetrics`
`overlap_profile`	`overlap_profile(window, hop_length, *, squared=True)`	`(H,)` ndarray
`overlap_add_certificate`	`overlap_add_certificate(window, hop_length, *, squared=True, require_constant=False, tolerance=1e-12)`	`Certificate`
`canonical_dual_window`	`canonical_dual_window(window, hop_length, *, tolerance=1e-12)`	`ComputationResult[np.ndarray]`
`BoundaryMode`	finite padding choices	type alias
`FrameBatch`	frozen framing record	record with three properties and `certificate()`
`frame_signal`	`frame_signal(signal, frame_length, hop_length=None, *, center=False, pad_end=False, boundary="zeros")`	`FrameBatch`
`overlap_add`	`overlap_add(frames, hop_length, *, synthesis_window=None, length=None)`	ndarray

31.6 Worked window/framing truth table

This example is directly runnable:

```
import numpy as np
from komorebi_math.signals import (
    canonical_dual_window,
    frame_signal,
    get_window,
    overlap_add,
    overlap_add_certificate,
    overlap_profile,
    window_metrics,
)

np.set_printoptions(precision=6, suppress=True)
w = get_window("hann", 8, periodic=True)
metrics = window_metrics(w, sample_rate=800.0)
cola = overlap_add_certificate(
    w, 4, squared=False, require_constant=True
)
dual = canonical_dual_window(w, 2)

batch = frame_signal(
    np.arange(7.0), 4, 3,
    center=True, pad_end=True, boundary="zeros",
)
raw = frame_signal(np.arange(8.0), 4, 2, boundary="none")

print("window", w)
print("metrics", metrics)
print("linear_profile", overlap_profile(w, 4, squared=False))
print("cola", cola.valid, cola.residuals, cola.assumptions_unchecked)
print("dual", dual.valid, dual.certificate.residuals)
print("starts", batch.starts, "padding", (batch.pad_left, batch.pad_right),
      "shape", batch.frames.shape)
print(batch.frames)
print("raw_ola", overlap_add(raw.frames, 2))
```

Observed with package `1.0.0b4`, Python 3.12.13, and NumPy 2.5.2:

```
window [0.       0.146447 0.5      0.853553 1.       0.853553 0.5      0.146447]
metrics WindowMetrics(length=8, coherent_gain=0.5, power_gain=0.37500000000000006,
   ↪  equivalent_noise_bandwidth_bins=1.5000000000000002, equivalent_noise_bandwidth_hz=150.00000000000003)
linear_profile [1. 1. 1. 1.]
cola True {'overlap_spread': 0.0, 'minimum_overlap': 1.0} ('finite-record boundary coverage',)
dual True {'dual_overlap': 0.0, 'minimum_squared_overlap': 1.5}
starts [0 3 6 9] padding (2, 4) shape (4, 4)
[[0. 0. 0. 1.]
 [1. 2. 3. 4.]
 [4. 5. 6. 0.]
 [0. 0. 0. 0.]]
raw_ola [ 0.  1.  4.  6.  8. 10.  6.  7.]
```

The last line is the intended warning: raw overlap-add sums the two interior copies. It is not normalized synthesis.

31.7 Validation and failure behavior

Operation	Failure	Public behavior
`get_window`	nonpositive/nonintegral length	`ValidationError`
`get_window`	explicit array is not 1-D or has wrong length	`DimensionError`
`get_window`	explicit entries are nonfinite. Invalid tuple/parameter/name	`ValidationError`
`window_metrics`	empty/non-1-D window	`DimensionError`
`window_metrics`	nonfinite entries, nonpositive/nonfinite rate, numerically zero coherent sum	`ValidationError`
overlap APIs	empty/non-1-D window	`DimensionError`
overlap APIs	invalid hop or $H > N$	`ValidationError`
`overlap_add_certificate`	negative/nonfinite tolerance	`ValidationError`
`canonical_dual_window`	vanishing squared profile	invalid `ComputationResult`. `.require()` raises `ValidationError`
`frame_signal`	empty/non-1-D input or short unpadded record	`DimensionError`
`frame_signal`	invalid lengths, $H > L$, forbidden/unknown required padding, one-sample reflection	`ValidationError`
`overlap_add`	empty/non-2-D frames or wrong synthesis-window length	`DimensionError`
`overlap_add`	invalid hop, $H > L$, or invalid requested length	`ValidationError`, except an overlong requested output is `DimensionError`

The implementation defects listed in Section 32.9 qualify this table. In particular, some validation occurs only on the execution branch that needs it.

32. Time-frequency and spectral analysis

Chapter 32 applies NumPy's finite DFT convention to the Chapter 31 framing model.

Choose the output by the question. Use an STFT when frame-by-frame complex coefficients or reconstruction are needed, a spectrogram for the corresponding time-frequency magnitudes or powers, a periodogram for one finite-record spectrum, and Welch averaging for a spectrum assembled from segments. Cross spectra add a second aligned signal. These outputs have different scaling and evidence fields, so retain the result record rather than only its plotted array.

For frame length L, hop H, FFT length $K \geq L$, frame count M, and bin count

$$F = \begin{cases} \lfloor K/2 \rfloor + 1, & \text{one-sided real transform,} \\ K, & \text{two-sided transform,} \end{cases}$$

the STFT is a typed finite map

$$\mathrm{STFT}_{w,H,K} : \mathbb{K}^N \longrightarrow \mathbb{C}^{M \times F}.$$

32.1 STFT and inverse STFT

A global shifted-window convention is

$$X[m,k] = \sum_n x[n] w[n - mH] e^{-2\pi i k n / N}.$$

The implementation instead uses local-frame coordinates and K for the FFT length. Translating the preceding display into that convention requires an index change and an explicit frame-dependent phase. Use the local-frame formula in Section 32.1.1 when reproducing the implementation. Comparing complex coefficients from the two conventions without that translation can produce a phase discrepancy even for the same signal.

32.1.1 STFT analysis and coordinates

```
stft(
    signal: Any,
    *,
    sample_rate: float = 1.0,
    frame_length: int = 256,
    hop_length: int | None = None,
    fft_length: int | None = None,
    window: WindowSpec = "hann",
    center: bool = True,
    pad_end: bool = True,
    boundary: BoundaryMode = "zeros",
    onesided: bool | None = None,
    detrend: DetrendMode = "none",
) -> STFTResult
```

The defaults are $H = \max(1, \lfloor L/4 \rfloor)$, $K = L$, a periodic Hann analysis window, centered framing, terminal padding, and zero boundary extension. `stft` delegates its exact framing to `frame_signal`.

For each local frame,

$$f_m[n] = x^{\mathrm{pad}}[mH + n], \qquad 0 \le n < L.$$

With `detrend="constant"`, it first replaces the frame by

$$f_m[n] - \frac{1}{L}\sum_{j=0}^{L-1} f_m[j].$$

It then computes

$$X[m,k] = \sum_{n=0}^{L-1} f_m[n]w[n]e^{-2\pi ikn/K},$$

implicitly zero-padding the windowed frame when $K > L$. The coefficient layout is `(frame, frequency_bin)`, not `(frequency_bin, frame)`.

One-sided frequencies are NumPy `rfftfreq` coordinates,

$$f_k = \frac{kf_s}{K}, \qquad k = 0, \dots, \lfloor K/2 \rfloor.$$

Two-sided frequencies use NumPy's signed `fftfreq` ordering. Frame times are centers in seconds:

$$t_m = \frac{mH + L/2 - p_L}{f_s}.$$

For odd L, these may lie on half-sample coordinates.

`STFTResult` is a frozen, slotted record:

Member	Shape/type	Meaning
`coefficients`	`(M, F)` complex ndarray	finite Fourier coefficients
`frequencies`	`(F,)` float ndarray	hertz
`times`	`(M,)` float ndarray	frame-center seconds
`sample_rate`	`float`	positive finite f_s
`frame_length`, `hop_length`, `fft_length`	`int`	L, H, K
`analysis_window`	`(L,)` ndarray	actual periodic or explicit analysis window
`original_length`	`int`	original N
`pad_left`, `pad_right`	`int`	actual analysis padding
`onesided`	`bool`	Fourier layout selector
`boundary`	`BoundaryMode`	recorded padding convention
`detrend`	`DetrendMode`	`"none"` or `"constant"`
`frame_count`	property	M
`inverse(...)`	method	delegates to `istft`
`roundtrip_certificate(...)`	method	compares normalized synthesis with a supplied source

The STFT definition has provenance record `KM-DSP-D03`. It returns metadata, not a certificate.

Cost. Framing and windowing cost $\Theta(ML)$. Batched transforms cost $\Theta(MK \log K)$. The result occupies $\Theta(MF + M + F + L)$, while peak materialization also includes frame and windowed-frame arrays of order ML.

32.1.2 Normalized inverse STFT and reconstruction certificates

```
istft(
    transform: STFTResult,
    *,
    synthesis_window: Any | None = None,
    length: int | None = None,
    tolerance: float = 1e-11,
) -> ComputationResult[np.ndarray]

STFTResult.inverse(
    self,
    *,
    synthesis_window: Any | None = None,
    length: int | None = None,
    tolerance: float = 1e-11,
) -> ComputationResult[np.ndarray]

STFTResult.roundtrip_certificate(
    self,
    signal: Any,
    *,
    tolerance: float = 1e-10,
) -> Certificate
```

The inverse rejects a transform produced with constant detrending because the removed frame means were not retained. Otherwise it applies `irfft` to one-sided coefficients or `ifft` to two-sided coefficients, truncates each inverse transform to its first L entries, and uses synthesis window

$$v = \overline{w}$$

by default. A caller may supply another length-L window.

For represented padded coordinate n, define

$$a[n] = \sum_m \hat{f}_m[n - mH]v[n - mH], \qquad d[n] = \sum_m w[n - mH]v[n - mH],$$

where only valid local frame indices contribute. The represented length is

$$R = (M - 1)H + L.$$

The requested output defaults to the original length N, cannot exceed N, and is read from padded indices

$$[p_L, p_L + N_{\text{req}}).$$

On that local interval, set

$$s = \max\left(1, \max_n |d[n]|\right), \qquad d_{\min} = \min_n |d[n]|.$$

Synthesis is valid only under the strict test

$$d_{\min} > \tau s.$$

If valid, $\hat{x}[n] = a[n]/d[n]$. The certificate's normalization residual is

$$r_{\text{norm}} = \max_n |\hat{x}[n]d[n] - a[n]|.$$

If invalid, the routine returns a zero array of the requested length paired with an invalid certificate. `.require()` raises `ValidationError`. Certificate `KM-DSP-T03` proves only the finite normalization identity and explicitly leaves source agreement unchecked.

`roundtrip_certificate` performs the separate check. It requires a one-dimensional source of exactly `original_length`, calls the inverse, and tests

$$r_{\text{rt}} = \|\hat{x} - x\|_2 \le \tau \max(1, \|x\|_2).$$

If inverse synthesis is invalid, it returns that inverse certificate unchanged.

Cost. Inverse FFT plus finite overlap-add takes $\Theta(MK \log K + ML)$ time. Peak storage includes all inverse frames, $\Theta(MK)$, and numerator/denominator arrays of length R.

32.2 Spectrograms

```
spectrogram(
    signal: Any,
    *,
    scaling: SpectrogramScaling = "density",
    **stft_options: Any,
) -> SpectrogramResult
```

`SpectrogramScaling` is `"density" | "spectrum" | "magnitude" | "power"`. The remaining keyword arguments are passed directly to `stft`, so misspelled or unsupported options fail according to Python call semantics.

Let $Z_{mk} = |X[m, k]|$,

$$D_{\text{density}} = f_s \sum_n |w_n|^2, \qquad D_{\text{spectrum}} = \left| \sum_n w_n \right|^2.$$

The four values are

$$S_{mk} = \begin{cases} Z_{mk}, & \text{magnitude}, \\ Z_{mk}^2, & \text{power}, \\ Z_{mk}^2 / D_{\text{density}}, & \text{density}, \\ Z_{mk}^2 / D_{\text{spectrum}}, & \text{spectrum}. \end{cases}$$

For one-sided output, `power`, `density`, and `spectrum` double the interior positive-frequency bins. DC is never doubled. For even K, the Nyquist bin is not doubled. `magnitude` is not doubled. Spectrum scaling rejects a denominator at or below machine epsilon. The density branch does not explicitly guard a zero-energy window. See Section 32.9.

`SpectrogramResult` is a frozen, slotted record:

Member	Shape/type	Meaning
`values`	`(M, F)` float ndarray	requested magnitude or power-like values
`frequencies`	`(F,)` float ndarray	same object coordinates as the transform
`times`	`(M,)` float ndarray	same frame times
`scaling`	`SpectrogramScaling`	applied normalization
`sample_rate`	`float`	f_s
`transform`	`STFTResult`	complete underlying STFT and synthesis metadata

Member	Shape/type	Meaning

The spectrogram definition has provenance record `KM-DSP-D04`. The result contains no certificate. Its cost is the STFT cost plus $\Theta(MF)$ scaling work and output storage.

32.3 Periodogram and Welch PSD

32.3.1 Modified periodogram

```
periodogram(
    signal: Any,
    *,
    sample_rate: float = 1.0,
    window: WindowSpec = "boxcar",
    fft_length: int | None = None,
    detrend: DetrendMode = "constant",
    scaling: SpectralScaling = "density",
    onesided: bool | None = None,
) -> PowerSpectrum
```

`SpectralScaling` is `"density" | "spectrum"`. The periodogram validates a finite, nonempty, one-dimensional signal and uses $K = N$ by default. A named window is constructed with `periodic=False`, unlike STFT and Welch.

Writing $\tilde{x} = x$ for no detrending and $\tilde{x} = x - \bar{x}$ for constant detrending,

$$P_{xx}[k] = \frac{|\mathcal{F}_K(\tilde{x}\, w)[k]|^2}{D_w},$$

where

$$D_w = \begin{cases} f_s \sum_n |w_n|^2, & \text{density}, \\ |\sum_n w_n|^2, & \text{spectrum}. \end{cases}$$

One-sided power is doubled on the same interior-bin rule as the spectrogram. The frequency resolution is

$$\Delta f = \frac{f_s}{K}.$$

The returned numerical certificate `KM-DSP-D05` uses fixed tolerance 10^{-12}. It checks that all ordinates are finite, that the minimum real power is no less than $-10^{-12}s$, and that any imaginary part is no greater than $10^{-12}s$, where $s = \max(1, \max|P|)$. It does not certify a stochastic model.

Cost. $\Theta(K \log K + N)$ time and $\Theta(K)$ transform/result storage.

32.3.2 Welch power spectral estimates

```
welch_psd(
    signal: Any,
    *,
    sample_rate: float = 1.0,
    frame_length: int = 256,
    hop_length: int | None = None,
    fft_length: int | None = None,
    window: WindowSpec = "hann",
    detrend: DetrendMode = "constant",
    scaling: SpectralScaling = "density",
    average: SpectralAverage = "mean",
```

```
    onesided: bool | None = None,
) -> PowerSpectrum
```

`SpectralAverage` is `"mean" | "median"`. Welch framing is uncentered, unpadded, and complete-frame only. It requires $N \geq L$, defaults to $H = \max(1, \lfloor L/2 \rfloor)$, and produces

$$M = 1 + \left\lfloor \frac{N - L}{H} \right\rfloor$$

segments. Its named window is periodic. Each segment is detrended before windowing and transformed using $K = L$ by default. If $Q_m[k]$ is the correspondingly scaled segment periodogram, then

$$\widehat{P}_{xx}[k] = \operatorname{Avg}_{m=0}^{M-1} Q_m[k].$$

Mean averaging is arithmetic mean. Median averaging is the elementwise median and includes no statistical median-bias correction. Certificate `KM-DSP-D06` is the same fixed-tolerance finite nonnegativity/finite-value check as the periodogram certificate. Statistical consistency remains unchecked.

Cost. $\Theta(ML + MK \log K)$ time. Peak arrays include M frames and M spectra, so storage is $\Theta(ML + MF)$.

32.3.3 Power-spectrum record and helpers

`PowerSpectrum` is a frozen, slotted record shared by periodogram and Welch:

Member	Shape/type	Meaning
`frequencies`	`(F,)` float ndarray	hertz in one-sided or NumPy signed order
`power`	`(F,)` float ndarray	density or spectrum ordinates
`sample_rate`	`float`	f_s
`scaling`	`SpectralScaling`	`"density"` or `"spectrum"`
`onesided`	`bool`	Fourier layout
`fft_length`	`int`	K
`segment_count`	`int`	1 for periodogram, M for Welch
`frame_length`, `hop_length`	`int`	segment geometry
`window`	`(L,)` ndarray	actual analysis window
`method`	`str`	`"periodogram"`, `"welch-mean"`, or `"welch-median"`
`certificate`	`Certificate`	finite numerical power check
`frequency_resolution`	property	f_s/K

Two helpers are available:

```
PowerSpectrum.dominant_frequency(
    self, *, ignore_dc: bool = False
) -> float

PowerSpectrum.integrated_power(self) -> float
```

`dominant_frequency` returns the coordinate of the largest stored ordinate, optionally starting its search at bin 1. `integrated_power` returns

$$\sum_k P[k]\Delta f$$

for density scaling and $\sum_k P[k]$ for spectrum scaling. These are integrations of the represented finite bins. The helper adds no modeling certificate.

32.4 Cross spectrum, phase, and coherence

```
cross_spectrum(
    input_signal: Any,
    output_signal: Any,
    *,
    sample_rate: float = 1.0,
    frame_length: int = 256,
    hop_length: int | None = None,
    fft_length: int | None = None,
    window: WindowSpec = "hann",
    detrend: DetrendMode = "constant",
    scaling: SpectralScaling = "density",
    average: SpectralAverage = "mean",
    onesided: bool | None = None,
    regularization: float = 0.0,
) -> CrossSpectrum
```

Input and output records must be finite, one-dimensional, nonempty, and equal in length. Framing, window periodicity, detrending, FFT length, one-sided doubling, and averaging match Welch. For paired segment transforms $X_m[k]$ and $Y_m[k]$,

$$P_{xx}[k] = \mathrm{Avg}_m \frac{|X_m[k]|^2 c_k}{D_w},$$
$$P_{yy}[k] = \mathrm{Avg}_m \frac{|Y_m[k]|^2 c_k}{D_w},$$
$$P_{xy}[k] = \mathrm{Avg}_m \frac{\overline{X_m[k]} Y_m[k] c_k}{D_w},$$

where c_k is the one-sided interior-bin factor or one for two-sided spectra. For median averaging, real and imaginary parts of the complex cross-power segments are median-averaged separately. No median-bias correction is applied.

There is no separate phase field. The represented cross phase is obtained from the stored complex array as `np.angle(report.cross_power)`, that is,

$$\phi_{xy}[k] = \arg P_{xy}[k].$$

Phase at a zero or numerically negligible cross-power bin has no stable inferential meaning. The result record does not attach a phase-validity mask.

Given finite ridge $\rho \geq 0$, the implementation computes

$$\gamma^2_{\mathrm{raw}}[k] = \frac{|P_{xy}[k]|^2}{(P_{xx}[k] + \rho)(P_{yy}[k] + \rho)}$$

only where the denominator is positive and uses zero elsewhere. The returned coherence is

$$\gamma^2[k] = \mathrm{clip}(\gamma^2_{\mathrm{raw}}[k], 0, 1).$$

The H1 estimate is

$$H_1[k] = \frac{P_{xy}[k]}{P_{xx}[k] + \rho}$$

where its denominator is positive, and zero elsewhere.

Before clipping, the certificate records

$$r_{\text{bound}} = \max\left(0, \max_k \gamma^2_{\text{raw}}[k] - 1, -\min_k \gamma^2_{\text{raw}}[k]\right).$$

`KM-DSP-D07` is valid only if every returned array is finite and $r_{\text{bound}} \le 10^{-12}$. It records the ridge and segment count. The linear time-invariant data-generating model and statistical consistency are unchecked. High coherence on one finite record is not a causal identification theorem.

`CrossSpectrum` is a frozen, slotted record:

Member	Shape/type	Meaning
`frequencies`	`(F,)` float ndarray	Fourier coordinates in hertz
`cross_power`	`(F,)` ndarray	P_{xy}, generally complex
`input_power`, `output_power`	`(F,)` float ndarray	P_{xx}, P_{yy}
`coherence`	`(F,)` float ndarray	clipped magnitude-squared coherence
`transfer_h1`	`(F,)` complex ndarray	regularized H1 estimate
`sample_rate`	`float`	f_s
`scaling`	`SpectralScaling`	density or spectrum
`onesided`	`bool`	Fourier layout
`fft_length`	`int`	K
`segment_count`	`int`	M
`certificate`	`Certificate`	finite and pre-clipping bound check

Cost. Two framed transforms plus three segment products require $\Theta(ML + MK \log K)$ time with a larger constant than Welch. Peak storage is $\Theta(ML + MF)$.

32.5 Parseval and reconstruction certificates

The Parseval certificate below checks full-DFT energy. The reconstruction certificates are `KM-DSP-T03`: `istft` checks normalized finite overlap, while `STFTResult.roundtrip_certificate` separately compares synthesis with the supplied source, as specified in Section 32.1.2.

32.5.1 Finite Parseval certificate

```
parseval_certificate(
    signal: Any,
    *,
    tolerance: float = 1e-12,
) -> Certificate
```

For the full NumPy DFT,

$$X_k = \sum_{n=0}^{N-1} x_n e^{-2\pi i k n/N},$$

the checked identity is

$$\sum_{n=0}^{N-1} |x_n|^2 = \frac{1}{N} \sum_{k=0}^{N-1} |X_k|^2.$$

With time and frequency energies E_t, E_f, certificate `KM-DSP-T04` records

$$r_P = |E_t - E_f|$$

and is valid if

$$r_P \le \tau \max(1, E_t, E_f).$$

The function validates finite real or complex input and validates a finite nonnegative tolerance. It always uses the complete DFT, independently of the one-sided spectral-estimator APIs.

Cost. $\Theta(N \log N)$ time and $\Theta(N)$ transform storage.

32.5A Stateful and certified streaming STFT

```
StreamingSTFT(
    frame_length: int = 256,
    hop_length: int | None = None,
    fft_length: int | None = None,
    window: WindowSpec = "hann",
    sample_rate: float = 1.0,
    onesided: bool = True,
    detrend: DetrendMode = "none",
)

StreamingSTFT.process(
    self, chunk: Any
) -> StreamingSTFTBatch

StreamingSTFT.flush(
    self, *, pad_end: bool = True
) -> StreamingSTFTBatch

StreamingSTFT.reset(self) -> None

stream_stft(
    signal: Any,
    chunk_sizes: Iterable[int],
    *,
    frame_length: int = 256,
    hop_length: int | None = None,
    fft_length: int | None = None,
    window: WindowSpec = "hann",
    sample_rate: float = 1.0,
    onesided: bool = True,
    detrend: DetrendMode = "none",
    pad_end: bool = True,
    tolerance: float = 1e-11,
) -> ComputationResult[StreamingSTFTBatch]
```

Streaming uses the same default $H = \max(1, \lfloor L/4 \rfloor)$, periodic analysis window, detrending rule, and FFT coordinates as batch STFT. It intentionally matches the *uncentered* batch convention with zero terminal padding.

`process(chunk)` accepts a finite one-dimensional chunk, including an empty chunk, and emits every newly complete frame. After each completed call, the analyzer retains only overlap and unframed samples needed by a future frame. `buffered_samples` exposes that count and `total_samples` exposes the accepted input count. A one-sided analyzer rejects a complex chunk when a frame is transformed.

`flush(pad_end=True)` emits at most one terminal zero-padded frame, closes the analyzer, and releases its buffer. `flush(pad_end=False)` discards an incomplete tail and closes. Repeated flushes return an empty batch. Processing after flush raises `ValidationError`. `reset()` returns the instance to its deterministic empty, open state.

`StreamingSTFTBatch` is a frozen, slotted record:

Member	Shape/type	Meaning
`coefficients`	`(Q, F)` complex ndarray	frames emitted by one operation
`frequencies`	`(F,)` float ndarray	fixed bin coordinates
`times`	`(Q,)` float ndarray	$(s_m + L/2)/f_s$, with no center offset
`starts`	`(Q,)` integer ndarray	absolute source starts
`sample_rate`	`float`	f_s
`frame_length`, `hop_length`, `fft_length`	`int`	L, H, K
`onesided`	`bool`	Fourier layout
`frame_count`	property	Q

The mutable `StreamingSTFT` constructor exposes seven data fields: `frame_length`, `hop_length`, `fft_length`, `window`, `sample_rate`, `onesided`, and `detrend`. Its private buffer, buffer origin, next start, total count, and closed flag are state-machine implementation details rather than public constructor arguments. Its public properties are `frequencies`, `buffered_samples`, and `total_samples`.

The convenience function `stream_stft` requires nonempty finite input and a sequence of *positive* chunk sizes whose sum is exactly N. It feeds those chunks to a `StreamingSTFT`, flushes it, and compares the concatenated result with

```
stft(
    signal,
    center=False,
    pad_end=pad_end,
    boundary="zeros",
    ...matching parameters...
)
```

If coefficient shapes agree, it records

$$r_X = \max_{m,k} |X^{\text{stream}}_{mk} - X^{\text{batch}}_{mk}|, \qquad r_t = \max_{m} |t^{\text{stream}}_{m} - t^{\text{batch}}_{m}|.$$

Certificate `KM-DSP-T07` is valid when

$$r_X \le \tau \max(1, \max |X^{\text{batch}}|) \quad \text{and} \quad r_t \le \tau.$$

A shape mismatch records both residuals as infinity. The certificate checks contiguous declared chunks and matching finite STFT parameters. It does not extend the result to reordered, overlapping, missing, or duplicated chunks.

Cost and memory. For M emitted frames, analysis costs $\Theta(N + MK \log K + ML)$. The persistent analyzer state after a call retains fewer than L signal samples, but a single `process` call first materializes the supplied chunk and returns all frames emitted from it. The convenience `stream_stft` wrapper also retains all batches and constructs a complete batch STFT for comparison, so that certificate-producing wrapper has $\Theta(MF + ML)$ peak storage and is not a bounded-memory substitute for direct `StreamingSTFT` use.

32.6 `signals.time_frequency` complete class, function, and public-member reference

This table includes the adjoining `signals.spectral` and `signals.streaming` symbols needed to complete the reader workflow as well as every public member of `signals.time_frequency`.

Public symbol	Exact call or role	Return
`DetrendMode`	`"none" | "constant"`	type alias
`SpectrogramScaling`	density, spectrum, magnitude, power	type alias
`SpectralScaling`	density or spectrum	type alias
`SpectralAverage`	mean or median	type alias

Public symbol	Exact call or role	Return
`STFTResult`	frozen transform record	coefficients, coordinates, synthesis metadata, methods
`SpectrogramResult`	frozen spectrogram record	values plus underlying `STFTResult`
`PowerSpectrum`	frozen periodogram/Welch record	power, metadata, helpers, certificate
`CrossSpectrum`	frozen paired-spectrum record	auto/cross spectra, coherence, H1, certificate
`StreamingSTFTBatch`	frozen emission record	coefficients, coordinates, starts
`StreamingSTFT`	mutable analyzer	`process`, `flush`, `reset`
`stft`	full signature in Section 32.1	`STFTResult`
`istft`	full signature in Section 32.1	`ComputationResult[np.ndarray]`
`spectrogram`	full signature in Section 32.2	`SpectrogramResult`
`periodogram`	full signature in Section 32.3	`PowerSpectrum`
`welch_psd`	full signature in Section 32.3	`PowerSpectrum`
`cross_spectrum`	full signature in Section 32.4	`CrossSpectrum`
`parseval_certificate`	full signature in Section 32.5	`Certificate`
`stream_stft`	full signature in Section 32.5A	`ComputationResult[StreamingSTFTBatch]`

32.7 End-to-end finite example

This example exercises reconstruction, all spectral result families, Parseval, and adversarial chunk boundaries:

```
import numpy as np
from komorebi_math.signals import (
    cross_spectrum,
    parseval_certificate,
    periodogram,
    spectrogram,
    stft,
    stream_stft,
    welch_psd,
)

fs = 64.0
n = np.arange(64)
x = np.sin(2 * np.pi * 8 * n / fs)

transform = stft(
    x, sample_rate=fs,
    frame_length=16, hop_length=4, fft_length=32,
)
inverse = transform.inverse()
image = spectrogram(
    x, sample_rate=fs,
    frame_length=16, hop_length=4, fft_length=32,
    scaling="density",
)
line = periodogram(
    x, sample_rate=fs, window="boxcar", detrend="none"
)
welch = welch_psd(
    x, sample_rate=fs,
    frame_length=16, hop_length=8, detrend="none",
)
paired = cross_spectrum(
    x, -2.25 * x, sample_rate=fs,
```

```
    frame_length=16, hop_length=8, detrend="none",
)
parseval = parseval_certificate(x)
streamed = stream_stft(
    x, (1, 7, 56), sample_rate=fs,
    frame_length=16, hop_length=4, fft_length=32,
)

tone = np.argmax(paired.input_power)
print("stft", transform.coefficients.shape,
      "times", transform.times[[0, -1]],
      "frequencies", transform.frequencies[[0, -1]])
print("inverse", inverse.valid,
      "max_error", float(np.max(np.abs(inverse.value - x))),
      inverse.certificate.residuals)
print("spectrogram", image.values.shape, image.scaling)
print("periodogram", line.dominant_frequency(),
      line.integrated_power(), line.certificate.valid)
print("welch", welch.segment_count,
      welch.frequency_resolution, welch.certificate.valid)
print("cross_tone", paired.frequencies[tone],
      paired.coherence[tone], paired.transfer_h1[tone],
      paired.certificate.valid)
print("parseval", parseval.valid, parseval.residuals)
print("stream", streamed.value.frame_count,
      streamed.certificate.residuals, streamed.valid)
```

Observed output on the same environment as the Chapter 31 example:

```
stft (17, 17) times [0. 1.] frequencies [ 0. 32.]
inverse True max_error 2.220446049250313e-16 {'normalized_overlap_identity': 1.1102230246251565e-16,
    ↪ 'minimum_overlap': 1.25}
spectrogram (17, 17) density
periodogram 8.0 0.5 True
welch 7 4.0 True
cross_tone 8.0 0.9999999999999994 (-2.249999999999999-2.1028024000228914e-17j) True
parseval True {'parseval': 0.0}
stream 13 {'stream_batch_coefficients': 0.0, 'stream_batch_times': 0.0} True
```

The complex H1 value is numerically real. Its tiny imaginary component is FFT roundoff. The certificate establishes finite computations and bounds, not that arbitrary measured data obey the deterministic gain model used in this example.

32.8 Certificate and exception semantics

Komorebi Math distinguishes three failure channels:

1. Malformed dimensions, parameters, or a violated mandatory assumption raise immediately.
2. A mathematically meaningful computation with a failed numerical condition may return an invalid `Certificate` or `ComputationResult`.
3. Estimators may return a valid finite certificate while leaving stochastic or causal assumptions unchecked.

`Certificate.require()` returns the same certificate when `valid=True` and raises `ValidationError` otherwise. `ComputationResult.require()` first requires its certificate and then returns its value.

ID	Producer	Exactness	What validity means	Explicitly unchecked
`KM-DSP-D01`	`get_window` provenance	classical definition	requested finite window construction completed	no returned certificate

ID	Producer	Exactness	What validity means	Explicitly unchecked
KM-DSP-T01	window_metrics provenance	classical numerical diagnostic	metric preconditions passed	no returned certificate
KM-DSP-C01	overlap_add_certificate	numerical	nonzero residue overlap, plus constant overlap if requested	finite-record boundary coverage
KM-DSP-T02	canonical_dual_window	numerical	nonzero squared profile and unit cross-profile within tolerance	finite-record boundary coverage
KM-DSP-D02	FrameBatch.certificate()	exact	shape, starts, and coverage inclusion agree	source-sample equality is not checked
KM-DSP-D03	stft provenance	classical definition	finite transform completed	no returned certificate
KM-DSP-T03	istft	numerical	requested local overlap denominator is nonzero and normalization identity is represented	source agreement requires roundtrip_certificate
KM-DSP-D04	spectrogram provenance	classical definition	requested scaling completed	no returned certificate
KM-DSP-D05	periodogram	numerical	finite, numerically nonnegative power	stochastic consistency
KM-DSP-D06	welch_psd	numerical	finite, numerically nonnegative averaged power	stochastic consistency
KM-DSP-D07	cross_spectrum	numerical	finite arrays and pre-clipping coherence bound within 10^{-12}	LTI data model and statistical consistency
KM-DSP-T04	parseval_certificate	numerical	finite DFT energy residual satisfies scaled tolerance	none beyond finite DFT convention
KM-DSP-T07	stream_stft	numerical	coefficient and timestamp equality with matching batch STFT	only declared contiguous partition is covered

The principal intentional exceptions are:

API	Condition	Exception or returned state
stft	empty/non-1-D signal	DimensionError
stft	nonpositive/nonfinite rate. Invalid length. $K < L$. Invalid detrend. One-sided complex input. Framing failure	ValidationError or framing DimensionError
istft	input is not STFTResult	ValidationError
istft	transform used constant detrending	AssumptionError
istft	negative/nonfinite tolerance	ValidationError
istft	synthesis window wrong shape. Request exceeds original or represented range	DimensionError
istft	local denominator fails strict nonzero test	invalid result containing zeros. .require() raises ValidationError
spectrogram	unknown scaling. Zero coherent gain in spectrum scaling	ValidationError

API	Condition	Exception or returned state
spectral estimators	empty/non-1-D or nonfinite signal. Paired lengths differ. Record shorter than Welch frame	`DimensionError` or `ValidationError`
spectral estimators	invalid rate, hop, FFT length, detrend, scaling, average, one-sided complex data, or ridge	`ValidationError`
`parseval_certificate`	invalid tolerance	`ValidationError`
`StreamingSTFT`	invalid geometry/rate/detrend. Nonfinite or non-1-D chunk. One-sided complex transformed frame	`ValidationError` or `DimensionError`
`StreamingSTFT.process`	called after flush	`ValidationError`
`stream_stft`	empty/non-1-D/nonfinite source. Nonpositive chunk size. Chunk sum mismatch	`ValidationError` or `DimensionError`

32.9 Source-audit defects and unsupported inferences

These are observed behaviors of the `1.0.0b4` source, not recommended contracts. They should be treated as defects or validation gaps until changed and regression-tested:

1. `get_window("not-a-window", 1)` returns `[1.0]`. The length-one shortcut occurs before unknown bare-string dispatch.
2. `frame_signal(..., boundary="invalid")` accepts and records the invalid string when no padding is needed. `_pad` returns an unpadded copy before validating the boundary. `stft` inherits the same branch behavior.
3. `stft` does not reject NaN or infinity in its input. Nonfinite coefficients can therefore be returned without a certificate. This is an intentional absence of a uniform package guard, but it is hazardous for this transform API.
4. `overlap_profile` does not validate finite window entries. A NaN window produces a NaN profile. `overlap_add_certificate` then becomes invalid, but its `assumptions_checked` still says `finite window`.
5. `canonical_dual_window` does not validate that `tolerance` is finite and nonnegative. For example, `tolerance=-1` is accepted and stored in an invalid certificate instead of raising.
6. Density scaling has no explicit zero-window denominator guard. A zero window can make `spectrogram(..., scaling="density")` return nonfinite values without a certificate. `periodogram` and Welch can likewise divide by zero, but their `PowerSpectrum` certificate becomes invalid because the ordinates are nonfinite.
7. `stream_stft` does not validate that `tolerance` is finite and nonnegative. A negative or NaN tolerance is stored in an invalid batch-equivalence certificate instead of raising.

Additional boundaries are deliberate rather than defects:

- A COLA/NOLA or canonical-dual certificate does not settle finite edge coverage.
- An inverse-STFT normalization certificate does not compare with the original signal.
- Median Welch and cross-spectrum averaging has no bias correction.
- Coherence clipping does not turn a failed pre-clipping bound into a theorem.
- Spectral estimates do not certify stationarity, asymptotic consistency, causality, or the correctness of an LTI model.
- The streaming equality covers uncentered analysis with zero terminal padding and the exact declared chunk partition, not arbitrary stream edits.
- No GPU path exists in these four modules, and no hardware or real-time claim follows from NumPy execution.

32.10 Executed verification evidence

The evidence below was executed against the recovered `1.0.0b4` checkout for the reference baseline:

Evidence	Observed result	Scope
Focused unit tests: `test_block12_windows_time_frequency.py`, `test_block12_spectral_filtering.py`, `test_block12_denoise_streaming.py`	53 passed	windows, metrics, framing, STFT/inverse, spectrogram, Parseval, periodogram, Welch, cross-spectrum, streaming boundaries. The latter two files also contain adjacent DSP tests
`examples/production_dsp.py`	completed, exit 0	reported 73 Hz dominant line, 33 batch STFT frames, 29 streaming frames, and valid certificates across its DSP pipeline
`run_dsp_verification()`	11 of 11 passed	includes window/dual, normalized STFT, spectral/Parseval, coherence/H1, and streaming-STFT checks plus adjacent DSP checks
`verification.block12_deep_audit.run()`	815,779 of 815,779 scalar checks passed	relevant section counts: windows 117, STFT 114,190, streaming STFT 160, spectral 8,460. Remaining checks cover adjacent DSP routines
`verification.block12_scipy_reference_audit.run()`	520,920 of 520,920 comparisons passed	relevant section counts: windows 6,804 and spectral 76,502. Convention-matched comparison only, not API identity
Chapter 31 deterministic example	completed with displayed output	periodic Hann metrics, COLA, canonical dual, centered/end-padded frames, raw overlap-add
Chapter 32 deterministic example	completed with displayed output	STFT/inverse, spectrogram, periodogram, Welch, cross/H1, Parseval, chunk invariance

The focused pytest command initially failed because `pytest` was absent from the primary runtime. It was rerun in the existing `.venv-guide` environment, where Python 3.12.13, NumPy 2.5.2, and pytest 9.1.1 were available. Both independent audits were invoked through their read-only `run()` functions so their committed JSON reports were not rewritten.

The passing evidence establishes the finite cases actually executed. It does not erase the source-audit defects above, expand the supported input domain, or convert estimator diagnostics into stochastic theorems.

> **Chapters 31 through 32 summary.** Construct windows under an explicit periodic or symmetric convention. Read gain and overlap diagnostics as finite numerical records. Keep framing geometry and boundary padding in the result. Use raw overlap-add only when summation is intended. Use `istft` for denominator-normalized synthesis. Distinguish transform metadata from a roundtrip certificate, and treat periodograms, Welch averages, coherence, and H1 as finite estimators whose modeling assumptions remain visible. For streams, use `StreamingSTFT` for bounded retained state and `stream_stft` when a batch-equivalence certificate is worth its full materialization cost.

33. Filtering and convolution

`komorebi_math.signals` implements finite, one-dimensional filtering on NumPy arrays. Two-input signal/kernel application functions take the signal first and the kernel second. Constructors and design routines have their own documented signatures. The routines in this chapter use zero extension unless the mode is explicitly `"circular"`. None silently changes to periodic boundaries. All certificate results in this chapter are numerical, even when the finite indexing identity is mathematically exact.

These APIs are on the complete research namespace:

```
from komorebi_math.signals import fir_filter, fft_convolve
```

They are not all re-exported from the package root, and the production DSP surface is not part of the frozen `komorebi_math.stable` contract in `1.0.0b4`. Import from `komorebi_math.signals` when the names form part of an application interface.

33.1 FIR design and application

For a signal $x \in \mathbb{K}^N$ and a kernel $h \in \mathbb{K}^K$, finite linear convolution means

$$(h * x)[n] = \sum_{j=0}^{K-1} h[j]x[n-j],$$

where samples outside $0 \le n < N$ are zero. The direct FIR entry point is

```
fir_filter(signal: Any, taps: Any, *, mode: FIRMode = "causal") -> np.ndarray
```

`taps` may be a one-dimensional array or an `FIRFilter`. Both the signal and the taps must be nonempty, one dimensional, and finite. `fir_filter` delegates the full calculation to `numpy.convolve` and then applies the package's crop convention.

The design vocabulary is

```
FIRKind = Literal["lowpass", "highpass", "bandpass", "bandstop"]
FIRMode = Literal["causal", "full", "same", "valid"]
```

The public constructors are

```
design_fir(
    kind: FIRKind,
    cutoff: float | tuple[float, float],
    *,
    num_taps: int = 101,
    sample_rate: float = 1.0,
    window: WindowSpec = "hann",
    scale: bool = True,
) -> FIRFilter

design_lowpass(cutoff: float, **options: Any) -> FIRFilter
design_highpass(cutoff: float, **options: Any) -> FIRFilter
design_bandpass(cutoff: tuple[float, float], **options: Any) -> FIRFilter
design_bandstop(cutoff: tuple[float, float], **options: Any) -> FIRFilter
```

The ideal low-pass seed at cutoff f_c and sample rate f_s is

$$h_n^{\text{ideal}} = 2\frac{f_c}{f_s}\,\operatorname{sinc}\left(2\frac{f_c}{f_s}\left[n - \frac{K-1}{2}\right]\right).$$

High-pass and band-stop designs use spectral inversion. A band-pass design is the difference of two low-pass seeds. The selected symmetric window is then applied. With `scale=True`, the implementation normalizes magnitude at DC for low-pass and band-stop, at Nyquist for high-pass, and at the midpoint of the two cutoffs for band-pass. This construction requires an odd `num_taps`, so its group delay is the integer

$$\tau_g = \frac{K-1}{2}.$$

The design record and sampled response record have these exact constructors and public members:

```
FIRFilter(
    taps: np.ndarray,
    kind: FIRKind,
    cutoff: tuple[float, ...],
    sample_rate: float = 1.0,
    window_name: str = "custom",
    reference_frequency: float | None = None,
    reference_gain: float = 1.0,
) -> None

FIRFilter.order -> int
FIRFilter.group_delay_samples -> float
FIRFilter.apply(signal: Any, *, mode: FIRMode = "causal") -> np.ndarray
FIRFilter.response(*, points: int = 512, whole: bool = False) -> FrequencyResponse
FIRFilter.certificate(*, tolerance: float = 1e-10) -> Certificate

FrequencyResponse(
    frequencies: np.ndarray,
    response: np.ndarray,
    sample_rate: float,
) -> None

FrequencyResponse.magnitude -> np.ndarray
FrequencyResponse.phase -> np.ndarray
FrequencyResponse.magnitude_db -> np.ndarray

fir_frequency_response(
    taps: Any,
    *,
    points: int = 512,
    sample_rate: float = 1.0,
    whole: bool = False,
) -> FrequencyResponse
```

The sampled transfer function is

$$H(e^{i\omega}) = \sum_{n=0}^{K-1} h_n e^{-i\omega n}.$$

`whole=False` covers $0 \le f \le f_s/2$, including the endpoint. `whole=True` covers $0 \le f < f_s$. Response values are complex, `phase` is unwrapped, and `magnitude_db` clips magnitude at the smallest positive floating value before taking the logarithm.

`FIRFilter.certificate` checks only tap symmetry and the stored reference gain:

$$r_{\text{sym}} = \max_n |h_n - h_{K-1-n}|, \qquad r_{\text{gain}} = \left| |H(f_{\text{ref}})| - g_{\text{ref}} \right| .$$

It reports theorem `KM-DSP-C02`. It does not certify a transition width, pass-band ripple, stop-band attenuation, or an application-specific filter specification.

Failure cases are explicit. Cutoffs must be finite and strictly inside $(0, f_s/2)$. Band edges must be increasing. Low-pass and high-pass take one cutoff, while band-pass and band-stop take two. The sample rate and point count must be positive, the tap count must be odd, and normalization fails when the selected reference gain is numerically zero.

33.2 Streaming FIR

`StreamingFIR` is the mutable causal executor:

```
StreamingFIR(taps: Any) -> None

StreamingFIR.taps: np.ndarray
StreamingFIR.processed_samples: int
StreamingFIR.process(chunk: Any) -> np.ndarray
StreamingFIR.flush() -> np.ndarray
StreamingFIR.reset() -> None

stream_fir_filter(
    signal: Any,
    taps: Any,
    chunk_sizes: Iterable[int],
    *,
    tolerance: float = 1e-12,
) -> ComputationResult[np.ndarray]
```

The persistent state is the most recent $K - 1$ input samples. `process` accepts an empty chunk and otherwise emits exactly one causal output for every input sample. Therefore, for any ordered complete partition $x = x^{(0)} \| \cdots \| x^{(q-1)}$,

$$\text{concat}_j \, \text{process}(x^{(j)}) = \text{fir_filter}(x, h, \texttt{mode="causal"}).$$

`flush` emits the remaining $K - 1$ full-convolution samples and closes the object. A second flush returns an empty array. Processing after flush raises `ValidationError`. `reset` restores zero history, clears the sample count, and reopens the object.

The `stream_fir_filter` convenience wrapper requires strictly positive chunk sizes whose sum is exactly the signal length. Its `KM-DSP-T05` certificate compares only the concatenated `process` outputs with causal batch filtering. It excludes the full tail because the wrapper does not call `flush`.

For a streaming comparison, decide first whether the desired output is the causal prefix or the complete finite convolution. Compare the concatenated `process` outputs with the causal prefix. Include the single `flush` output when comparing with full convolution. A missing tail in the first comparison is intentional; adding it to only one side makes the comparison inconsistent.

For a chunk of length C, the current direct implementation performs a convolution of the chunk plus history, costing $O((C+K)K)$ arithmetic in the usual direct-convolution model. Persistent memory is $O(K)$, in addition to the current chunk and temporary convolution array. This is chunk-invariant execution, not a hard real-time or fixed-latency guarantee.

33.3 Recursive filtering and stable biquads

`LinearFilter` represents the normalized rational transfer function

$$H(z) = \frac{\sum_{j=0}^{q} b_j z^{-j}}{1 + \sum_{j=1}^{q} a_j z^{-j}}.$$

The constructor divides both coefficient arrays by the first denominator coefficient, pads them to a common length, and stores floating or complex arrays:

```
LinearFilter(numerator: Any, denominator: Any = (1.0,)) -> None

LinearFilter.numerator: np.ndarray
LinearFilter.denominator: np.ndarray
LinearFilter.order -> int
LinearFilter.zeros -> np.ndarray
LinearFilter.poles -> np.ndarray
LinearFilter.process(
    signal: Any,
    *,
    initial_state: Any | None = None,
) -> FilterOutput
LinearFilter.response(
    *,
    points: int = 512,
    sample_rate: float = 1.0,
    whole: bool = False,
) -> FrequencyResponse
LinearFilter.stability_certificate(*, tolerance: float = 1e-12) -> Certificate

FilterOutput(samples: np.ndarray, final_state: np.ndarray) -> None

lfilter(
    numerator: Any,
    denominator: Any,
    signal: Any,
    *,
    initial_state: Any | None = None,
) -> FilterOutput
```

Execution uses direct form II transposed with state $s \in \mathbb{K}^q$:

$$y_n = b_0 x_n + s_0,$$

$$s_j \leftarrow s_{j+1} + b_{j+1} x_n - a_{j+1} y_n, \qquad s_{q-1} \leftarrow b_q x_n - a_q y_n.$$

The returned `final_state` is the exact state to pass as `initial_state` for the next contiguous chunk. Integer coefficients are promoted to floating point. A complex signal or coefficient promotes the recursion to complex arithmetic. `np.real_if_close` may return a real array when a complex result is numerically real.

Zeros and poles are numerical roots of the stored numerator and denominator coefficient polynomials. The `KM-DSP-C04` stability certificate computes

$$r_{\max} = \max_{\lambda \in \text{poles}} |\lambda|, \qquad m = 1 - r_{\max},$$

and requires the strict inequality $m >$ `tolerance`. It is a coefficient-level BIBO diagnostic. It does not cover unrepresented coefficient quantization, arithmetic overflow, limit cycles, or robustness margins under perturbation.

The included biquad constructor is

```
BiquadKind = Literal["lowpass", "highpass", "bandpass", "notch", "allpass"]

design_biquad(
    kind: BiquadKind,
    frequency: float,
    *,
    q: float = np.float64(0.7071067811865475),
    sample_rate: float = 1.0,
) -> LinearFilter
```

It uses

$$\omega_0 = 2\pi f_0 / f_s, \qquad \alpha = \frac{\sin \omega_0}{2Q},$$

and the standard normalized low-pass, high-pass, band-pass, notch, or all-pass coefficient table implemented in `signals.recursive`. This is not a general high-order IIR design facility.

Mutable recursive streaming is available as

```
StreamingLinearFilter(filter: LinearFilter) -> None

StreamingLinearFilter.filter: LinearFilter
StreamingLinearFilter.state: np.ndarray
StreamingLinearFilter.processed_samples: int
StreamingLinearFilter.process(chunk: Any) -> np.ndarray
StreamingLinearFilter.reset() -> None

stream_lfilter(
    filter_: LinearFilter,
    signal: Any,
    chunk_sizes: Any,
    *,
    tolerance: float = 1e-12,
) -> ComputationResult[np.ndarray]
```

There is no recursive-filter flush: a causal recursion has no separately emitted FIR tail. `stream_lfilter` consumes positive requested chunk sizes, clips a chunk that would extend past the end, ignores later sizes after the signal is exhausted, and automatically processes any unlisted remainder. Its `KM-DSP-T09` certificate checks maximum absolute equality with zero-state batch execution.

Filtering costs $O(Nq)$ time and $O(q)$ continuation state. Computing a complete sampled response costs $O(Pq)$ for P frequency points. Invalid inputs include a zero first denominator coefficient, a nonfinite signal or state, a state with length other than `order`, a response denominator that vanishes on the requested grid, $f_0 \notin (0, f_s/2)$, and nonpositive Q. An unstable denominator constructs successfully. Its stability certificate is invalid and callers may enforce it with `.require()`.

Example 33-B: FIR and IIR streaming

This example uses irregular chunks, explicitly includes the FIR tail, and checks a stable biquad.

```
import numpy as np

from komorebi_math.signals import (
    LinearFilter,
    StreamingFIR,
    design_biquad,
    stream_lfilter,
)

x = np.arange(1.0, 8.0)
```

```
fir = StreamingFIR([0.25, 0.50, 0.25])
fir_pieces = [
    fir.process(x[:1]),
    fir.process(x[1:4]),
    fir.process(x[4:]),
    fir.flush(),
]
print("FIR pieces:", [piece.tolist() for piece in fir_pieces])
print("FIR full:", np.concatenate(fir_pieces).tolist())

biquad = design_biquad("lowpass", 100.0, q=0.8, sample_rate=1000.0)
biquad.stability_certificate().require()
iir = stream_lfilter(biquad, x, (1, 3, 3))
iir.certificate.require()
print("IIR:", np.round(iir.value, 8).tolist())
print("IIR stream residual:", iir.certificate.residuals)

unstable = LinearFilter([1.0], [1.0, -1.01])
print("unstable certificate:", unstable.stability_certificate().valid)
```

Observed with NumPy `2.3.5` and Komorebi Math `1.0.0b4`:

```
FIR pieces: [[0.25], [1.0, 2.0, 3.0], [4.0, 5.0, 6.0], [5.0, 1.75]]
FIR full: [0.25, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, 5.0, 1.75]
IIR: [0.06983611, 0.36198303, 0.95472051, 1.80029766, 2.80599239, 3.88417736, 4.97406059]
IIR stream residual: {'streaming_batch_max_abs': 0.0}
unstable certificate: False
```

33.4 Direct, FFT, and overlap-add convolution

`fft_convolve` pads to

$$L_{\mathrm{FFT}} = 2^{\lceil \log_2 (N+K-1) \rceil}$$

and evaluates

$$y = \mathcal{F}^{-1}_{L_{\mathrm{FFT}}} \left(\mathcal{F}(x) \odot \mathcal{F}(h) \right)_{0:N+K-1}.$$

Real inputs use `numpy.fft.rfft` and `irfft`. Any complex input uses the two-sided complex transform. The public call is

```
fft_convolve(
    signal: Any,
    kernel: Any,
    *,
    mode: FIRMode = "full",
) -> np.ndarray
```

It costs $O(L_{\mathrm{FFT}} \log L_{\mathrm{FFT}})$ time and $O(L_{\mathrm{FFT}})$ temporary memory. No heuristic chooses between direct and FFT convolution. The caller chooses the entry point.

Overlap-add divides the input into blocks of length B and uses

$$L_B = 2^{\lceil \log_2 (B+K-1) \rceil}.$$

Its public surfaces are

```
OverlapAddConvolver(kernel: np.ndarray, block_length: int = 1024) -> None

OverlapAddConvolver.kernel: np.ndarray
OverlapAddConvolver.block_length: int
OverlapAddConvolver.fft_length: int
OverlapAddConvolver.processed_samples: int
OverlapAddConvolver.buffered_samples -> int
OverlapAddConvolver.process(chunk: Any) -> np.ndarray
OverlapAddConvolver.flush() -> np.ndarray
OverlapAddConvolver.reset() -> None

overlap_add_convolve(
    signal: Any,
    kernel: Any,
    *,
    block_length: int = 1024,
    mode: FIRMode = "full",
) -> np.ndarray

certified_overlap_add_convolve(
    signal: Any,
    kernel: Any,
    *,
    block_length: int = 1024,
    mode: FIRMode = "full",
    tolerance: float = 1e-11,
) -> ComputationResult[np.ndarray]
```

The mutable object stores the kernel spectrum, fewer than B untransformed samples after each call, and $K-1$ overlap samples. `process` accepts arbitrary and empty chunks and emits every complete transform block. `flush` transforms a final partial block, emits the convolution tail once, and closes the object. A repeated flush is empty. Processing after flush fails. `reset` restores the open zero-overlap state. A real-kernel processor promotes itself to complex FFTs if a complex chunk arrives.

For $J = \lceil N/B \rceil$, work is $O(JL_B \log L_B)$. Retained processor memory is $O(L_B + B + K)$. The peak for one `process` call also includes the supplied chunk because the implementation concatenates it before draining blocks.

The implementation here is NumPy-only and executes through `numpy.fft`. It does not accept a CUDA device, stream, backend, or workspace parameter. GPU qualification elsewhere in the package does not certify these DSP functions.

33.5 Convolution modes and output lengths

Two mode aliases are intentionally distinct:

```
ConvolutionMode = Literal["full", "same", "valid", "circular"]
FIRMode         = Literal["causal", "full", "same", "valid"]
```

For signal length N and kernel length K, the exact crop conventions are:

Mode	Length	Selection or boundary law
`full`	$N + K - 1$	complete zero-extended convolution
`causal`	N	full indices $0 : N$. FIR APIs only
`same`	N	starts at $\lfloor (K-1)/2 \rfloor$
`valid`	$\max(N - K + 1, 0)$	starts at $K - 1$. Empty when $K > N$
`circular`	N	source index $(n - j)$ mod N. Finite-convolution APIs only

Unlike `numpy.convolve(..., mode="same")`, package `same` is always the signal length, including when $K > N$. `convolution_output_length`, `convolution_matrix`, `convolve_signal`, and the finite polyphase APIs accept `ConvolutionMode`. They reject `"causal"`. `fir_filter`, `fft_convolve`, and the overlap-add APIs accept `FIRMode`. They reject `"circular"`.

The finite matrix APIs are

```
convolution_output_length(
    input_length: int,
    kernel_length: int,
    mode: ConvolutionMode,
) -> int

convolution_matrix(
    kernel: Any,
    input_length: int,
    *,
    mode: ConvolutionMode = "full",
) -> np.ndarray

convolve_signal(
    signal: Any,
    kernel: Any,
    *,
    mode: ConvolutionMode = "full",
) -> np.ndarray
```

They construct $H_h^{\mathrm{mode}} \in \mathbb{K}^{M \times N}$ such that $y = H_h^{\mathrm{mode}} x$. The matrix dtype is `np.result_type(kernel.dtype, float)`, so integer kernels produce floating matrices and complex kernels remain complex. This route stores MN values and matrix application costs $O(MN)$. Use direct or FFT convolution when the dense operator itself is not needed.

For packet order q, define source and target residue indices

$$I_s^X = \{s, s+q, s+2q, \ldots\} \cap [0, N), \qquad I_t^Y = \{t, t+q, t+2q, \ldots\} \cap [0, M).$$

The finite transfer blocks are literal submatrices

$$H_{ts} = H_h^{\mathrm{mode}}[I_t^Y, I_s^X], \qquad y_t = \sum_s H_{ts} x_s.$$

The exact public API is

```
PolyphaseConvolution(
    kernel: np.ndarray,
    input_length: int,
    order: int,
    mode: ConvolutionMode = "full",
) -> None

PolyphaseConvolution.matrix -> np.ndarray
PolyphaseConvolution.output_length -> int
PolyphaseConvolution.source_indices(residue: int) -> np.ndarray
PolyphaseConvolution.target_indices(residue: int) -> np.ndarray
PolyphaseConvolution.blocks() -> tuple[tuple[np.ndarray, ...], ...]
PolyphaseConvolution.apply_coordinates(
    coordinates: PolyphaseCoordinates,
) -> PolyphaseCoordinates
PolyphaseConvolution.apply(signal: Any) -> np.ndarray
PolyphaseConvolution.certificate(
    signal: Any,
    *,
    tolerance: float = 1e-11,
) -> ComputationResult[np.ndarray]
```

```
PolyphaseBlockMatrix(
    blocks: tuple[tuple[np.ndarray, ...], ...],
    order: int,
    input_length: int,
    output_length: int,
) -> None

finite_polyphase_blocks(
    kernel: Any,
    input_length: int,
    order: int,
    *,
    mode: ConvolutionMode = "full",
) -> PolyphaseBlockMatrix

polyphase_convolution(
    signal: Any,
    kernel: Any,
    order: int,
    *,
    mode: ConvolutionMode = "full",
    tolerance: float = 1e-11,
) -> ComputationResult[np.ndarray]
```

`FinitePolyphaseKernel` and `finite_polyphase_filter_kernels` are public aliases of `PolyphaseBlockMatrix` and `finite_polyphase_blocks`. The `PSC-V-T07` certificate compares packet reconstruction with the dense matrix product using the Euclidean residual. It does not compare against an infinite causal kernel. In particular, the tempting formula $h[qm + t - s]$ cannot replace these finite boundary blocks unless boundary equivalence has been proved.

Example 33-A: all convolution modes

Here $K = 4 > N = 3$, so `valid` is intentionally empty and `same` remains length three. FFT and overlap-add are compared only where their `FIRMode` vocabulary matches.

```
import numpy as np

from komorebi_math.signals import (
    convolution_matrix,
    convolve_signal,
    fft_convolve,
    overlap_add_convolve,
    polyphase_convolution,
)

x = np.array([1.0, 2.0, 3.0])
h = np.array([1.0, -1.0, 2.0, 0.5])

for mode in ("full", "same", "valid", "circular"):
    matrix = convolution_matrix(h, x.size, mode=mode)
    direct = convolve_signal(x, h, mode=mode)
    packet = polyphase_convolution(x, h, 2, mode=mode)
    packet.certificate.require()
    print(mode, matrix.shape, direct.tolist(), packet.certificate.residuals)
    if mode != "circular":
        assert np.allclose(fft_convolve(x, h, mode=mode), direct)
        assert np.allclose(
            overlap_add_convolve(x, h, block_length=2, mode=mode), direct
        )
```

Observed output:

```
full (6, 3) [1.0, 1.0, 3.0, 1.5, 7.0, 1.5] {'transfer_law': 0.0}
same (3, 3) [1.0, 3.0, 1.5] {'transfer_law': 0.0}
valid (0, 3) [] {'transfer_law': 0.0}
circular (3, 3) [2.5, 8.0, 4.5] {'transfer_law': 0.0}
```

33.6 Certified overlap-add error

`certified_overlap_add_convolve` computes the overlap-add result and an independent direct `numpy.convolve` reference under the same crop. Its certificate records

$$r_{\mathrm{OLA}} = \|y_{\mathrm{OLA}} - y_{\mathrm{direct}}\|_\infty$$

and accepts when the shapes agree and

$$r_{\mathrm{OLA}} \le \texttt{tolerance}\,\max(1, \|y_{\mathrm{direct}}\|_\infty).$$

The theorem identifier is `KM-DSP-T10`. Checked assumptions are finite ordered input and linear zero-padded convolution. This establishes finite numerical agreement for the supplied arrays, block length, mode, NumPy version, and tolerance. It does not prove exact arithmetic, favorable performance, a frequency-domain specification, real-time scheduling, or GPU execution.

Across the chapter, nonempty one-dimensional finite arrays are required by FIR, FFT, overlap-add, and recursive filtering. The older finite convolution matrix layer requires nonempty one-dimensional arrays but does not perform the same explicit finite-entry check. A nonpositive block length, input length, kernel length, or packet order is invalid. Mode strings outside the relevant alias fail with `ValidationError`.

34. Resampling and adaptive filters

The signal layer contains two finite batch facilities. Rational resampling uses a centered zero-extension plan with explicit polyphase/reference equivalence. Adaptive filtering records every coefficient iterate of an LMS, NLMS, or RLS recursion. Neither facility currently exposes a mutable streaming state class.

34.1 Upsampling, downsampling, interpolation, and decimation

Primitive upsampling inserts zeros:

$$(\uparrow_U x)[n] = \begin{cases} x[n/U], & n \equiv 0 \pmod{U}, \\ 0, & \text{otherwise}, \end{cases}$$

while downsampling retains one residue class:

$$(\downarrow_{D,r} x)[m] = x[r + mD], \qquad 0 \le r < D.$$

The functions are

```
upsample(signal: Any, factor: int) -> np.ndarray
downsample(signal: Any, factor: int, *, phase: int = 0) -> np.ndarray

interpolate(
    signal: Any,
    factor: int,
    *,
    num_taps: int | None = None,
    window: WindowSpec = ("kaiser", 8.0),
) -> np.ndarray

decimate(
    signal: Any,
    factor: int,
    *,
    num_taps: int | None = None,
    window: WindowSpec = ("kaiser", 8.0),
) -> np.ndarray
```

`upsample` and `downsample` are unfiltered primitives and preserve input dtype. `interpolate(x, U)` is exactly the filtered rational call with ratio `(U, 1)`. `decimate(x, D)` is the filtered call with ratio `(1, D)`. Thus the latter two include the finite default low-pass and centered boundary convention. They are not aliases for primitive insertion or selection.

All factors must be positive integers. `phase` must be an integer in $[0, D)$, and the signal must be nonempty, one dimensional, and finite.

34.2 Rational polyphase resampling

For requested integers $u, d > 0$, the implementation first reduces the rate:

$$g = \gcd(u, d), \qquad U = u/g, \qquad D = d/g.$$

Plan metadata, tap design, and output length all use U/D, with

$$N_{\text{out}} = \left\lceil \frac{NU}{D} \right\rceil = \left\lfloor \frac{NU + D - 1}{D} \right\rfloor.$$

The basic design and length calls are

```
resampled_length(input_length: int, up: int, down: int) -> int

design_resample_filter(
    up: int,
    down: int,
    *,
    num_taps: int | None = None,
    window: WindowSpec = ("kaiser", 8.0),
) -> np.ndarray
```

The default odd tap count is

$$K = 20 \max(U, D) + 1.$$

On the upsampled grid, the windowed-sinc seed has cutoff

$$f_c = \frac{1}{2 \max(U, D)}$$

cycles per high-rate sample and is scaled so that

$$\sum_{j=0}^{K-1} h_j = U.$$

The plan and result records expose:

```
RationalResamplingPlan(up: int, down: int, taps: np.ndarray) -> None

RationalResamplingPlan.up: int
RationalResamplingPlan.down: int
RationalResamplingPlan.taps: np.ndarray
RationalResamplingPlan.delay -> int
RationalResamplingPlan.polyphase_components -> tuple[np.ndarray, ...]
RationalResamplingPlan.output_length(input_length: int) -> int
RationalResamplingPlan.apply(signal: Any) -> np.ndarray
RationalResamplingPlan.explicit_reference(signal: Any) -> np.ndarray
RationalResamplingPlan.certificate(
    signal: Any,
    *,
    tolerance: float = 1e-12,
) -> Certificate

ResamplingResult(
    signal: np.ndarray,
    plan: RationalResamplingPlan,
    input_length: int,
```

```
    certificate: Certificate,
) -> None
```

For centered delay $\delta = (K-1)/2$, the U polyphase components are

$$h^{(r)} = (h_r, h_{r+U}, h_{r+2U}, \ldots), \qquad 0 \le r < U.$$

For output sample m, the direct plan sets

$$q_m = \delta + mD, \qquad r_m = q_m \bmod U,$$

then evaluates

$$y_m = \sum_{\substack{0 \le j < K \\ j \equiv r_m \ (U)}} h_j x_{(q_m - j)/U},$$

omitting out-of-range source indices. `explicit_reference` independently inserts zeros, performs full convolution, removes the centered delay, and takes every D-th sample. This is a zero-extension boundary rule, so startup and terminal transients are part of the contract.

The public wrappers are

```
resample_poly_result(
    signal: Any,
    up: int,
    down: int,
    *,
    taps: Any | None = None,
    num_taps: int | None = None,
    window: WindowSpec = ("kaiser", 8.0),
    tolerance: float = 1e-12,
) -> ResamplingResult

resample_poly(
    signal: Any,
    up: int,
    down: int,
    *,
    taps: Any | None = None,
    num_taps: int | None = None,
    window: WindowSpec = ("kaiser", 8.0),
) -> np.ndarray
```

Supplying `taps` bypasses filter design. `num_taps` and `window` then have no effect. A custom plan still requires a nonempty finite one-dimensional odd kernel. It may be applied even when its DC gain is not U, but its certificate will be invalid if the gain residual exceeds tolerance.

`KM-DSP-T06` records

$$r_{\text{poly}} = \|y_{\text{plan}} - y_{\text{explicit}}\|_\infty, \qquad r_{\text{DC}} = \left| \sum_j h_j - U \right|.$$

The first residual is scaled by the maximum reference magnitude. The second is scaled by $\max(1, U)$. The certificate checks the centered zero-extension convention and reduced rate. It explicitly leaves application-specific alias rejection and boundary-transient acceptability unchecked. A passing result is not a universal anti-aliasing or signal-fidelity guarantee.

Designed taps are real `float64`. Primitive up/down sampling preserves dtype. Plan application uses the result type of the signal and taps, supports complex values, and applies `np.real_if_close` to numerically real output. The

direct polyphase loop costs $O(N_{\text{out}}\lceil K/U \rceil)$ time and stores $O(N_{\text{out}} + K)$ values. Materializing `polyphase_components` copies K tap values. The explicit reference additionally materializes NU zero-inserted samples and uses direct `numpy.convolve`. It is principally a verification construction.

Invalid cases include nonpositive or nonintegral rates, nonpositive input length, even tap count, nonfinite signal or taps, invalid downsample phase, and a designed window whose DC sum is numerically zero.

Example 34-A: coprime and reducible resampling

```
import numpy as np

from komorebi_math.signals import (
    downsample,
    resample_poly_result,
    resampled_length,
    upsample,
)

x = np.array([0.0, 1.0, 0.0, -1.0, 0.0])
reducible = resample_poly_result(x, 6, 4)
coprime = resample_poly_result(x, 3, 2)
reducible.certificate.require()
coprime.certificate.require()

print("ratios:", (reducible.plan.up, reducible.plan.down),
      (coprime.plan.up, coprime.plan.down))
print("lengths:", reducible.signal.size, coprime.signal.size,
      resampled_length(x.size, 6, 4))
print("tap count/delay/phases:", reducible.plan.taps.size,
      reducible.plan.delay,
      [part.size for part in reducible.plan.polyphase_components])
print("same taps/output:",
      np.array_equal(reducible.plan.taps, coprime.plan.taps),
      np.array_equal(reducible.signal, coprime.signal))
print("output:", np.round(reducible.signal, 8).tolist())
print("residuals:", reducible.certificate.residuals)
print("upsample:", upsample([1, 2, 3], 3).tolist())
print("downsample:", downsample(np.arange(10), 3, phase=1).tolist())
```

Observed output:

```
ratios: (3, 2) (3, 2)
lengths: 8 8 8
tap count/delay/phases: 61 30 [21, 20, 20]
same taps/output: True True
output: [0.0, 0.72745807, 0.97255322, 0.0, -0.97255322, -0.72745807, -0.0, 0.10426563]
residuals: {'polyphase_reference': 0.0, 'dc_gain': 8.881784197001252e-16}
upsample: [1, 0, 0, 2, 0, 0, 3, 0, 0]
downsample: [1, 4, 7]
```

The final nonzero sample is a finite boundary transient, not a ratio-reduction failure. The certificate intentionally does not judge whether that transient is acceptable for a particular application.

When adapting this example, record the original sample rate and the reduced rate ratio, check the planned output length, and inspect both ends of the output as well as its interior. The direct reference is useful for confirming the implemented finite convention. Application-specific alias rejection and acceptable edge behavior still need their own criteria.

34.3 LMS, NLMS, and RLS

Let the tap count be p, and define the zero-prefixed regressor

$$u_n = (x_n, x_{n-1}, \dots, x_{n-p+1})^{\mathsf{T}}.$$

The routines use

$$y_n = w_n^* u_n, \qquad e_n = d_n - y_n.$$

Real inputs are promoted at least to floating point. Complex inputs use `numpy.vdot` and conjugate updates. Every result has

$$y, e \in \mathbb{K}^N, \qquad w_N \in \mathbb{K}^p, \qquad W_{\text{hist}} \in \mathbb{K}^{(N+1)\times p}.$$

The method alias, result record, and diagnostics are

```
AdaptiveMethod = Literal["lms", "nlms", "rls"]

AdaptiveFilterResult(
    output: np.ndarray,
    error: np.ndarray,
    final_weights: np.ndarray,
    weight_history: np.ndarray,
    method: AdaptiveMethod,
    certificate: Certificate,
) -> None

AdaptiveFilterResult.mean_squared_error -> float
AdaptiveFilterResult.tail_mean_squared_error(fraction: float = 0.25) -> float
```

They compute

$$\text{MSE} = \frac{1}{N}\sum_n |e_n|^2$$

and a tail MSE over `ceil(N * fraction)` final samples. The fraction must lie in $(0, 1]$.

Leaky LMS is

$$w_{n+1} = (1 - \mu\lambda) w_n + \mu u_n \overline{e_n}, \qquad \mu > 0, \quad \lambda \geq 0,$$

with API

```
lms_filter(
    input_signal: Any,
    desired_signal: Any,
    num_taps: int,
    *,
    step_size: float = 0.01,
    leakage: float = 0.0,
    initial_weights: Any | None = None,
) -> AdaptiveFilterResult
```

NLMS uses

$$g_n = \varepsilon + u_n^* u_n,$$

$$w_{n+1} = \left(1 - \frac{\mu\lambda}{g_n}\right) w_n + \frac{\mu}{g_n} u_n \overline{e_n}, \qquad \varepsilon > 0,$$

with API

```
nlms_filter(
    input_signal: Any,
    desired_signal: Any,
    num_taps: int,
    *,
    step_size: float = 0.5,
    epsilon: float = 1e-8,
    leakage: float = 0.0,
    initial_weights: Any | None = None,
) -> AdaptiveFilterResult
```

RLS initializes $P_0 = \delta I$, with $\delta > 0$, and for forgetting factor $0 < \gamma \leq 1$ applies

$$k_n = \frac{P_n u_n}{\gamma + u_n^* P_n u_n},$$

$$w_{n+1} = w_n + k_n \overline{e_n}, \qquad P_{n+1} = \gamma^{-1}(P_n - k_n u_n^* P_n).$$

The implementation symmetrizes each inverse covariance update:

$$P_{n+1} \leftarrow \frac{1}{2}(P_{n+1} + P_{n+1}^*).$$

Its API is

```
rls_filter(
    input_signal: Any,
    desired_signal: Any,
    num_taps: int,
    *,
    forgetting_factor: float = 0.99,
    delta: float = 1.0,
    initial_weights: Any | None = None,
) -> AdaptiveFilterResult
```

LMS and NLMS cost $O(Np)$ time. RLS costs $O(Np^2)$ time and retains the $p \times p$ inverse covariance during execution. All three intentionally store the complete $O(Np)$ weight history. There is no option to disable it.

Input and desired signals must be nonempty, finite, one dimensional, and equal in length. `num_taps` must be a positive integer, and initial weights must be a finite vector of exactly that length. LMS/NLMS require a positive finite step and nonnegative finite leakage. NLMS also requires positive finite `epsilon`. RLS requires `forgetting_factor` in $(0, 1]$, positive finite `delta`, and a nonvanishing gain denominator.

Every adaptive result certificate checks only that the finite recursion and stored trajectory are finite after validating declared parameter ranges. It records initial- and final-quarter MSE, plus method parameters. RLS also records the maximum Hermitian residual. It leaves persistent excitation, stochastic independence, and convergence for the supplied step or forgetting factor unchecked.

There is a source-metadata inconsistency in `1.0.0b4`: provenance identifiers are `KM-DSP-D12`, `KM-DSP-D13`, and `KM-DSP-D14` for LMS, NLMS, and RLS, respectively, but `AdaptiveFilterResult.certificate.theorem_id` is `KM-DSP-D12` for all three. Applications must treat the returned field as the runtime value rather than silently rewriting it.

Example 34-B: finite system identification

```
import numpy as np

from komorebi_math.signals import (
    fir_filter,
    lms_filter,
    nlms_filter,
    rls_filter,
)

rng = np.random.default_rng(12203)
x = rng.normal(size=4000)
target = np.array([0.7, -0.4, 0.2])
d = fir_filter(x, target, mode="causal")

results = {
    "LMS": lms_filter(x, d, 3, step_size=0.01),
    "NLMS": nlms_filter(x, d, 3, step_size=0.8),
    "RLS": rls_filter(x, d, 3, forgetting_factor=0.999, delta=10.0),
}

for name, result in results.items():
    result.certificate.require()
    print(
        name,
        np.round(result.final_weights, 8).tolist(),
        f"error={np.linalg.norm(result.final_weights - target):.3e}",
        f"mse={result.mean_squared_error:.3e}",
        f"tail={result.tail_mean_squared_error(0.2):.3e}",
        result.certificate.theorem_id,
    )
```

Observed output:

```
LMS [0.7, -0.4, 0.2] error=7.855e-16 mse=8.860e-03 tail=1.815e-30 KM-DSP-D12
NLMS [0.7, -0.4, 0.2] error=6.206e-17 mse=3.818e-04 tail=1.071e-32 KM-DSP-D12
RLS [0.69999866, -0.39999929, 0.19999963] error=1.558e-06 mse=2.759e-04 tail=6.082e-12 KM-DSP-D12
```

These numbers are a fixed-seed finite experiment, not a convergence theorem. In particular, lack of excitation and an excessive but still finite step are not parameter-validation failures. For example, NLMS on an all-zero input and all-one desired signal returns zero weights, MSE `1.0`, and a valid finite recursion certificate. In the same environment, twenty LMS samples with `step_size=10.0` produced MSE `9.014e+38` while the certificate remained valid because every stored value was still finite. By contrast, `forgetting_factor=1.1` raises `ValidationError: forgetting_factor must lie in (0, 1]`.

34.4 Streaming and chunk invariance

The state laws across Chapters 32 through 34 are different and should not be interchanged:

Facility	Mutable state	Chunk guarantee	Flush behavior
`StreamingFIR`	$K-1$ input-history samples	`process` concatenation equals causal FIR	emits $K-1$ full tail samples once
`StreamingLinearFilter`	direct-form state $s \in \mathbb{K}^q$	transported state equals batch recursion	no flush
`OverlapAddConvolver`	transform buffer, kernel spectrum, $K-1$ overlap	process plus flush equals full convolution	final block and tail once
`StreamingSTFT`	overlap/unframed sample buffer	emitted frames equal matching batch framing	optional terminal padded frame
`RationalResamplingPlan`	none. Immutable finite plan	no public chunk-invariance contract	batch only
LMS, NLMS, RLS	none exposed. Local recurrence state plus complete returned history	no public chunk-invariance contract	batch only

Splitting a resampling or adaptive-filter input into independent calls resets its finite boundary or recurrence state and is not guaranteed to reproduce one batch call. A caller can build a higher-level streaming system only by defining and testing the missing delay/phase or regressor/weight state itself. The library does not currently provide that contract.

The same device boundary applies here as in Chapter 33. Resampling and adaptive filtering are NumPy host implementations with no CUDA backend, device-array, stream, or workspace parameter. Their finite certificates do not extend to hardware qualification or real-time scheduling.

34.5 Verification evidence and known limitations

The focused unit suites exercise FIR modes and design validation, complex and irregular FIR streaming, independent recursive difference equations, state continuation, every biquad kind, unstable poles, real and complex FFT convolution, overlap-add block sizes from 1 through 256, irregular complex chunks, rational rates including reducible `6/4`, complex resampling, primitive phase conventions, and real and complex adaptive identification.

Against the recovered `1.0.0b4` source, the four directly relevant suites `test_block12_spectral_filtering.py`, `test_block12_recursive_fft.py`, `test_block12_resampling_adaptive.py`, and `test_signals_polyphase_filterbanks.py` pass 68 of 68 tests.

The recorded deterministic signal audit used seed `12012026` and reports `815779` of `815779` scalar checks passing. Relevant section counts are `93170` FIR, `142577` recursive, `413058` FFT-convolution, `27863` resampling, and `240` adaptive checks. Its environment record is Python `3.13.5`, NumPy `2.3.5`, and package version `0.12.0a1`. The algorithms remain present in the `1.0.0b4` source. The independent SciPy convention audit reports `520920` of `520920` comparisons passing and expressly limits its scope to matched finite conventions, not API identity.

Known limitations are therefore part of the contract: no general high-order IIR designer beyond the listed biquads, no automatic direct/FFT cost planner, no streaming rational resampler, no streaming adaptive-filter class, no stochastic convergence theorem, no application-specific alias-rejection certificate, no hard real-time guarantee, and no hardware-validated GPU DSP path.

35. Filter banks, wavelets, and packet trees

The finite signal APIs in this chapter turn analysis/synthesis operators into explicit matrices, pairwise Haar transforms, reversible lifting steps, complete binary packet trees, optimal additive prunings, and deterministic shrinkage pipelines. The common design rule is simple: every transform acts on a finite array under a declared boundary convention. None of these routines silently replaces the finite problem by an infinite convolution theorem.

Choose a representation. Start with one-level Haar analysis to understand low and high channels. Use multilevel Haar decomposition when only the low branch should be refined, and a packet tree when both branches should be refined. Best-basis selection chooses a complete pruning of that packet tree under a supplied additive cost. Explicit finite or periodic filter-bank matrices are most useful when the operator itself must be inspected; consult Section 35.8 before using them at a large signal length.

Three public modules supply the chapter:

```
from komorebi_math.signals import filterbanks, wavelets, denoise
```

Their objects are also re-exported from `komorebi_math.signals`. In version `1.0.0b4` the `signals` feature is implemented, but the names documented here are part of the research public surface rather than the curated `komorebi_math.beta` or `komorebi_math.stable` surfaces. Pin the package version if an application depends on these signatures.

The chapter uses these claim strengths:

- a matrix shape, packet cover, or dynamic-programming choice is an exact finite statement.
- An SVD, pseudoinverse, floating Haar roundtrip, or norm residual is numerical.
- A denoising comparison against a supplied clean array is an observed finite comparison, not a population-risk theorem.
- Universal and SURE thresholds retain their noise-model assumptions.

35.1 Periodic and finite filter banks

35.1.1 Periodic analysis and synthesis

Let the signal length be $N > 0$, let the decimation factor $D > 0$ divide N, and let there be C analysis filters h_c and C synthesis filters g_c. Circular convolution in this module means

$$(C_h x)[n] = \sum_{t=0}^{K-1} h[t]x[(n-t) \bmod N].$$

The downsampler keeps indices $0, D, 2D, \dots, N-D$. If Q_D is its $(N/D) \times N$ matrix and Q_D^{T} is the zero-inserting upsampler, channel c has matrices

$$A_c = Q_D C_{h_c}, \qquad S_c = C_{g_c} Q_D^{\mathsf{T}}.$$

The complete operators are

$$A = \begin{bmatrix} A_0 \\ \vdots \\ A_{C-1} \end{bmatrix} \in \mathbb{K}^{(CN/D)\times N}, \qquad S = \begin{bmatrix} S_0 & \cdots & S_{C-1} \end{bmatrix} \in \mathbb{K}^{N\times(CN/D)}.$$

`PeriodicFilterBank.analyze` computes Ax and returns it as C arrays of length N/D. `synthesize` concatenates those channels in channel order and computes Sc. The declared output length, when supplied, must equal the common channel length times D.

Perfect reconstruction is the finite matrix identity

$$SA = I_N.$$

The certificate stores the absolute spectral-norm defect

$$r_{\mathrm{PR}} = \|SA - I_N\|_2$$

and accepts exactly when $r_{\mathrm{PR}} \leq \tau$. This comparator is absolute. It does not multiply the tolerance by a signal or operator scale.

```
import numpy as np

from komorebi_math.signals import PeriodicFilterBank

bank = PeriodicFilterBank(
    analysis_filters=([1.0],),
    synthesis_filters=([1.0],),
    decimation=1,
)

x = np.arange(4.0)
channels = bank.analyze(x)
reconstructed = bank.synthesize(channels)
certificate = bank.perfect_reconstruction_certificate(length=4)

print(channels)
print(reconstructed)
print(certificate.residuals)
print(bank.frame_bounds(4))
```

Observed with NumPy `2.5.2`:

```
(array([0., 1., 2., 3.]),)
[0. 1. 2. 3.]
{'reconstruction_operator': 0.0}
(1.0, 1.0)
```

This identity bank is intentionally elementary: it exposes channel order and the circular finite convention without hiding phase choices inside a named infinite-wavelet design.

35.1.2 Frame diagnostics and the canonical synthesis matrix

If $A \in \mathbb{K}^{M \times N}$ has full column rank, its frame bounds are

$$\alpha = \sigma_{\min}(A)^2, \qquad \beta = \sigma_{\max}(A)^2,$$

and

$$\alpha \|x\|_2^2 \leq \|Ax\|_2^2 \leq \beta \|x\|_2^2.$$

The canonical dual synthesis operator is the Moore-Penrose pseudoinverse

$$S_{\mathrm{can}} = A^{\dagger} = (A^* A)^{-1} A^*$$

when the displayed full-column-rank formula applies. The method `PeriodicFilterBank.canonical_synthesis_matrix` always returns NumPy's pseudoinverse. It does not first prove full column rank and does not mutate the bank's declared synthesis filters. Callers that need reconstruction must check

$$\|A^{\dagger}A - I_N\|_2$$

or establish the rank separately.

There is an important finite-dimensional reporting boundary. NumPy returns only `min(M, N)` singular values. When $M < N$, the implemented `frame_bounds` method squares the smallest returned value even though the analysis map necessarily has a nontrivial nullspace and its mathematical lower frame bound on all of $\mathbb{K}^N$ is zero. Treat the reported lower value as a singular-value diagnostic until full column rank has been established.

35.1.3 General finite analysis/synthesis pairs

`FiniteFilterBank` removes the convolution structure and accepts an explicit analysis matrix

$$E \in \mathbb{K}^{m \times n}$$

together with an explicit synthesis matrix

$$R \in \mathbb{K}^{n \times m}.$$

It computes

$$c = Ex, \qquad \hat{x} = Rc, \qquad \mathcal{R} = RE.$$

`report()` returns the squares of the smallest and largest singular values returned by NumPy, the absolute spectral defect

$$r = \|RE - I_n\|_2,$$

and a numerical certificate. `canonical_dual()` is stricter than the periodic pseudoinverse helper: it checks `matrix_rank(E) == n` and raises `ValidationError` when the analysis matrix is rank deficient.

For perturbations ΔE and ΔR, the package evaluates

$$\begin{aligned}\|(R + \Delta R)(E + \Delta E) - I\|_2 \le \|RE - I\|_2 + \|\Delta R\|_2\|E\|_2 \\ + \|R\|_2\|\Delta E\|_2 + \|\Delta R\|_2\|\Delta E\|_2.\end{aligned}$$

The method returns the right-hand side. It is an operator-norm upper bound, not a recomputed perturbed reconstruction error.

```
import numpy as np

from komorebi_math.signals import FiniteFilterBank

np.set_printoptions(precision=6, suppress=True)

E = np.array(
    [
        [1.0, 0.0],
        [0.0, 1.0],
        [1.0, 1.0],
    ]
)

bank = FiniteFilterBank(E, np.linalg.pinv(E)).canonical_dual()
report = bank.report()

x = np.array([2.0, -1.0])
print(bank.synthesis_matrix)
print(report.lower_frame_bound, report.upper_frame_bound)
```

```
print(report.reconstruction_residual)
print(bank.synthesize(bank.analyze(x)))
```

Observed output:

```
[[ 0.666667 -0.333333  0.333333]
 [-0.333333  0.666667  0.333333]]
1.0 2.9999999999999996
3.5502063685515195e-16
[ 2. -1.]
```

The rank check and the compatible finite dimensions are exact structural facts. The pseudoinverse entries, singular values, and residual are numerical.

35.2 Haar analysis and synthesis

`HaarFilterBank` acts on adjacent pairs. For (x_{2j}, x_{2j+1}), normalized analysis is

$$a_j = \frac{x_{2j} + x_{2j+1}}{\sqrt{2}}, \qquad d_j = \frac{x_{2j} - x_{2j+1}}{\sqrt{2}},$$

and synthesis is

$$x_{2j} = \frac{a_j + d_j}{\sqrt{2}}, \qquad x_{2j+1} = \frac{a_j - d_j}{\sqrt{2}}.$$

Consequently,

$$\|x\|_2^2 = \|a\|_2^2 + \|d\|_2^2.$$

With `normalized=False`, analysis omits the denominator and synthesis divides by two:

$$a_j = x_{2j} + x_{2j+1}, \qquad d_j = x_{2j} - x_{2j+1}, \qquad (x_{2j}, x_{2j+1}) = \left(\frac{a_j + d_j}{2}, \frac{a_j - d_j}{2} \right).$$

The unnormalized transform reconstructs, but its coefficient energy is twice the signal energy. `HaarFilterBank.certificate` therefore requires the energy residual only when `normalized=True`.

The boundary convention here is finite adjacent pairing, not circular convolution: the input length must be even, and the pair at the right boundary is the final two samples. Low and high channels must be equal one-dimensional arrays for synthesis.

```
import numpy as np

from komorebi_math.signals import HaarFilterBank, haar_analyze, haar_synthesize

np.set_printoptions(precision=6, suppress=True)

x = np.array([3.0, 1.0, -1.0, 5.0, 2.0, 0.0, 4.0, -2.0])
low, high = haar_analyze(x)
checked = HaarFilterBank().certificate(x)

print(low)
print(high)
print(haar_synthesize(low, high))
print(checked.certificate.residuals)
```

Observed output:

```
[2.828427 2.828427 1.414214 1.414214]
[ 1.414214 -4.242641  1.414214  4.242641]
[ 3.  1. -1.  5.  2.  0.  4. -2.]
{'reconstruction': 1.1430445635548515e-15,
 'energy': 1.4210854715202004e-14}
```

`haar_matrix(N)` constructs the one-level analysis matrix by applying the transform to every coordinate vector. `haar_filter_bank(N)` inverts that matrix numerically and returns a `FiniteFilterBank`. These conveniences require a positive even N. The direct `HaarFilterBank.analyze` method checks only one-dimensionality and evenness.

35.3 Lifting schemes

35.3.1 Periodic predict and update

Split an even signal into the subsequences

$$e_j = x_{2j}, \qquad o_j = x_{2j+1}, \qquad 0 \le j < N/2.$$

For a finite filter $p = (p_0, \dots, p_{K_p-1})$, the implementation's circular subsequence filter is

$$(Pe)_j = \sum_{t=0}^{K_p-1} p_t e_{(j-t) \bmod (N/2)}.$$

The update filter U uses the same convention. Analysis performs

$$d = o - Pe, \qquad s = e + Ud.$$

Synthesis reverses the operations in the necessary order:

$$e = s - Ud, \qquad o = d + Pe,$$

and interleaves e, o. This algebra is reversible for arbitrary finite predict and update filters. Floating arithmetic still makes the returned certificate numerical.

`periodic_five_three_lifting()` returns

$$p = (1/2, 1/2), \qquad u = (1/4, 1/4).$$

Thus the implemented phase convention is

$$d_j = o_j - \tfrac{1}{2}e_j - \tfrac{1}{2}e_{j-1}, \qquad s_j = e_j + \tfrac{1}{4}d_j + \tfrac{1}{4}d_{j-1},$$

with indices taken modulo $N/2$. This explicit formula is safer than assuming the phase convention of another library's $5/3$ transform.

```
import numpy as np

from komorebi_math.signals import periodic_five_three_lifting

np.set_printoptions(precision=6, suppress=True)
x = np.array([3.0, 1.0, -1.0, 5.0, 2.0, 0.0, 4.0, -2.0])

scheme = periodic_five_three_lifting()
smooth, detail = scheme.analyze(x)
checked = scheme.certificate(x)
```

```
print(smooth)
print(detail)
print(checked.value)
print(checked.certificate.residuals)
```

For the preceding eight-sample `x`, the observed output is

```
[ 1.125 -0.625  2.875  2.625]
[-2.5  4.  -0.5 -5. ]
[ 3.  1. -1.  5.  2.  0.  4. -2.]
{'lifting_roundtrip': 0.0}
```

`PeriodicLiftingScheme.synthesize` accepts either one iterable containing `(smooth, detail)` or two positional channels. In both forms the channels must be equal one-dimensional arrays.

35.4 Haar packet trees and pruning

35.4.1 Complete trees

A packet path is either a binary string or a tuple of binary integers. The root is the empty string `""`. Appending `"0"` selects the low Haar child and appending `"1"` selects the high child. At depth J, a complete tree has

$$1 + 2 + \cdots + 2^J = 2^{J+1} - 1$$

nodes. Every depth-j level contains N coefficients in total, so the stored coefficient count across the complete tree is $(J + 1)N$.

`HaarPacketTree.analyze(x, J)` requires a nonempty one-dimensional input and

$$2^J \mid N.$$

Unlike an ordinary multilevel discrete wavelet transform, packet analysis splits both the low and high child at every nonterminal node.

The principal tree views are:

Member	Meaning
`signal`	copied root signal
`depth`	complete binary depth
`normalized`	local Haar normalization flag
`nodes`	shallow copy of the complete path-to-array dictionary
`coefficients`	compatibility alias returning the same kind of copy
`coefficient(path)`	coefficient array at one validated path
`paths_at_depth(j)`	sorted paths at depth j
`full_leaves`	all sorted paths at the terminal depth

`HaarPacketTree.decompose` is an alias of `analyze`.

35.4.2 Valid prunings

A selected path set L is a complete pruning exactly when

1. every selected path is a node of the tree.
2. No selected path is the ancestor of another selected path.
3. Every full-depth path has exactly one selected ancestor.

Equivalently, L is a prefix-free complete cover of the terminal leaves. `validate_pruning` deduplicates the supplied paths, sorts them, and returns the canonical tuple. The root alone, `("",)`, and all terminal leaves are both valid prunings.

Reconstruction descends from the root. At a selected path it returns the stored coefficients. At an unselected internal path it recursively reconstructs both children and applies Haar synthesis. `PrunedPacketCoefficients` stores a validated pruning together with its source tree and exposes the chosen coefficient dictionary, reconstruction, energy, and certificate.

For normalized Haar and any complete pruning,

$$\|x\|_2^2 = \sum_{p \in L} \|c_p\|_2^2.$$

The reconstruction certificate stores absolute Euclidean reconstruction and absolute energy residuals. The energy term is required only for a normalized tree.

```
import numpy as np

from komorebi_math.signals import HaarPacketTree, packet_energy

x = np.arange(16.0)
tree = HaarPacketTree.analyze(x, depth=3)
pruned = tree.prune(("0", "10", "110", "111"))

print(tree.full_leaves)
print(pruned.leaves)
print(np.linalg.norm(pruned.reconstruct() - x))
print(packet_energy(pruned), np.vdot(x, x).real)
```

`haar_packet_synthesize(tree, leaves)` and `packet_energy(tree, leaves)` are functional wrappers. When passed a `PrunedPacketCoefficients` object, both wrappers reject an additional `leaves` argument because the pruning is already fixed.

35.5 Best-basis selection and costs

35.5.1 Additive dynamic programming

Let $C(p, c_p)$ be a finite real cost for node p. The minimum additive pruning cost below p satisfies

$$B(p) = \begin{cases} C(p, c_p), & |p| = J, \\ \min\{C(p, c_p), B(p0) + B(p1)\}, & |p| < J. \end{cases}$$

`best_basis(tree, cost)` evaluates this recurrence bottom-up. `cost` can be a mapping containing every visited path, a callable `cost(coefficients, path)`, or a one-argument callable `cost(coefficients)`. Every returned cost must be finite.

The tie policy is deterministic:

$$C(p, c_p) \le B(p0) + B(p1) \quad \Longrightarrow \quad \text{keep } p.$$

The reported margin is

$$\Delta_p = \left| C(p, c_p) - B(p0) - B(p1) \right|$$

for internal nodes and infinity for terminal nodes. A small margin means a small cost perturbation can change the local choice. `BestBasisResult` stores the selected `leaves`, optimum `cost`, every node's `decisions` and `margins`, and an exact certificate for the finite dynamic-programming selection.

That exactness label does not convert floating cost evaluation into exact arithmetic. It means only that, for the finite values supplied to the recurrence, the returned pruning attains its additive minimum with the stated tie policy.

35.5.2 Built-in costs

For coefficient energies $e_j = |c_j|^2$ and total $E = \sum_j e_j$, entropy cost is

$$C_{\text{ent}}(c) = -\sum_{j : q_j > 0} q_j \log q_j, \qquad q_j = e_j / E.$$

The zero vector has cost zero. `entropy_cost` implements this formula. `shannon_entropy_cost(coefficients, path="")` is a compatibility wrapper that calls `entropy_cost`. It is behaviorally equivalent but is not the same function object.

`lp_cost(p)` requires finite $p > 0$ and returns the callable

$$C_p(c) = \sum_j |c_j|^p.$$

The name is a positive-power coefficient cost. It does not claim to be a norm when $0 < p < 1$.

```python
import numpy as np

from komorebi_math.signals import (
    HaarPacketTree,
    best_basis,
    entropy_cost,
    lp_cost,
)

tree = HaarPacketTree.analyze(np.arange(16.0), depth=2)
costs = {path: 10.0 for path in tree.nodes}
costs.update({"": 9.0, "0": 1.0, "10": 1.0, "11": 1.0})

result = best_basis(tree, costs)
entropy_result = best_basis(tree, entropy_cost)
l1_result = best_basis(tree, lp_cost(1.0))

print(result.leaves, result.cost)
print(result.decisions)
print(result.margins)
print(entropy_result.leaves, entropy_result.cost)
print(l1_result.leaves, l1_result.cost)
```

Observed output:

```
('0', '10', '11') 3.0
{'00': 'keep', '01': 'keep', '0': 'keep',
 '10': 'keep', '11': 'keep', '1': 'split', '': 'split'}
{'00': inf, '01': inf, '0': 19.0,
 '10': inf, '11': inf, '1': 8.0, '': 6.0}
('',) 2.309540025247866
('00', '01', '10', '11') 71.99999999999999
```

For the selected mapping-cost basis, reconstruction had Euclidean residual `6.425400768188728e-15`. Selected energy was `1239.9999999999998` against root energy `1240.0`.

35.6 Denoising and risk certificates

35.6.1 Multilevel Haar decomposition

`haar_decompose(x, levels=J)` follows only the low branch. Starting from $a^{(0)} = x$, it computes

$$(a^{(j)}, d^{(j)}) = \mathrm{HaarAnalyze}(a^{(j-1)}), \qquad 1 \le j \le J.$$

The stored detail tuple is ordered from finest to coarsest:

$$(d^{(1)}, d^{(2)}, \dots, d^{(J)}).$$

The final approximation is $a^{(J)}$. The signal must be nonempty, finite, one dimensional, and divisible in length by 2^J, with $J > 0$.

`HaarDecomposition.reconstruct()` traverses the details in reverse order. Supplying a replacement detail tuple requires one correctly shaped array for every level. Its certificate checks

$$r_x = \|\hat{x} - x\|_2$$

and, for normalized Haar,

$$r_E = \left| \|a^{(J)}\|_2^2 + \sum_{j=1}^{J} \|d^{(j)}\|_2^2 - \|x\|_2^2 \right|.$$

Unlike the one-level Haar certificate, this comparator is scaled. Both residuals are compared with

$$\tau \max\{1, \|x\|_2, \|x\|_2^2\}.$$

35.6.2 Noise scale and threshold rules

For a finite vector v,

$$\mathrm{MAD}(v; c) = \mathrm{median}_j \, |v_j - c|.$$

`median_absolute_deviation` uses the sample median as c unless a finite center is supplied. The white-noise scale helper fixes $c = 0$ and returns

$$\hat{\sigma} = \frac{\mathrm{median}_j \, |d_j|}{0.6744897501960817}.$$

The universal threshold for $n > 0$ coefficients is

$$\lambda_{\text{univ}} = \sigma\sqrt{2\log n}.$$

For SURE, let

$$u_{(1)} \le \cdots \le u_{(n)}$$

be the sorted squared normalized magnitudes $u_j = (|d_j|/\sigma)^2$. For candidate rank k, the implementation evaluates

$$R_k = n - 2k + \sum_{j=1}^{k} u_{(j)} + (n-k)u_{(k)}$$

and returns

$$\lambda_{\text{SURE}} = \sigma\sqrt{u_{(k_*)}}, \qquad k_* = \operatorname*{argmin}_k R_k.$$

When $\sigma = 0$, `sure_threshold` returns zero immediately. This is a finite selection among observed coefficient magnitudes. Its usual statistical interpretation requires the relevant noise model.

35.6.3 Shrinkage maps

For $\lambda \ge 0$, the three supported modes are

$$T_{\text{hard}}(z) = z\mathbf{1}_{|z|\ge\lambda},$$

$$T_{\text{soft}}(z) = z\frac{\max(|z| - \lambda, 0)}{|z|},$$

The corresponding garrote rule is

$$T_{\text{garrote}}(z) = z\frac{\max(|z|^2 - \lambda^2, 0)}{|z|^2}.$$

The implementation uses zero-safe division in the last two formulas. For complex coefficients, both maps preserve the phase of retained values.

`wavelet_denoise` never thresholds the final approximation. It thresholds each stored detail array and then synthesizes. Its rule behavior is:

- `"fixed"`: required explicit nonnegative finite `threshold`.
- `"universal"`: noise scale times the universal factor for each detail length.
- `"sure"`: finite SURE selection within each detail array.

When `sigma=None`, the common default scale is estimated from the first, finest detail. With `level_dependent=True`, and only when `sigma` is not supplied, each detail gets its own MAD estimate. A supplied `sigma` is used for every level. An explicit `threshold` is rejected unless `rule="fixed"`.

The returned `WaveletDenoiseResult` contains the reconstructed `signal`, source `decomposition`, `thresholded_details`, one `thresholds` entry per level, `noise_sigma`, normalized `rule` and `mode` strings, and a certificate. Its `removed_energy` property is

$$\sum_{j=1}^{J} \|d^{(j)} - \tilde{d}^{(j)}\|_2^2.$$

The shrinkage certificate checks only that the reconstructed array is finite and that coefficient magnitudes did not increase. Its fixed internal tolerance is `1e-12`. `wavelet_denoise` does not expose that tolerance as a parameter. The certificate intentionally leaves unchecked the white-Gaussian interpretation or the applicability of a supplied scale and optimality beyond the selected finite rule.

35.6.4 Observed risk is not population risk

Given a supplied clean reference x, noisy observation y, and estimate $\hat{x}$, `denoising_risk_certificate` computes

$$e_{\text{noisy}} = \frac{1}{N}\sum_{n=0}^{N-1} |y_n - x_n|^2, \qquad e_{\text{denoised}} = \frac{1}{N}\sum_{n=0}^{N-1} |\hat{x}_n - x_n|^2.$$

It is valid exactly when

$$e_{\text{denoised}} \le e_{\text{noisy}} + \tau, \qquad \tau \ge 0.$$

This is an observed finite error comparison conditioned on the supplied clean array. It does not estimate unseen risk, prove distributional optimality, or certify that another signal will improve.

```
import numpy as np

from komorebi_math.signals import (
    denoising_risk_certificate,
    wavelet_denoise,
)

rng = np.random.default_rng(12303)
clean = np.repeat(np.array([0.0, 2.0, -1.0, 1.5]), 256)
noisy = clean + rng.normal(scale=0.35, size=clean.size)

result = wavelet_denoise(
    noisy,
    levels=5,
    rule="universal",
    mode="soft",
)
risk = denoising_risk_certificate(clean, noisy, result.signal)

print(result.noise_sigma)
print(result.thresholds)
print(result.removed_energy)
print(result.certificate.assumptions_unchecked)
print(risk.valid, risk.residuals)
```

Observed output:

```
0.3803110080909681
(1.3433459777978087, 1.2665187338406718,
 1.1847197939906322, 1.0968373978749237,
 1.0012709745522745)
131.82889808658055
('Gaussian white-noise interpretation',
 'threshold optimality outside the selected finite risk rule')
True {'noisy_mse': 0.1328856705568,
      'denoised_mse': 0.0038218147825770732}
```

The clean reference makes this example reproducible and makes its claim narrow: this one finite realization improved under the displayed metric.

35.7 `signals.filterbanks` periodic, finite, Haar, lifting, canonical-dual, and perturbation APIs

35.7.1 `signals.filterbanks`

The module exports exactly eleven names.

- **`PeriodicFilterBank`:** `(analysis_filters: Iterable[Any], synthesis_filters: Iterable[Any], decimation: int)`. Periodic structured bank.
- **`HaarFilterBank`:** `(normalized: bool = True)`. One-level adjacent-pair Haar bank.
- **`PeriodicLiftingScheme`:** `(predict: Any, update: Any)`. Reversible circular lifting pair.
- **`FiniteFilterBank`:** `(analysis_matrix: Any, synthesis_matrix: Any)`. Explicit finite analysis/synthesis pair.
- **`FilterBankReport`:** immutable diagnostic record with fields `lower_frame_bound`, `upper_frame_bound`, `reconstruction_residual`, and `certificate`.
- **`haar_analyze`:** `(signal: Any, *, normalized: bool = True)`. Returns `(low, high)`.
- **`haar_synthesize`:** `(low: Any, high: Any, *, normalized: bool = True)`. Reconstructed array.
- **`haar_matrix`:** `(length: int, *, normalized: bool = True)`. One-level analysis matrix.
- **`haar_filter_bank`:** `(length: int, *, normalized: bool = True)`. Returns a `FiniteFilterBank`.
- **`periodic_five_three_lifting`:** `()`. Preset `PeriodicLiftingScheme`.
- **`reconstruction_error`:** `(bank: FiniteFilterBank)`. Absolute spectral defect.

`PeriodicFilterBank` members:

- `analysis_filters`, `synthesis_filters`, and `decimation`: stored immutable constructor fields.
- `channels`: number of filters in either bank.
- `analysis_matrix(length: int) -> ndarray`.
- `synthesis_matrix(length: int) -> ndarray`.
- `analyze(signal: Any) -> tuple[ndarray, ...]`.
- `synthesize(coefficients: Iterable[Any], *, length: int | None = None) -> ndarray`.
- `reconstruction_operator(length: int) -> ndarray`.
- `perfect_reconstruction_certificate(length: int, *, tolerance: float = 1e-10) -> Certificate`.
- `frame_bounds(length: int) -> tuple[float, float]`.
- `canonical_synthesis_matrix(length: int, *, rcond: float | None = None) -> ndarray`.
- `reconstruction_error_bound(length: int) -> float`.

`FiniteFilterBank` members:

- `analysis_matrix` and `synthesis_matrix`: stored immutable arrays.
- `input_dimension`: number of analysis columns.
- `coefficient_dimension`: number of analysis rows.
- `analyze(signal: Any) -> ndarray`.
- `synthesize(coefficients: Any) -> ndarray`.
- `reconstruction_operator() -> ndarray`.
- `report(*, tolerance: float = 1e-10) -> FilterBankReport`.
- `canonical_dual(*, rcond: float | None = None) -> FiniteFilterBank`.
- `perturbation_bound(analysis_error: Any, synthesis_error: Any) -> float`.

`HaarFilterBank` supplies `analyze(signal)`, `synthesize(coefficients)`, and `certificate(signal, *, tolerance=1e-12)`. `PeriodicLiftingScheme` supplies `analyze(signal)`, `synthesize(coefficients, detail_channel=None)`, and `certificate(signal, *, tolerance=1e-11)`.

All five records are frozen slotted dataclasses, but stored NumPy arrays remain mutable objects. Dataclass immutability does not make their buffers read-only.

35.7.2 `signals.wavelets`

Public symbol	Signature / role
`PacketPath`	`str | tuple[int, ...]` type alias
`CostFunction`	callable type alias
`HaarPacketTree`	complete tree record. Construct with `analyze` or `decompose`
`PrunedPacketCoefficients`	`(tree, leaves)` validated pruning record
`BestBasisResult`	`(leaves, cost, decisions, margins, certificate)` result record
`best_basis`	`(tree, cost) -> BestBasisResult`
`entropy_cost`	`(coefficients, _="") -> float`
`shannon_entropy_cost`	`(coefficients, path="") -> float` compatibility wrapper
`lp_cost`	`(exponent: float) -> CostFunction`
`haar_packet_analyze`	`(signal, depth, *, normalized=True) -> HaarPacketTree`
`haar_packet_synthesize`	`(tree_or_coefficients, leaves=None) -> ndarray`
`packet_energy`	`(tree_or_coefficients, leaves=None) -> float`

Use `HaarPacketTree.analyze` instead of manually supplying the dataclass's public low-level fields `signal`, `depth`, `normalized`, and `_nodes`. The classmethod constructs the complete invariant that reconstruction assumes.

35.7.3 `signals.denoise`

Public symbol	Exact signature or role
`ThresholdMode`	`Literal["soft", "hard", "garrote"]`
`ThresholdRule`	`Literal["universal", "sure", "fixed"]`
`median_absolute_deviation`	`(values, *, center=None) -> float`
`estimate_white_noise_sigma`	`(detail_coefficients) -> float`
`universal_threshold`	`(sigma: float, coefficient_count: int) -> float`
`sure_threshold`	`(coefficients, sigma: float) -> float`
`threshold_coefficients`	`(coefficients, threshold, *, mode="soft") -> ndarray`
`haar_decompose`	`(signal, levels, *, normalized=True) -> HaarDecomposition`
`wavelet_denoise`	`(signal, *, levels=1, mode="soft", rule="universal", threshold=None, sigma=None, level_dependent=False, normalized=True) -> WaveletDenoiseResult`
`denoising_risk_certificate`	`(clean_signal, noisy_signal, denoised_signal, *, tolerance=0.0) -> Certificate`

`HaarDecomposition` fields are `approximation`, `details`, `normalized`, and `original_length`. Its public members are `levels`, `reconstruct(details=None)`, and `certificate(original, *, tolerance=1e-11)`. `WaveletDenoiseResult` fields are `signal`, `decomposition`, `thresholded_details`, `thresholds`, `noise_sigma`, `rule`, `mode`, and `certificate`. `removed_energy` is its one derived property.

35.7.4 Certificate ledger

- **`PeriodicFilterBank.perfect_reconstruction_certificate`:** theorem `PSC-V-T09`. Numerical. `reconstruction_operator` under an absolute operator norm.
- **`FiniteFilterBank.report`:** theorem `PSC-V-T09`. Numerical. `reconstruction` under an absolute operator norm.
- **`HaarFilterBank.certificate`:** theorem `PSC-V-T10`. Numerical. `reconstruction` and `energy` as absolute residuals.
- **`PeriodicLiftingScheme.certificate`:** theorem `PSC-V-T11`. Numerical. `lifting_roundtrip` as an absolute Euclidean residual.

- **`HaarPacketTree.reconstruction_certificate`:** theorem `PSC-V-T13`. Numerical. `reconstruction` and `energy` as absolute residuals.
- **`best_basis`:** theorem `PSC-V-T14`. Exact finite additive recursion. No residual map.
- **`HaarDecomposition.certificate`:** theorem `KM-DSP-T06`. Numerical. `haar_reconstruction` and `haar_energy` use a scaled comparator.
- **`wavelet_denoise`:** theorem `KM-DSP-D10`. Numerical. `shrinkage_monotonicity` with a fixed internal tolerance.
- **`denoising_risk_certificate`:** theorem `KM-DSP-C03`. Numerical. `noisy_mse` and `denoised_mse` are an observed clean-reference comparison.

The two `PSC-V-T09` producers share a reconstruction theorem identifier but use different residual-key names. Consumers should therefore read certificate fields by producer rather than assuming one global residual schema.

35.8 Cost and storage model

These counts describe the shipped dense algorithms. They are operation and storage models, not timing measurements.

- Build one circular convolution matrix: work $O(NK)$ for K taps. Storage N^2.
- Periodic analysis after matrices exist: work $O(CN^2/D)$. Storage CN/D output values.
- Periodic synthesis after matrices exist: work $O(CN^2/D)$. Storage N output values.
- Periodic perfect-reconstruction operator: dense SA, work $O(CN^3/D)$. Storage N^2.
- SVD or pseudoinverse of an $M \times N$ analysis matrix: work $O(MN \min(M, N))$. Dense factorization-dependent storage.
- Finite-bank analysis or synthesis: work $O(mn)$. Output-only additional storage.
- One-level Haar: work $O(N)$. Storage N coefficients.
- Construct `haar_matrix(N)`: work $O(N^2)$. Storage N^2.
- Construct `haar_filter_bank(N)`: dense-inverse work $O(N^3)$. Storage two N^2 matrices.
- Lifting with K_p, K_u taps: work $O(N(K_p + K_u))$. Storage N coefficients.
- Complete depth-J packet tree: work $O(JN)$. Storage $(J + 1)N$ coefficients plus the node dictionary.
- Best basis with linear coefficient costs: work $O(JN)$. Storage $O(2^J)$ decisions and margins.
- Multilevel low-branch Haar decomposition: geometric-total work $O(N)$. Storage N coefficients.
- Threshold and synthesis: work $O(N)$. Storage $O(N)$ result and coefficient records.

The periodic bank is intentionally an explicit-matrix reference API. It does not use FFT convolution, polyphase kernels, sparse storage, or GPU execution. Large N therefore incurs quadratic matrix storage and dense matrix costs. The Haar, lifting, packet, and denoising routines use direct vector operations.

35.9 Boundaries, failures, and source-observed defects

35.9.1 Declared failure surface

Condition	Public behavior
empty filter bank	`ValidationError`
empty or non-1-D individual filter	`DimensionError`
unequal analysis/synthesis channel counts	`DimensionError`
nonpositive decimation after integer conversion	`ValidationError`
periodic length not divisible by decimation	`DimensionError`
periodic signal or coefficient channel not 1-D	`DimensionError`
wrong channel count, unequal channel lengths, or inconsistent declared output length	`DimensionError`
nonmatrix finite-bank operator or incompatible transpose shapes	`DimensionError`
finite signal or coefficient dimension mismatch	`DimensionError`
rank-deficient finite canonical dual	`ValidationError`
perturbation shape mismatch	`DimensionError`

Condition	Public behavior
odd Haar or lifting analysis length	`DimensionError`
unequal Haar or lifting coefficient shapes	`DimensionError`
noninteger, negative, or Boolean packet depth	`ValidationError`
packet input empty, not 1-D, or not divisible by 2^J	`DimensionError`
nonbinary or unknown packet path	`ValidationError`
empty, overlapping, or incomplete pruning	`ValidationError`
missing mapping cost or nonfinite node cost	`ValidationError`
nonpositive or nonfinite p in `lp_cost`	`ValidationError`
denoising signal empty, non-1-D, or nonfinite	`DimensionError` or `ValidationError`
nonpositive level or incompatible dyadic length	`ValidationError` or `DimensionError`
negative/nonfinite threshold or sigma	`ValidationError`
unknown shrinkage mode or threshold rule	`ValidationError`
fixed rule without threshold, or explicit threshold with another rule	`ValidationError`
unequal clean/noisy/denoised lengths	`DimensionError`
negative/nonfinite risk tolerance	`ValidationError`

`HaarFilterBank.synthesize` and `PeriodicLiftingScheme.synthesize` unpack two channels before their dimensional checks. Supplying other than exactly two can therefore raise Python `ValueError`, not a package `DimensionError`.

35.9.2 Recorded implementation boundaries

These behaviors were reproduced directly against version `1.0.0b4`. They are boundaries to work around, not promises to preserve:

- `PeriodicFilterBank` converts `decimation` with `int()` before checking it. For example `decimation=1.9` is stored as `1`. `haar_matrix(2.9)` similarly constructs a length-two matrix, and `universal_threshold(..., coefficient_count=1.9)` uses count one. Validate integer-valued public inputs before these calls.
- A tuple packet path is converted elementwise with `int()`. Thus `(0.9, 1.9)` is currently read as path `"01"`. Supply actual integers or binary strings.
- The periodic, one-level Haar, lifting, finite-bank, packet-tree, and decomposition certificate/report tolerances are not validated. A negative tolerance merely makes an otherwise exact residual certificate invalid. Nonfinite tolerances can produce misleading comparisons. Pass a finite nonnegative tolerance. The separate denoising-risk helper does validate its tolerance.
- Filter-bank constructors do not reject nonfinite matrix or filter entries. Linear algebra may propagate `NaN`/`Inf` or fail downstream.
- Direct one-level Haar and lifting analysis accept an empty one-dimensional array because zero is even. Their convenience matrix/tree and denoising entry points do enforce nonempty or positive sizes.
- `PeriodicFilterBank.frame_bounds` and `FiniteFilterBank.report` can report a positive lower value for an undercomplete analysis matrix. For example $E = [1\ 0]$ reports `(1.0, 1.0)` even though the true lower frame bound on $\mathbb{R}^2$ is zero. Establish full column rank before interpreting the lower number as a frame bound.
- `FiniteFilterBank.report().certificate` has numerical exactness, but its success message says `"finite filter bank reconstructs exactly"`. Read the `Exactness.NUMERICAL` field and residual, not that wording, as the claim strength.
- `sure_threshold` does not validate coefficient finiteness when called directly: inputs containing `NaN` or `Inf` can return a nonfinite threshold and may emit a NumPy warning. `wavelet_denoise` screens its input signal for finiteness, but direct callers should screen coefficient arrays too.
- The two-argument best-basis callback adapter catches any `TypeError` and then retries the callable with one argument. A `TypeError` raised inside a valid two-argument callback can consequently be masked by a misleading missing-argument error. Keep cost callbacks small and test them independently.

No certificate in this chapter verifies perceptual quality, stationarity, independence, whiteness, Gaussianity, compression quality, application-specific frequency selectivity, or an asymptotic wavelet theorem. Those claims require separate hypotheses and evidence.

35.10 Verification evidence

The chapter's observed examples were executed from the recovered `1.0.0b4` source tree with Python `3.12.13` and NumPy `2.5.2`. Additional checks were also run:

- 25 focused filter-bank, Haar, lifting, packet-tree, best-basis, threshold, and denoising tests passed. Seven unrelated tests in the three selected test files were deselected.
- `verification/block4_deep_audit.py` passed all 18,068 checks, including 360 filter-bank and 480 wavelet checks.
- `verification.block12_deep_audit.run()` passed all 815,779 checks, including 15,944 denoising checks.
- Public signatures were reflected from the three shipped modules and matched the ledgers above.

These executions demonstrate the finite cases covered by the suites. They do not close the source-observed validation gaps in §35.9.2.

> **Chapter 35 summary.** Use `PeriodicFilterBank` when the circular convolution phase and explicit dense matrices are part of the model. Use `FiniteFilterBank` for a general finite analysis/synthesis pair and enforce full column rank before calling a pseudoinverse a canonical dual. Haar and lifting provide linear-time reversible local transforms. Packet trees split both branches, valid prunings are complete prefix-free covers, and `best_basis` exactly minimizes the supplied finite additive costs with a keep-on-tie policy. Denoising thresholds only detail channels, and its risk certificate compares one supplied finite clean reference. Always inspect the residual, exactness, and unchecked assumptions before promoting a finite computation to a stochastic or infinite-dimensional claim.

36. Singular packets and recovery

The singular-packet layer separates a sampled signal into a regular component and a finite family of explicitly represented singular terms. It can then approximate only the regular component and restore either the exact packet or an estimate. The accompanying jump-recovery routines are intentionally conditional: they check a finite contrast gap, but they do not infer the unknown signal's smoothness, noise law, jump size, or separation from the samples.

Choose the information you actually have. With a known packet, use the retained-packet reconstruction route and judge the approximation of the remaining smooth component. With an estimated packet, keep the packet-error term visible. With only samples, the jump-recovery routines need declared smoothness, noise, jump-size, and separation information. Their output cannot establish those declarations for unknown data. The worked example in Section 36.4 uses known synthetic parameters so each comparison has a reference.

These APIs are in the broad research surface:

```
from komorebi_math import (
    SingularPacket1D,
    recover_separated_jumps,
    retained_packet_reconstruct,
)

from komorebi_math.signals import (
    TruncatedPowerTerm,
    recover_vector_jumps,
)
```

Only `SingularPacket1D`, `recover_separated_jumps`, and `retained_packet_reconstruct` are re-exported from `komorebi_math` itself. The complete surface is exported by `komorebi_math.signals`. None of the names in this chapter is promoted into the curated `komorebi_math.stable` or `komorebi_math.beta` namespace in version `1.0.0b4`. Pin the package version if these signatures are part of an application contract.

36.1 Truncated-power packets

For a location $\xi \in \mathbb{R}$, amplitude $a \in \mathbb{C}$, and integer order $r \geq 0$, a packet term is

$$T_{\xi,a,r}(x) = a\frac{(x-\xi)_+^r}{r!}.$$

At order zero the implementation defines the basis separately as $\mathbf{1}_{x\geq\xi}$. Thus the value at the jump is the right-hand value, not zero and not one half. A finite packet is

$$j(x) = \sum_{k=1}^{J} T_{\xi_k,a_k,r_k}(x).$$

The primary types are frozen, slotted dataclasses.

Type	Public members	Meaning
`TruncatedPowerTerm`	`location: float, amplitude: complex, order: int = 0`	One validated finite term. Construction normalizes the amplitude to Python `complex`, the location to `float`, and the order to `int`.
`SingularPacket1D`	`components: tuple[TruncatedPowerTerm, ...]`	A finite, possibly empty sum. Every component must already be a `TruncatedPowerTerm`.

Type	Public members	Meaning
`RetainedPacketResult`	`smooth_component`, `smooth_approximation`, `packet`, `reconstruction`, `error`: arrays. `certificate: Certificate`. `packet_error: array | None`	Full retained-packet execution record.

`TruncatedPowerPacket` is an exact alias of `TruncatedPowerTerm`. `RetainedPacketReconstruction` is an exact alias of `RetainedPacketResult`. Neither name denotes a distinct subclass.

The class surface is:

```
TruncatedPowerTerm(location: float, amplitude: complex, order: int = 0)
    .evaluate(points: Any) -> ndarray
    .location_bound(
        estimated_location: float,
        *, p: float = 2.0,
        interval: tuple[float, float] = (0.0, 1.0),
    ) -> float

SingularPacket1D(components: Iterable[TruncatedPowerTerm])
    .from_jumps(
        locations: Iterable[float],
        amplitudes: Iterable[complex],
        *, orders: Iterable[int] | None = None,
    ) -> SingularPacket1D
    .evaluate(points: Any) -> ndarray
    .remove(signal: Any, points: Any) -> ndarray
    .restore(smooth: Any, points: Any) -> ndarray
    .trace_jumps() -> dict[float, dict[int, complex | float]]
```

`evaluate` converts the grid to `dtype=float`, preserves its shape, and calls `numpy.real_if_close(..., tol=1000)` on the result. A genuinely complex packet therefore returns complex data, while roundoff-level imaginary parts may be discarded. `remove` and `restore` require exact shape equality between the sample array and evaluated packet. They do not broadcast. `trace_jumps` combines equal `(location, order)` entries by addition.

The constructor rejects non-finite locations and amplitudes, negative orders, and nonintegral orders with `ValidationError`. `from_jumps` raises `DimensionError` when the location, amplitude, and optional order sequences do not have equal lengths.

36.1.1 Location perturbation

For two equal-amplitude steps on the whole real line,

$$\left\| a\mathbf{1}_{x\geq\xi} - a\mathbf{1}_{x\geq\hat{\xi}} \right\|_{L^p} = |a|\,|\xi-\hat{\xi}|^{1/p}, \qquad 0 < p < \infty.$$

For $p=\infty$, the value is $|a|$ when the displacement is nonzero. `step_location_lp_error(amplitude, location, estimated_location, *, p=2.0)` implements this whole-line formula.

`TruncatedPowerTerm.location_bound` instead works on the finite declared interval $[L,R]$. For order zero it clips the interval between the two locations to $[L,R]$, so it returns the exact finite-interval norm. This distinction matters when both locations lie outside the interval. For positive order it returns the mean-value bound

$$\left\| T_{\xi,a,r} - T_{\hat{\xi},a,r} \right\|_{L^p([L,R])} \leq \frac{|a|S^{r-1}}{(r-1)!}|\xi-\hat{\xi}|\,(R-L)^{1/p},$$

where

$$S = \max(0, R - \min(\xi, \hat{\xi})).$$

For $p = \infty$, the measure factor is one. Both helpers require positive finite p or `math.inf`. `location_bound` also requires finite increasing interval endpoints. `step_location_lp_error` does not itself reject non-finite locations or amplitudes, so callers needing a finite result must validate those inputs before calling it.

36.2 Retained and estimated reconstruction

Let $f = g + j$, where j is an exactly retained packet and Q is a shape-preserving approximation procedure. Then

$$\hat{f} = Q(f - j) + j = Qg + j$$

and the exact algebraic identity is

$$f - \hat{f} = g - Qg.$$

The callable form is:

```
retained_packet_reconstruct(
    signal: Any,
    packet: Any,
    approximator: Callable[[ndarray], Any],
    *, tolerance: float = 1e-11,
) -> RetainedPacketResult
```

The signal and packet may have any equal shape. The approximator receives `signal - packet` and must return the same shape. The certificate is `Exactness.NUMERICAL` because it measures the algebraic identity with a floating Euclidean norm. The default acceptance condition is residual $\leq 10^{-11}$. This verifies the supplied finite-array identity. It does not show that the retained packet is the true singular component or that Q is an optimal approximation.

For an estimated packet $\hat{j}$ and an explicit $N \times N$ matrix Q,

$$\hat{f} = Q(f - \hat{j}) + \hat{j}, \qquad f - \hat{f} = (I - Q)(f - \hat{j}).$$

If a true decomposition $f = g + j$ is supplied, the implementation also checks

$$f - \hat{f} = (I - Q)g + (I - Q)(j - \hat{j}).$$

The matrix forms are:

```
retained_packet_reconstruction(
    signal: Any,
    estimated_packet: Any,
    approximation_matrix: Any,
    *,
    true_smooth: Any | None = None,
    true_packet: Any | None = None,
    tolerance: float = 1e-10,
) -> RetainedPacketResult

estimated_packet_reconstruct(
    signal: Any,
    estimated_packet: Any,
    approximation_matrix: Any,
    *, tolerance: float = 1e-10,
) -> ComputationResult[ndarray]
```

These forms require one-dimensional signal and packet arrays of equal length; empty arrays are allowed. The matrix must have shape `(N, N)`. Supplying just one of `true_smooth` and `true_packet` raises `ValidationError`. Supplying either true component with a wrong shape raises `DimensionError`. The compatibility wrapper returns only the reconstruction in `.value` while retaining the same certificate.

`RetainedPacketResult.packet` is the packet actually supplied to the routine. In the estimated form, `.packet_error` is `true_packet - estimated_packet` when truth was supplied and is otherwise `None`. `.smooth_component` is the declared true smooth component when available. Otherwise it is `signal - estimated_packet`.

The packet error term can dominate the smooth approximation term. In particular, no bound on

$$\|(I - Q)(j - \hat{j})\|$$

is inferred merely because the algebraic certificate is valid.

36.3 Scalar and vector jump recovery

Suppose the uniform grid is $x_i = x_0 + ih$ and the samples satisfy

$$y_i = g(x_i) + j(x_i) + \eta_i.$$

The declared deterministic assumptions are

$$\mathrm{Lip}(g) \le M, \qquad |\eta_i| \le \varepsilon, \qquad |a_k| \ge a_{\min}.$$

For scalar data, and for vector data after replacing absolute value by the Euclidean norm, an inactive-cell contrast is bounded by

$$B = Mh + 2\varepsilon.$$

The theorem requires

$$a_{\min} > 2B, \qquad B < \theta < a_{\min} - B.$$

A cell is detected when

$$\|y_{i+1} - y_i\| > \theta.$$

Its reported location is the midpoint $x_i + h/2$, its amplitude estimate is the signed scalar contrast or vector contrast, its location-error scale is $h/2$, and its amplitude-error scale is B. Those bounds have theorem meaning only when the unchecked signal assumptions hold and each active cell contains one jump.

36.3.1 Strict scalar API

```
recover_separated_jumps(
    samples: Sequence[float],
    *,
    spacing: float,
    lipschitz_bound: float,
    noise_bound: float,
    minimum_jump: float,
    threshold: float | None = None,
    start: float = 0.0,
    minimum_separation: float | None = None,
) -> JumpRecoveryResult
```

`samples` is converted to a float vector and must contain at least two entries. The default threshold is `minimum_jump / 2`. Invalid finite parameters raise `ValidationError`. A closed contrast gap, an invalid threshold interval, or a declared `minimum_separation < spacing` raises `AssumptionError` rather than returning a failed certificate.

The scalar result types are:

Type	Fields and properties
`JumpDetection`	`cell: int`, `left_position: float`, `right_position: float`, `location: float`, `amplitude: float`
`JumpRecoveryResult`	`detections: tuple[JumpDetection, ...]`, `threshold`, `background_bound`, `location_error_bound`, `amplitude_error_bound`, `certificate`. Derived `.cells: tuple[int, ...]`, `.locations: ndarray`, `.amplitudes: ndarray`

The certificate has `Exactness.CONDITIONAL`. It checks the finite threshold conditions but lists the true Lipschitz bound, noise bound, jump lower bound, and one-jump-per-cell model under `assumptions_unchecked`.

36.3.2 Scalar/vector API

The second implementation accepts samples of shape `(N,)` or `(N, D)` and is exported with disambiguating package aliases:

```
recover_vector_jumps(
    samples: Any,
    *,
    spacing: float,
    lipschitz_bound: float,
    noise_bound: float,
    minimum_jump: float,
    origin: float = 0.0,
    threshold: float | None = None,
) -> VectorJumpRecoveryResult

recover_vector_jumps_subgaussian(
    samples: Any,
    *,
    spacing: float,
    lipschitz_bound: float,
    sigma: float,
    minimum_jump: float,
    failure_probability: float,
    origin: float = 0.0,
) -> VectorJumpRecoveryResult
```

`VectorJumpRecoveryResult` is the package alias for `komorebi_math.signals.edge_recovery.JumpRecoveryResult`. It is a different class from the scalar `JumpRecoveryResult` above.

Member	Scalar input `(N,)`	Vector input `(N, D)`
`.cells`	tuple of contrast indices	same
`.locations`	shape `(K,)`	shape `(K,)`
`.amplitudes`	shape `(K,)`	shape `(K, D)`
`.contrasts`	shape `(N-1,)`	shape `(N-1, D)`
`.packet()`	builds an order-zero `SingularPacket1D`	raises `ValidationError`
Remaining fields	`threshold`, `background_bound`, `location_error_bound`, `amplitude_error_bound`, `certificate`	same

Unlike `recover_separated_jumps`, the vector-capable routine does not raise solely because the contrast-gap condition $a_{\min} > 2B$ fails or the threshold falls outside its allowed interval. It returns the detections with `certificate.valid == False`. Call `result.certificate.require()` when a failed finite theorem gap must stop the workflow.

Adjacent detected cells are recorded in `assumptions_checked`, but the current implementation does not use that observation when setting `certificate.valid`. The actual separation of the unknown jumps remains unchecked in both APIs.

36.3.3 Sub-Gaussian wrappers

For N scalar samples, the scalar helper uses the simultaneous contrast scale

$$B_\eta = 2\sigma\sqrt{\log(2N/\delta)}.$$

```
subgaussian_noise_bound(
    sample_count: int,
    sigma: float,
    delta: float,
) -> float

recover_jumps_subgaussian(
    samples: Sequence[float],
    *,
    spacing: float,
    lipschitz_bound: float,
    sigma: float,
    delta: float,
    minimum_jump: float,
    threshold: float | None = None,
    start: float = 0.0,
    minimum_separation: float | None = None,
) -> JumpRecoveryResult
```

The wrapper passes `noise_bound = B_eta / 2` to the deterministic routine, so its background becomes $Mh + B_\eta$. It reports probability at least $1 - \delta$ only under the unchecked model that the noises are independent, centered, and σ-sub-Gaussian.

For `(N, D)` data, the vector wrapper uses $N - 1$ contrast cells and

$$b_{\mathrm{coord}} = 2\sigma\sqrt{\log\left(\frac{2\max(N-1,1)D}{\delta}\right)}, \qquad B_\eta = \sqrt{D}\, b_{\mathrm{coord}}.$$

It passes `noise_bound = B_eta / 2` to `recover_vector_jumps`. The coordinate and Euclidean bounds are stored under `certificate.residuals["coordinate_noise_bound"]` and `["simultaneous_noise_difference_bound"]`. The probability statement is not an empirical confidence estimate. It depends on the external independence, centering, and tail-scale assumptions.

36.4 Breakpoint bands and edge recovery

For a normalized Haar function on an interval of length L, a Lipschitz background and one step obey

$$|\langle g, \psi_L\rangle| \le \frac{ML^{3/2}}{4}, \qquad |\langle a\mathbf{1}_{x\ge\xi}, \psi_L\rangle| = |a|\sqrt{L}\min(u, 1-u),$$

where $u \in [0, 1]$ is the relative jump location. Two pairs of helpers expose the same formulas with different argument order:

```
haar_lipschitz_bound(lipschitz_constant, support_length) -> float
haar_step_coefficient(amplitude, support_length, relative_location) -> float

smooth_haar_coefficient_bound(lipschitz_bound, interval_length) -> float
step_haar_coefficient(amplitude, relative_location, interval_length) -> float
```

The first pair comes from `signals.recovery`. The second comes from `signals.edge_recovery`. All lengths must be positive and finite, smoothness bounds nonnegative, and relative positions in `[0, 1]`.

`half_shift_distance(point, cell_length)` compares the distance from `point` to the nearest grid boundary with the corresponding half-shifted-grid distance, then returns the **larger** of those two nearest-boundary distances. Despite the docstring phrase "better distance," the implementation uses `max(first, second)`, not `min`.

For forward difference step s,

$$(\Delta_s x)_n = x_{n+s} - x_n, \qquad \Delta_s^q = \underbrace{\Delta_s \circ \cdots \circ \Delta_s}_{q \text{ times}}.$$

The package-level difference routine and breakpoint detector are:

```
finite_difference(
    values: Sequence[Any], *, order: int = 1, step: int = 1,
) -> ndarray

detect_piecewise_polynomial_breaks(
    samples: Sequence[float],
    *, degree: int,
    noise_bound: float,
    threshold: float | None = None,
) -> BreakpointBandResult
```

An order-zero difference returns a copy. A positive order that exhausts the available samples returns an empty array. The detector computes order $q = d + 1$ with unit step. On a degree-d polynomial segment, that response vanishes away from boundaries. Uniform sample noise bounded by ε has worst-case amplification

$$B_q = 2^q \varepsilon.$$

The default threshold is B_q. A supplied threshold below it raises `AssumptionError`. The frozen `BreakpointBandResult` stores `indices: tuple[int, ...]`, `response: ndarray`, `threshold: float`, `noise_amplification: float`, and `certificate: Certificate`.

Each output index is the start of an above-threshold difference response. It is a response band, not automatically a unique physical breakpoint. The piecewise-polynomial model and uniform noise bound remain unchecked.

There is also a module-level compatibility routine:

```
komorebi_math.signals.singular_packets.finite_difference(signal, order=1)
```

It is implemented with `numpy.diff`. The same module also provides `difference_noise_bound(noise_bound, order)`. The former is listed in that module's `__all__`, but it is not the `finite_difference` selected by `komorebi_math.signals`, which exports the keyword-only, arbitrary-step routine from `signals.recovery`.

Exact region-error formulas

For true scalar value a, estimate b, overlap measure μ_I, true-only measure μ_T, and estimate-only measure μ_E,

$$\|a\mathbf{1}_T - b\mathbf{1}_E\|_p^p = |a-b|^p\mu_I + |a|^p\mu_T + |b|^p\mu_E.$$

For labeled partitions with $M_{ij} = \mu(T_i \cap E_j)$,

$$\|f - \hat{f}\|_p = \left(\sum_{i,j} M_{ij}|a_i - b_j|^p\right)^{1/p}.$$

For $p = \infty$, each routine takes the largest mismatch attached to a region of positive measure.

```
scalar_region_lp_error(
    true_value, estimated_value,
    intersection_measure, true_only_measure, estimated_only_measure,
    *, p: float = 2.0,
) -> float

overlap_partition_lp_error(
    true_values, estimated_values, overlap_matrix,
    *, p: float = 2.0,
) -> float

scalar_region_error(
    true_mask, true_value, estimated_mask, estimated_value,
    *, p: float = 2.0, tolerance: float = 1e-12,
) -> ComputationResult[float]

overlap_matrix_error(
    true_labels, true_values, estimated_labels, estimated_values,
    *, p: float = 2.0, tolerance: float = 1e-12,
) -> ComputationResult[float]
```

The first two evaluate formulas from supplied measures. The latter two build empirical count measures from equal-shaped masks or integer label arrays and compare the formula with the direct finite-array norm. Their certificates are `Exactness.NUMERICAL`, even though the underlying finite counting identities are exact, because residual comparison uses floating arithmetic.

Negative or non-finite measures, a wrong overlap-matrix shape, invalid p, unequal mask/label shapes, negative labels, and labels outside the corresponding value table are rejected. Label arrays are coerced with `dtype=int`. Callers should not rely on this function to reject a fractional label before coercion.

Worked recovery and reconstruction

The repository example `examples/singular_packet_recovery.py` constructs two steps on 513 points, with a sinusoidal background and no added noise:

```
import numpy as np

from komorebi_math.signals import (
    SingularPacket1D,
    recover_separated_jumps,
    retained_packet_reconstruction,
)

count = 512
h = 1.0 / count
x = np.arange(count + 1) * h
locations = np.array([0.23, 0.71])
amplitudes = np.array([0.45, -0.35])

smooth = 0.04 * np.sin(2.0 * np.pi * x)
signal = smooth.copy()
for location, amplitude in zip(locations, amplitudes, strict=True):
    signal += amplitude * (x >= location)

recovery = recover_separated_jumps(
    signal,
    spacing=h,
    lipschitz_bound=0.08 * np.pi,
    noise_bound=0.0,
    minimum_jump=float(np.min(np.abs(amplitudes))),
    minimum_separation=0.4,
)
recovery.certificate.require()

packet = SingularPacket1D.from_jumps(
    recovery.locations,
    recovery.amplitudes,
).evaluate(x)

identity = retained_packet_reconstruction(
    signal,
    packet,
    np.eye(signal.size),
    true_smooth=signal - packet,
    true_packet=packet,
)
identity.certificate.require()

print("detected cells:", recovery.cells)
print("estimated locations:", recovery.locations)
print("estimated amplitudes:", recovery.amplitudes)
```

Observed with the recovered `1.0.0b4` source:

```
detected cells: (117, 363)
estimated locations: [0.22949219 0.70996094]
estimated amplitudes: [ 0.45006308 -0.35012219]
```

This run checks the result against known synthetic construction parameters. The valid certificate alone would not establish that the supplied Lipschitz constant or jump lower bound is true for unknown data. The identity example uses `Q = I`, so exact reconstruction is expected for every supplied packet. It is a check of plumbing, not evidence of approximation quality.

36.5 Smoothness, noise, and separation assumptions

Claim or result	Status	What is actually checked
Truncated-power evaluation	definition	finite term parameters and finite sample-grid conversion
Order-zero finite-interval location norm	exact formula	declared interval and values
Positive-order location estimate	deterministic bound	declared term, interval, and displacement
Retained-packet identity	numerical check of exact algebra	shapes and floating residual only
Deterministic jump locations/amplitudes	conditional	parameter gap and observed contrasts. Signal hypotheses remain external
Sub-Gaussian probability	conditional	finite confidence formula. Noise law remains external
Haar helpers	deterministic formulas	supplied scalars only
Breakpoint output	conditional band	difference order and declared noise threshold
Region identities	exact finite formula, numerically certified	input measures or empirical finite counts

36.6 Failure cases that must remain conditional

These cases must not be upgraded into unconditional recovery claims:

- Two jumps in one sample cell can cancel in the adjacent contrast.
- Adjacent active cells violate the separated-cell interpretation.
- A low-amplitude jump below the contrast gap is outside this theorem.
- Incorrect smoothness, noise, jump-size, or probability-model declarations invalidate the theorem interpretation even if execution succeeds.
- A finite-difference band can cover multiple indices and need not identify one exact breakpoint.
- An inaccurate packet can make the packet-estimation term larger than the smooth approximation error.

Implementation boundary notes in `1.0.0b4`:

- `recover_separated_jumps` only checks that a supplied `minimum_separation` is not less than one grid spacing. It does not check the detected-cell gaps against that value. `minimum_separation=float("nan")` also passes that comparison and can yield a valid certificate.
- `recover_vector_jumps` records adjacent detections but does not make them invalidate the certificate. For `[0, 1, 2]` with zero declared background and `minimum_jump=0.5`, the observed result is `cells == (0, 1)` with `certificate.valid == True`.
- The vector API does not validate `origin`. A non-finite origin can therefore produce non-finite reported locations while the certificate remains valid.
- Recovery accepts arrays containing non-finite sample values. Comparisons with `NaN` simply fail to trigger detections. Prevalidate finite sample data when this is not desired.
- Reconstruction tolerances are compared directly but are not validated as finite and nonnegative. Use an explicit finite nonnegative tolerance.

Cost, memory, and scaling

Let P be the number of evaluation points, J the number of packet terms, N the number of samples, D the vector dimension, $q = d + 1$ the difference order, and A, B the numbers of true and estimated regions.

Operation	Arithmetic cost	Additional/output storage
One term evaluation	$O(P)$	$O(P)$
`SingularPacket1D.evaluate`	$O(JP)$	$O(P)$ result plus per-term temporaries

Operation	Arithmetic cost	Additional/output storage
Callable retained reconstruction	cost of `approximator` + $O(P)$	$O(P)$ arrays
Matrix retained reconstruction	dense $O(N^2)$ matvec work	input matrix $O(N^2)$. Identity/matrix temporaries can also be $O(N^2)$
Scalar recovery	$O(N)$	$O(N)$ differences and up to $O(N)$ detections
Vector recovery	$O(ND)$	$O(ND)$ contrasts
Order-q iterative difference	$O(qN)$	$O(N)$ live response, with repeated allocations
Scalar mask error	$O(P)$	$O(P)$ boolean/numeric temporaries
Labeled overlap error	$O(P + AB)$	$O(P + AB)$ including overlap table

There is no streaming recovery interface here, no sparse approximation-matrix specialization, and no GPU backend. NumPy executes all kernels on host memory. The implementation does not impose an explicit resource limit, so callers must budget dense `N x N` approximation matrices and large overlap tables.

36A. Approximation, nonlinear packet products, and Smith charts

This group of tools combines finite Fourier truncation, a narrow positive-contrast heuristic, cyclic coefficient products, real polynomial shift interactions, and normalized impedance coordinates. These tools share a signal namespace, but they do not share a single theorem: each result must be read at its own claim strength.

Public surface.

All names below are exported by `komorebi_math.signals`.

- **`fft_lowpass_1d`:** `(signal: ndarray | Sequence[float], modes: int) -> ndarray`. Finite numerical Fourier truncation.
- **`fft_lowpass_2d`:** `(image: ndarray, cutoff: int) -> ndarray`. Finite numerical Fourier truncation.
- **`otsu_threshold`:** `(values: ndarray | Sequence[float], bins: int = 256) -> float`. Deterministic finite histogram choice.
- **`estimate_positive_packet_1d`:** `(signal, *, bins: int = 256) -> PacketEstimate1D`. Heuristic record.
- **`coefficient_packets`:** `(coefficients: Sequence[complex], order: int) -> tuple[ndarray, ...]`. Exact residue split in array arithmetic.
- **`packet_product`:** `(a: Any, b: Any, order: int) -> ComputationResult[tuple[ndarray, ...]]`. Finite identity with numerical certificate.
- **`nonlinear_shift_filter`:** `(signal: Sequence[float], alpha: float = 0.25, *, shift: int = 1, shifts: Sequence[int] | None = None, coefficients: Sequence[float] | None = None) -> ndarray`. Finite real polynomial map.
- **`gamma_from_impedance`:** `(impedance: ArrayLike) -> ndarray`. Numerical Cayley map.
- **`impedance_from_gamma`:** `(gamma: ArrayLike) -> ndarray`. Numerical inverse Cayley map.
- **`phase_mobius`:** `(impedance: ArrayLike, order: int, phase: int) -> ndarray`. Numerical rational phase action.
- **`smith_sensitivity`:** `(gamma: ArrayLike, *, regularization: float = 0.0) -> ndarray`. Numerical diagnostic.

Here `ArrayLike` means `ndarray | Sequence[complex] | complex`. Even scalar input is returned as a zero-dimensional NumPy array/scalar-like array result, not normalized to a Python `complex`.

36A.1 Fourier low-pass approximation and Gibbs behavior

For a length-N vector, `fft_lowpass_1d` computes the unnormalized NumPy FFT, zeros every integer-frequency bin with magnitude greater than `modes`, and applies the inverse FFT:

$$\hat{x}_k^{(M)} = \hat{x}_k \mathbf{1}_{|\nu_k| \le M}, \qquad x^{(M)} = \mathcal{F}_N^{-1} \hat{x}^{(M)},$$

where `nu = np.fft.fftfreq(N) * N`. The input must be a nonempty 1-D array and `modes` a nonnegative integer. Boolean and fractional cutoffs are rejected. Modes beyond the represented Nyquist range simply retain every bin.

For an `H x W` image, `fft_lowpass_2d` uses `fftshift(fft2(image))` and the rectangular index mask

$$|i - \lfloor H/2 \rfloor| \le M, \qquad |j - \lfloor W/2 \rfloor| \le M.$$

This is a rectangular centered cutoff, not a radial-frequency disk. With even dimensions, the centered Nyquist indexing follows NumPy's `fftshift` convention. Both routines call `real_if_close(tol=1000)` after inverse transformation, so real inputs usually return real arrays and genuinely complex outputs remain complex.

Fourier truncation is a deterministic finite approximation, not an edge-aware method. For a periodic length-32 step and three retained mode pairs, the observed samples around the edge were:

```
[-0.014852, 0.148468, 0.375000, 0.625000, 0.851532, 1.014852]
```

The direct maximum error was `0.37500000000000006`. The undershoot and overshoot are finite-grid Gibbs ringing. Increasing the grid or mode count does not justify a universal pointwise edge-preservation claim.

If the exact step packet is removed first, low-pass filtering a zero smooth remainder and restoring that exact packet gives zero error in this synthetic case:

```python
import numpy as np

from komorebi_math.signals import (
    SingularPacket1D,
    fft_lowpass_1d,
    retained_packet_reconstruct,
)

x = np.r_[np.zeros(16), np.ones(16)]
grid = np.arange(x.size, dtype=float)

packet = SingularPacket1D.from_jumps([16.0], [1.0]).evaluate(grid)
kept = retained_packet_reconstruct(
    x,
    packet,
    lambda smooth: fft_lowpass_1d(smooth, 3),
)

assert np.max(np.abs(kept.error)) == 0.0
kept.certificate.require()
```

This example isolates the value of exact side information. It does not show that an estimated packet always improves a direct Fourier approximation.

36A.2 Otsu thresholding and heuristic positive-packet estimation

Given histogram probabilities p_k, bin centers c_k, cumulative class probability ω_t, cumulative mean μ_t, and total mean μ_T, the implemented Otsu score is

$$\sigma_B^2(t) = \frac{(\mu_T \omega_t - \mu_t)^2}{\omega_t(1-\omega_t)}.$$

Bins with a zero denominator receive score zero. `otsu_threshold` returns the center of the first maximum-scoring bin because it uses `numpy.argmax`. If all values are numerically equal according to `numpy.isclose(low, high)`, it returns that common minimum directly.

`estimate_positive_packet_1d` forms

$$M_i = \mathbf{1}_{x_i > t}$$

and estimates the amplitude by

$$\hat{a} = \operatorname{median}(x_i : M_i = 1) - \operatorname{median}(x_i : M_i = 0).$$

If every point is selected, it uses the selected median alone. If no point is selected, it returns amplitude zero. The frozen result contains:

`PacketEstimate1D` member	Meaning
`mask: ndarray`	Boolean mask selected by strict `value > threshold`
`amplitude: float`	Median contrast heuristic
`threshold: float`	Chosen histogram-bin center
`certificate: Certificate`	Always valid, `Exactness.HEURISTIC`

For 30 zeros followed by 20 ones, the default 256-bin run selected 20 samples, returned threshold `0.001953125`, and amplitude `1.0`. This is consistent with the intended two-class positive-contrast model. It is not a theorem for negative contrasts, multiple regions, heavy gradients, outliers, or unstable histogram binning.

The source checks only `bins < 2`, then calls `int(bins)`. A fractional value such as `2.9` is therefore silently truncated rather than rejected as nonintegral. Non-finite signal values are not explicitly rejected and may fail inside NumPy histogram construction. Validate finite data and integral bin counts at an external boundary when those are contract requirements.

36A.3 Coefficient packets, cyclic products, and nonlinear shift filters

For cyclic order $q \geq 1$, `coefficient_packets` returns the full-length, zero-filled residue arrays

$$a_n^{(r)} = a_n \mathbf{1}_{n \equiv r \pmod q}, \qquad a = \sum_{r=0}^{q-1} a^{(r)}.$$

The input must be one-dimensional and the order a positive non-Boolean integer. The function permits an empty coefficient array and returns `q` empty arrays. `packet_product` is stricter for flat inputs and rejects empty arrays.

`packet_product` accepts exactly one of two representations:

1. two nonempty flat coefficient arrays, or
2. two explicit compact channel families, each with exactly `q` nonempty one-dimensional arrays.

Mixing one flat input with one compact family raises `ValidationError`. Malformed or empty explicit channels raise `DimensionError` when they are recognized as a channel family. A nested sequence whose outer length is not `q` is not recognized as explicit. Its later conversion may consequently fail with a NumPy error rather than a package-specific representation error.

For flat residue-supported arrays, the output packet is

$$c^{(t)} = \sum_{r+s \equiv t \pmod q} a^{(r)} * b^{(s)}.$$

Each returned channel has the full direct-product length $N + M - 1$, remains supported on its routed residue positions, and the direct convolution is reconstructed by summing the channels.

Compact arrays use coarse indices. The channel route must therefore propagate the radix carry

$$t = (r + s) \bmod q, \qquad \kappa = \left\lfloor \frac{r+s}{q} \right\rfloor.$$

The convolution of compact channels r, s is added to output channel t starting at coarse index κ. Omitting that shift gives the wrong polynomial product.

```python
import numpy as np

from komorebi_math.signals import packet_product
```

```
left = (np.array([1.0, 2.0]), np.array([3.0, -1.0]))
right = (np.array([2.0, 1.0]), np.array([4.0]))

result = packet_product(left, right, order=2)
channels = result.require()

assert [channel.tolist() for channel in channels] == [
    [2.0, 17.0, -2.0],
    [10.0, 9.0, -1.0],
]
assert result.certificate.residuals["cyclic_channel_law"] == 0.0
```

The certificate reconstructs both inputs, compares the interleaved output with `numpy.convolve`, and accepts a maximum absolute residual at the fixed tolerance `1e-10`. The coefficient law is an exact finite polynomial identity. Its implementation certificate is `Exactness.NUMERICAL`. The routine promotes working storage to a complex-compatible dtype, then applies `real_if_close` to each output channel. It does not reason about convergence of infinite series.

Nonlinear shift filters

Let $R_s x = \mathrm{roll}(x, s)$ with periodic wraparound. The legacy map is

$$F(x) = x + \alpha x \odot R_s x.$$

The generalized map is

$$F(x) = x + \alpha x \odot \left(\sum_{k=1}^{K} c_k R_{s_k} x \right).$$

```
from komorebi_math.signals import nonlinear_shift_filter

y = nonlinear_shift_filter(
    [0.0, 1.0, 2.0, 3.0],
    alpha=0.1,
    shifts=[0, 1],
    coefficients=[1.0, 0.5],
)
```

The input is coerced with `numpy.asarray(signal, dtype=float)`, so this API is a real-valued map $\mathbb{R}^N \to \mathbb{R}^N$, not a generic complex packet operation. It requires a one-dimensional array but permits the empty vector. Supply either neither generalized list or both. The paired lists must be nonempty and have equal lengths.

`shift` and generalized shifts are converted with `int`, coefficients and `alpha` with `float`. Nonintegral shifts are silently truncated, and no explicit finite-value check is made for `alpha` or the coefficients. Complex input conversion can emit `ComplexWarning` and discard the imaginary part. Callers should validate integer shifts, finite real coefficients, and finite real input when silent coercion is unacceptable.

The operation is a finite polynomial transform. No contractive, energy, invertibility, fixed-point, or nonlinear stability theorem is attached. `packet_product`, in contrast, accepts complex coefficient data and certifies a finite convolution identity.

36A.4 Smith/Cayley impedance coordinates

The normalized impedance-to-reflection map and its inverse are

$$\Gamma = \frac{Z - 1}{Z + 1}, \qquad Z = \frac{1 + \Gamma}{1 - \Gamma}.$$

With their domains made explicit, these are

$$\Gamma = \frac{Z-1}{Z+1}, \qquad Z \neq -1,$$

$$Z = \frac{1+\Gamma}{1-\Gamma}, \qquad \Gamma \neq 1.$$

For cyclic order q and phase index p, let

$$\zeta = e^{2\pi i (p \bmod q)/q}.$$

Disk rotation $\Gamma \mapsto \zeta\Gamma$, pulled back formally to impedance coordinates, gives

$$Z \longmapsto \frac{(1+\zeta)Z + (1-\zeta)}{(1-\zeta)Z + (1+\zeta)}.$$

`phase_mobius` requires a positive integer order, reduces the converted phase modulo that order, and checks its own denominator. Phase zero is the identity. It evaluates the rational formula directly. It does not call `gamma_from_impedance` and therefore accepts some points, such as `Z == -1`, where the two-stage Cayley interpretation itself is undefined.

A finite roundtrip example is:

```
import numpy as np

from komorebi_math.signals import (
    gamma_from_impedance,
    impedance_from_gamma,
    phase_mobius,
    smith_sensitivity,
)

z = np.array([0.5, 1.0, 2.0, 1.0 + 0.2j])
gamma = gamma_from_impedance(z)

assert np.allclose(impedance_from_gamma(gamma), z)
assert np.allclose(phase_mobius(z, order=5, phase=0), z)

sensitivity = smith_sensitivity(gamma, regularization=1e-6)
```

Observed values were:

```
Gamma = [-0.333333+0.j        0.000000+0.j
          0.333333+0.j        0.009901+0.099010j]
maximum roundtrip error = 4.440892098500626e-16
sensitivity = [2.812495, 1.999998, 2.812495, 1.981152]
```

This is a pointwise floating roundtrip, not an exact symbolic identity.

36A.5 Numerical sensitivity and chart singularities

The diagnostic

$$S_\rho(\Gamma) = \frac{1}{|1-\Gamma|^2 + \rho} + \frac{1}{|1+\Gamma|^2 + \rho}, \qquad \rho \geq 0,$$

highlights both chart boundaries. With $\rho = 0$, it diverges at $\Gamma = 1$ and $\Gamma = -1$. Positive regularization caps either individual pole contribution at $1/\rho$, but it changes the diagnostic rather than removing the underlying Cayley singularity. Near $\Gamma = 1$, the inverse derivative

$$\frac{dZ}{d\Gamma} = \frac{2}{(1-\Gamma)^2}$$

also shows quadratic amplification. A small roundtrip residual far from the pole does not imply good conditioning near it.

The implemented practical domain is narrower than exact nonzero-denominator arithmetic. `gamma_from_impedance`, `impedance_from_gamma`, and `phase_mobius` reject a denominator whenever `numpy.isclose(denominator, 0.0)` is true. With NumPy defaults and a zero comparison, this is essentially an absolute `1e-8` exclusion around zero. They raise built-in `ZeroDivisionError`, not `ValidationError`.

`smith_sensitivity` rejects negative regularization but does not check that it is finite. `regularization=float("nan")` returns `nan`. Positive infinity can collapse both terms toward zero. At an unregularized exact pole, NumPy can return `inf` with a runtime warning rather than raise. Inputs to all Smith helpers are converted to complex arrays but are not checked for `NaN` or infinity.

`phase_mobius` validates `order` as an integer but merely applies `int(phase)`. A fractional phase such as `1.9` is silently treated as phase `1`. Validate the phase index externally if truncation is not intended.

Failure and numerical-sensitivity cards

Symptom	Cause	Required interpretation or response
Fourier ringing at a jump	hard spectral cutoff	expected Gibbs behavior. Do not claim edge preservation
Fourier result has tiny imaginary parts removed	`real_if_close(tol=1000)`	compare numerical values and documented dtype behavior
Otsu mask finds the wrong region	heuristic assumes one dominant positive contrast	inspect sign, gradients, region multiplicity, and bin dependence
Mixed flat/compact product rejected	representations have different routing semantics	convert both operands to the same representation
Product channel appears shifted	compact radix carry omitted by external code	include `floor((r+s)/q)` coarse shift
Nonlinear result loses imaginary data	real `dtype=float` coercion	use another implementation for complex transforms
Nonlinear output grows rapidly	polynomial interaction has no stability bound	constrain data/coefficients using an application-specific analysis
`ZeroDivisionError` near a Smith pole	practical `np.isclose` denominator exclusion	change chart or move away from the boundary
Huge inverse impedance perturbation	`Gamma` is close to `1`	report sensitivity. Do not interpret the chart as well-conditioned
Infinite/NaN sensitivity	exact pole, zero regularization, or non-finite input	validate finiteness and choose a declared positive regularization for diagnostics

Cost, memory, and backend behavior

Let N be a 1-D sample count, $P = HW$ a 2-D pixel count, B the histogram bin count, q the cyclic order, $L = N+M-1$ a flat product length, and K the number of nonlinear shifts.

Operation	Arithmetic cost	Storage and traffic
1-D Fourier cutoff	$O(N \log N)$	$O(N)$ spectrum, mask, and output
2-D Fourier cutoff	$O(P \log P)$	$O(P)$ spectrum, coordinate mask, and output
Otsu threshold	$O(N + B)$ after flattening	$O(N + B)$ including converted values and histogram arrays
Positive-packet estimate	Otsu + $O(N)$ medians/mask	$O(N + B)$
Flat `coefficient_packets`	$O(qN)$	q full-length arrays: $O(qN)$

Operation	Arithmetic cost	Storage and traffic
Flat `packet_product`	current zero-filled implementation can do $O(q^2NM)$ direct-convolution work, plus verification	$O(q(N+M+L))$ packet/output storage and convolution temporaries
Compact `packet_product`	sum of all pairwise channel convolutions, plus direct verification. Naive dense worst case is quadratic in reconstructed lengths	output channels, pair terms, reconstructed operands, and direct product are all materialized
Nonlinear shift filter	$O(KN)$, or $O(N)$ in legacy form	$O(N)$ interaction/output, with a rolled temporary per shift
Smith/Cayley pointwise map	$O(N)$	$O(N)$ complex temporaries and output

All implementations use NumPy on host memory. There is no CuPy dispatch, streaming FFT, sparse packet-product kernel, or explicit memory budget. The product certificate always computes a direct convolution reference, so verification is part of runtime and memory cost rather than metadata-only bookkeeping.

Verification evidence and observed defects

The source audit covered the public topology in `signals/__init__.py`, all six defining modules (`singular_packets.py`, `recovery.py`, `edge_recovery.py`, `approximation.py`, `nonlinear.py`, and `smith.py`), the signal release description, the expanded Chapter 36/36A specification, the repository example, and the four focused test files `test_signals_wavelets_singular.py`, `test_signals_recovery.py`, `test_signals_extended.py`, and `test_block4_hardening.py`.

The checked-in singular recovery example ran successfully from source and produced the values printed in Section 36.4. A direct source smoke run also observed zero retained-packet residual for the synthetic exact step, zero compact-product residual, and a Smith roundtrip error of about 4.44×10^{-16}. The exact four-file focused Pytest slice passed **28/28** cases in the qualification environment. The wider Part VI slice passed **212/212**. The recovered runtime's primary interpreter did not itself contain Pytest, so these executions used the declared guide qualification environment.

These reproducible implementation defects or contract weaknesses are preserved in this guide rather than papered over:

1. Scalar `minimum_separation=NaN` can pass validation. Its magnitude is not checked against detected gaps.
2. Vector `origin=NaN` can yield `certificate.valid == True` and `NaN` locations.
3. Adjacent vector detections are diagnosed but do not invalidate the certificate.
4. Non-finite samples and several non-finite tolerance/regularization values lack explicit guards.
5. Otsu bin counts and Smith phase indices are converted with `int` without an integrality check.
6. `nonlinear_shift_filter` silently relies on numeric coercions that can truncate shifts or discard complex components.
7. The direct phase Möbius formula accepts `Z=-1` for tested nonzero phases, although the conceptual route through `Gamma` is undefined there.

Treat these notes as version-specific source observations. They do not expand the accepted mathematical domain and should not be used as guarantees that a future release will preserve the same weak validation.

Part VII. Nonlinear calculus and finite dynamics

This part offers several routes through finite nonlinear and dynamical problems. The common prerequisite is finite-dimensional linear algebra, including linear maps, kernels, images, and projectors. Directional derivatives are introduced in Chapter 37. The finite-field route in Chapter 42 uses exact modular arithmetic instead of floating matrix analysis.

Your task	Reading route	Main result to inspect
Differentiate a finite map	Chapter 37, then Chapter 38 for packet blocks	Provider assumptions, derivative order, and reconstruction
Expand a polynomial fixed-point problem	Chapter 39	Finite tree sum; use the separate majorant for a conditional convergence bound
Decide whether a defect can be corrected	Chapters 40 and 41	Obstruction status and the residual equation that remains
Lift or compute through finite filtration levels	Chapter 42	Exact correction space, branch depth, or spectral page
Execute, persist, or profile packet jets	Chapter 43 after Chapters 37 and 38	Fresh execution plan, complete stored data, and matched timing scope
Follow moving projector ranges	Chapter 44	Derivative, generator, and transport certificates
Evolve or reduce a finite matrix model	Chapters 45 and 46	State convention, finite-time residual, and retained/hidden coupling

Read a result's certificate together with its answer fields. A valid record may certify a nonzero obstruction, an incomplete prefix, or a correctly computed residual. The sections below identify the field that answers each mathematical question.

37. Derivative providers and automatic differentiation

Komorebi Math separates nonlinear differentiation from packet projection. A *derivative provider* owns a finite-dimensional map and its directional derivatives. Chapter 38 then restricts those derivatives to source and target packet ranges. This separation is essential: a packet jet can only be as mathematically reliable as the provider from which it was built.

Throughout this chapter,

$$F : X \to Y, \qquad X \cong \mathbb{K}^{d_X}, \qquad Y \cong \mathbb{K}^{d_Y},$$

where $\mathbb{K}$ may be an exact symbolic or rational domain, or a numerical real or complex domain. A directional derivative is evaluated without materializing a full Jacobian or higher tensor unless the chosen provider already stores such a tensor.

The nonlinear feature record is available from the namespace:

```
from komorebi_math.nonlinear import FEATURE_KEY, require, status
```

- `FEATURE_KEY` is the literal string `"nonlinear"`.
- `status() -> FeatureSpec` returns the registry entry titled *Nonlinear packet calculus*. In release `1.0.0b4` its status is `implemented`.
- `require() -> None` confirms that the base nonlinear package is present. It does not import or validate SymPy, JAX, PyTorch, or CuPy.

There are three practical import tiers.

- The root package, `komorebi_math`, re-exports the common concrete providers, the two external AD adapters, and the main construction functions.
- `komorebi_math.nonlinear` is the complete public nonlinear namespace. Protocol aliases, packet-address records, result records, partition helpers, and package controls should be imported here.
- `ad_framework_diagnostics` is public in `komorebi_math.nonlinear.autodiff` but is not re-exported by `komorebi_math.nonlinear` in this release. Code that needs probe details must import it from the implementation module.

API stability is narrower than namespace visibility. The curated beta surface contains `DerivativeProvider`, `CallableDerivativeProvider`, `FiniteDifferenceDerivativeProvider`, and `PolynomialDerivativeProvider` from Chapter 37. From Chapter 38 it contains `PacketJet`, `PacketJetAddress`, `PacketJetFamily`, `PacketJetSupport`, `packet_jet_support`, `PacketJetCoefficient`, `PacketJetSnapshot`, `snapshot_packet_jet`, `SparsePolynomialDerivativeProvider`, `SparseSymmetricTensor`, and `SparseTensorEntry`. Other Chapter 37 through 38 names are research-surface APIs in this release, and no Part VII name belongs to the frozen stable surface.

The claim boundary is uniform. `Exactness.EXACT` means that the declared coefficients, directions, backend operations, and substitutions are exact. `Exactness.NUMERICAL` permits a residual tolerance. `Exactness.CONDITIONAL` records an incomplete finite audit or a result with visible assumptions. Exactness is partly caller-declared. Selecting `Exactness.EXACT` does not inspect an object array for hidden binary floats, and `SympyDerivativeProvider` cannot prevent a caller from substituting `sympy.Float` values. Use exact labels only with exact input objects.

37.1 Provider protocol

For every provider $\mathfrak{D}_F$, document (d_X, d_Y, e_F, n_F), where e_F is exactness and n_F is the provider name.

$$\mathfrak{D}_F.\,\text{value}(x) = F(x), \qquad \mathfrak{D}_F.\,\text{derivative}(r, x, V) = D^r F(x)[V].$$

The public typing surface is:

```
DirectionalDerivative = Callable[[Any, tuple[Any, ...]], Any]

class DerivativeProvider(Protocol):
    source_dimension: int
    target_dimension: int
    exactness: Exactness
    name: str

    def value(self, point: Any) -> Any: ...

    def derivative(
        self,
        order: int,
        point: Any,
        directions: Sequence[Any],
    ) -> Any: ...

    def supports_order(self, order: int) -> bool: ...
```

`DerivativeProvider` is runtime-checkable. It describes structure, not semantic truth. Passing `isinstance(provider, DerivativeProvider)` establishes that the required attributes are present. It does not prove that `derivative` differentiates `value`.

Universal guards are as follows.

- A point and every direction must be vector-like with length d_X. Row and column vectors are accepted by several providers and normalized locally, but callers should prefer one-dimensional vectors for portability across providers.
- `value` and `derivative` must return a vector-like object with length d_Y.
- A derivative order is positive. Exactly that many directions must be supplied.
- `supports_order(r)` reports availability. A caller should still expect `ValidationError` if an invalid order reaches `derivative`.
- `DimensionError` reports incompatible source or target dimensions. `ValidationError` reports invalid orders, counts, steps, tolerances, or declarations. `BackendUnavailableError` reports an absent or unusable optional framework.
- A certificate returned by a provider is a finite record. Calling `certificate.require()` raises `ValidationError` when `certificate.valid` is false.

The protocol imposes no common dtype or device. A SymPy provider returns a SymPy matrix. A polynomial provider commonly returns a NumPy array, possibly with `dtype=object`. JAX and PyTorch adapters copy their final result to a host NumPy array. Provider interchangeability is therefore mathematical and structural, not a promise of identical Python container types.

Cost model. Let C_F denote one evaluation of `value` and C_{D_r} one provider-specific order-r directional derivative. The protocol itself adds only dimension checks and vector conversion. It does not promise a bound on C_F, C_{D_r}, temporary storage, tracing, or device transfer.

37.2 Callable, polynomial, finite-difference, and SymPy providers

The four provider families in this section expose the same finite directional derivative protocol but obtain their values in different ways: declared callables, stored polynomial tensors, recursive central differences, and symbolic differentiation. Their common interface does not erase their different exactness, storage, and failure boundaries.

For a first provider, choose the representation already available for the map: exact polynomial tensors for a finite polynomial, SymPy expressions for symbolic differentiation, declared callables when derivatives are supplied, or an AD adapter for a function that its framework can trace. Finite differences are a numerical fallback and a small-probe comparison tool. Check one value and one directional derivative before constructing a packet family; this separates provider problems from packet-layout problems.

37.2.1 Declared callable derivatives

`CallableDerivativeProvider` stores a function and a map from positive derivative orders to user-supplied directional callables.

```
CallableDerivativeProvider(
    function: Callable[[Any], Any],
    derivatives: Mapping[int, DirectionalDerivative],
    source_dimension: int,
    target_dimension: int,
    exactness: Exactness = Exactness.NUMERICAL,
    name: str = "declared derivative provider",
)
```

The declaration is

$$\mathcal{D} = \{r \mapsto \mathcal{D}_r\}, \qquad \mathcal{D}_r(x; v_1, \dots, v_r) \overset{\text{declared}}{=} D^r F(x)[v_1, \dots, v_r].$$

The callable at order r receives `(point, directions)`, where `directions` is a tuple of length r. The provider validates the point, direction, and output dimensions, then returns the callable's value without coercing it to a particular backend.

The member surface is:

- `available_orders -> tuple[int, ...]` returns sorted declared orders.
- `supports_order(order: int) -> bool` accepts only an explicitly declared positive integer order. A Boolean is not an order.
- `value(point: Any) -> Any` evaluates the declared map and checks the target dimension.
- `derivative(order, point, directions) -> Any` evaluates one declared directional derivative.
- `validation_certificate(point, directions, *, tolerance=1e-9, check_taylor=False, increment=None) -> Certificate` performs finite probes under theorem record `PSC-III-D02`.

For every available order not exceeding the number of probe directions, validation evaluates all permutations of the selected prefix. Its finite symmetry residual is

$$\rho_{\text{sym}} = \max_{r, \sigma \in S_r} \|\mathcal{D}_r(x; v_{\sigma(1)}, \dots, v_{\sigma(r)}) - \mathcal{D}_r(x; v_1, \dots, v_r)\|.$$

If no declared order fits within the supplied probe prefix, no derivative is checked and the zero residual passes. Supply at least as many probe directions as the largest order that must be audited, and inspect `diagnostics["checked_orders"]` before treating the record as evidence.

With `check_taylor=True`, `increment` is required and the diagnostic polynomial is

$$T_R(x; h) = F(x) + \sum_{r \in R} \mathcal{D}_r(x; h, \dots, h)/r!, \qquad \rho_T = \|F(x+h) - T_R(x; h)\|.$$

The certificate's validity is controlled only by ρ_{sym}. The Taylor residual is recorded under `truncated_taylor` but does not control validity. This permits two important negative cases.

- An asymmetric declaration fails even if it accidentally matches a few scalar Taylor probes.
- A symmetric but mathematically wrong declaration can pass the symmetry gate while producing a large Taylor diagnostic.

The certificate checks finite source and target dimensions and the selected permutations. It leaves global derivative correctness unchecked. If Taylor validation is requested, it also leaves the remainder beyond the largest declared order unchecked. Missing orders, wrong direction counts, nonpositive order keys, noncallable entries, and incompatible dimensions fail immediately.

Cost and storage. For a checked order r, the implementation performs $r!$ derivative calls, including the identity permutation. Across an order set R, the validation cost is

$$\Theta\left(\sum_{r\in R,\ r\le q} r!\, C_{D_r}\right),$$

where q is the number of supplied probe directions. Optional Taylor validation adds one shifted function evaluation and one repeated-direction derivative call per declared order. The provider stores the function, the derivative mapping, and scalar metadata. It does not cache evaluations.

37.2.2 Polynomial tensors

`PolynomialDerivativeProvider` represents a finite polynomial by dense symmetric coefficient tensors.

```
PolynomialDerivativeProvider(
    tensors: Mapping[int, Any],
    *,
    source_dimension: int | None = None,
    target_dimension: int | None = None,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float = 1e-10,
    name: str = "polynomial derivative provider",
)
```

Its factorial convention is

$$F(x) = \sum_{m=0}^{M} \frac{1}{m!} T_m[x^m], \qquad T_m \in Y \otimes (X^*)^{\otimes m}.$$

Thus `T_0` has shape `(d_Y,)`, and `T_m` has shape `(d_Y, d_X, ..., d_X)` with m source axes. The order-r directional derivative is

$$D^r F(x)[v_1, \dots, v_r] = \sum_{m=r}^{M} \frac{1}{(m-r)!} T_m[v_1, \dots, v_r, x^{m-r}].$$

This convention matters when moving formulas into code. For example, the scalar polynomial $3x^2$ is encoded by `T_2 = 6`, not `T_2 = 3`.

The member surface is:

- `degree -> int` is the largest stored tensor order.
- `supports_order(order) -> bool` accepts orders from 1 through `degree`, even when a particular intermediate tensor is absent. Missing tensors contribute zero.
- `value(point) -> Any` contracts every stored tensor against repeated copies of the point and divides by the appropriate factorial.
- `derivative(order, point, directions) -> Any` implements the displayed formula.
- `symmetry_certificate() -> Certificate` checks adjacent source-axis transpositions under `PSC-III-D04`.

For each $m \ge 2$, define

$$\rho_m = \max_{1 \le j < m} \|T_m - \operatorname{swap}_{j,j+1} T_m\|.$$

The certificate is exact when `exactness=Exactness.EXACT` and accepts only zero residual. Otherwise it accepts the maximum residual up to the provider's `tolerance`. Construction checks ranks, common target dimension, equal source axes, and common source dimension, but does not require symmetry. A nonsymmetric tensor can therefore be constructed and evaluated. Call `symmetry_certificate().require()` before using symmetric-derivative theorems.

An order-zero-only map cannot infer d_X. In that case `source_dimension` must be supplied. Empty tensor mappings, negative or Boolean orders, inconsistent ranks, inconsistent target dimensions, and unequal source axes fail during construction.

Exact arithmetic. `Exactness.EXACT` converts tensors to object arrays and uses `Fraction(1, m!)` for scaling. Exactness is preserved when coefficients, points, and directions are exact Python, `Fraction`, or symbolic objects. A binary float stored in an object array remains a binary float, despite the exactness label.

Cost and storage. Dense storage is

$$S_{\text{dense}} = \sum_{m \in \mathcal{M}} d_Y d_X^m$$

scalar entries for the stored order set $\mathcal{M}$. Direct value and derivative evaluation touch each applicable dense tensor. Their leading arithmetic work is proportional to the same applicable entry count, with additional contraction temporaries. Section 38.5.1 gives the orbit-sparse alternative.

37.2.3 Recursive central differences

`FiniteDifferenceDerivativeProvider` supplies a numerical fallback when a function can be evaluated at nearby points.

```
FiniteDifferenceDerivativeProvider(
    function: Callable[[np.ndarray], Any],
    source_dimension: int,
    target_dimension: int,
    step: float = 1e-4,
    max_order: int = 4,
    name: str = "central finite difference provider",
    exactness: Exactness = Exactness.NUMERICAL,
)
```

For a direction v, the actual displacement scale is

$$\eta(v) = h / \max(1, \|v\|), \qquad \Delta_v F(x) = \frac{F(x + \eta v) - F(x - \eta v)}{2\eta}.$$

Higher derivatives are recursive:

$$\Delta_{v_1,\dots,v_r} F = \Delta_{v_r}(\Delta_{v_1,\dots,v_{r-1}} F).$$

The provider accepts a positive finite `step`, a positive `max_order`, and positive dimensions. `value` and `derivative` require finite numeric vectors and finite output. Internally the point and directions are converted to complex arrays before recursion. A user function that cannot accept complex-valued arrays is therefore incompatible even when all original data are real.

The result is always numerical. Error depends on smoothness in the sampled neighborhood, derivative order, displacement scale, floating-point roundoff, cancellation, and the magnitude of the directions. The constructor exposes an `exactness` field and does not force it back to `NUMERICAL`, but changing that field cannot make a finite-difference calculation exact. Retain the default label. The provider does not estimate truncation error, compare multiple step sizes, or return a certificate. A reliable application should perform a step sweep and compare it with an analytic, symbolic, or AD oracle whenever one exists.

At order r, recursion performs exactly 2^r terminal function evaluations. Ignoring function cost, its vector arithmetic is $O(2^r d_X)$, with recursive depth r. This exponential dependence is appropriate for small validation probes, not high-order production differentiation.

The provenance record is `PSC-III-N03`. Its assumptions are sufficient local smoothness and a step that resolves the derivative. A nonpositive or nonfinite step, unsupported order, wrong direction count, nonfinite function output, or dimension mismatch fails explicitly.

37.2.4 SymPy derivatives

`SympyDerivativeProvider` differentiates a finite vector of SymPy expressions.

```
SympyDerivativeProvider(
    expressions: Sequence[Any],
    variables: Sequence[Any],
    *,
    name: str = "SymPy derivative provider",
)
```

For directions $v_1, \dots, v_r$, it computes

$$\nabla_{v_r} \cdots \nabla_{v_1} F = \sum_{i_1,\dots,i_r} v_{1,i_1} \cdots v_{r,i_r} \frac{\partial^r F}{\partial z_{i_r} \cdots \partial z_{i_1}}.$$

The implementation applies each directional differential symbolically, then substitutes the point. It reports `Exactness.EXACT`, supports every positive integer order, and returns a `sympy.Matrix`.

The exact label is justified when expressions, point entries, and direction entries are exact SymPy objects. Substitution of floating SymPy values can produce approximate results even though the class-level exactness field remains `EXACT`. This is a caller-visible semantic boundary, not an automatic coercion.

Construction imports SymPy lazily. An absent installation raises `BackendUnavailableError`. Empty expressions, empty variables, or repeated variables raise `ValidationError`. Points and directions with the wrong number of entries raise `DimensionError`. Symbolic differentiation cost depends on expression-tree growth and simplification behavior. There is no dimension-only complexity guarantee and no internal derivative-expression cache.

The finite symbolic claim is provenance record `PSC-III-E05`. It establishes exact evaluation of the constructed expression when exact symbolic data are used. It does not prove smoothness or equivalence to an independently specified map.

37.3 JAX and PyTorch nested-JVP adapters

The automatic-differentiation surface has a framework-neutral adapter plus lazy JAX and PyTorch adapters.

The JVP primitive is

$$\mathrm{jvp}(G, x, v) = (G(x), DG(x)[v]).$$

Nested construction uses

$$G_0 = F, \qquad G_j(x) = DG_{j-1}(x)[v_j], \qquad G_r(x) = D^r F(x)[v_1, \dots, v_r].$$

37.3.1 Framework-neutral JVP provider

```
AutomaticDifferentiationProvider(
    function: Callable[[Any], Any],
    jvp: DirectionalJVP,
    source_dimension: int,
    target_dimension: int,
    max_order: int = 4,
    exactness: Exactness = Exactness.NUMERICAL,
    name: str = "automatic differentiation provider",
)
```

`DirectionalJVP` is a runtime-checkable protocol for a callable returning `(primal, tangent)`. `AutomaticDifferentiationProvider.derivative` nests that callable. A malformed result that is not a two-tuple raises `ValidationError`.

The member surface is:

- `supports_order(order) -> bool` accepts positive integer orders through `max_order`.
- `value(point) -> Any` evaluates the function and checks target dimension.
- `derivative(order, point, directions) -> Any` performs nested JVPs.
- `validation_certificate(point, directions, *, tolerance=1e-8) -> Certificate` checks finite permutation symmetry.
- `to_dict() -> dict[str, Any]` reports name, dimensions, maximum order, and exactness.

The certificate is `PSC-III-N04A`. It checks only finite dimensions and selected permutation probes. It leaves global correctness of the supplied JVP and tracing outside the probes unchecked. An exactness label supplied here is a declaration about the JVP implementation. It is not inferred.

As with declared-callable validation, an empty direction list checks no derivative and produces a zero symmetry residual. The certificate's `checked_orders` diagnostic is therefore part of the evidence, not optional decoration.

37.3.2 JAX and PyTorch adapters

```
JaxDerivativeProvider(
    function: Callable[[Any], Any],
    source_dimension: int,
    target_dimension: int,
    max_order: int = 4,
    dtype: str | None = None,
    name: str = "JAX derivative provider",
    exactness: Exactness = Exactness.NUMERICAL,
)

TorchDerivativeProvider(
    function: Callable[[Any], Any],
    source_dimension: int,
    target_dimension: int,
    max_order: int = 4,
    dtype: str = "float64",
    device: str | None = None,
    name: str = "PyTorch derivative provider",
    exactness: Exactness = Exactness.NUMERICAL,
)
```

Both adapters force their stored exactness to `NUMERICAL`. Both expose `available()`, `value`, `derivative`, `validation_certificate`, and `to_dict`. JAX uses nested `jax.jvp`. PyTorch uses nested `torch.func.jvp`. Final values are detached or transferred as needed and returned as host NumPy arrays.

Availability states must remain distinct:

$$\text{installed} \overset{?}{\Longrightarrow} \text{importable} \overset{?}{\Longrightarrow} \text{JVP-capable} \overset{?}{\Longrightarrow} \text{function traceable}.$$

Komorebi Math probes JAX and PyTorch in isolated child interpreters. This prevents a failing native import from terminating an application that merely asks about capability. A successful probe establishes import and JVP capability only. The supplied function may still fail because it escapes to NumPy, mutates traced values, uses unsupported data-dependent control flow, requests an unavailable device, or uses an invalid dtype.

The discovery and factory calls are:

```
available_ad_frameworks() -> dict[str, bool]
available_autodiff_backends() -> dict[str, bool]

ad_framework_diagnostics(
    *, refresh: bool = False
) -> dict[str, dict[str, Any]]

autodiff_provider(
    framework: str,
    function: Callable[[Any], Any],
    source_dimension: int,
    target_dimension: int,
    *,
    max_order: int = 4,
    **options: Any,
) -> JaxDerivativeProvider | TorchDerivativeProvider

automatic_derivative_provider = autodiff_provider
```

`available_autodiff_backends` is an alias of `available_ad_frameworks`, and `automatic_derivative_provider` is an alias of `autodiff_provider`. Framework names are case-normalized. `"jax"`, `"torch"`, and `"pytorch"` are accepted. Unknown names raise `ValidationError`. There is no silent numerical fallback after an AD failure.

`ad_framework_diagnostics` returns, for each framework, `discovered`, `available`, `version`, `returncode`, and bounded diagnostic `detail`. Its result describes the active Python interpreter and can change with environment repairs. The Chapter 37 reference run found neither optional framework installed, so its two optional tests were skipped rather than treated as failures.

The JAX class record is `PSC-III-N04J`. The PyTorch class record is `PSC-III-N04T`. Both adapters inherit the framework-neutral `validation_certificate`, whose emitted runtime `theorem_id` is the generic `PSC-III-N04A`. Consumers should therefore qualify an identifier by its emitting class or method rather than treating the string alone as a globally unique evidence key. Device placement, precision, compilation, and derivative cost belong to the external runtime. Nested order r requires r levels of JVP transformation, but tracing and execution may duplicate work. No backend-independent timing or memory bound is claimed.

37.4 Composition of providers

`ComposedDerivativeProvider(outer, inner, *, name=None)` presents $F \circ G$ as another derivative provider when the target dimension of `inner` equals the source dimension of `outer`. Its value is `outer.value(inner.value(point))`. Its order-r derivative is assembled by the finite Faà di Bruno routine documented in Section 38.3. An order is supported only when both component providers supply every order from one through r. The combined exactness is the weaker of the two component declarations. This constructor checks finite-dimensional compatibility and provider availability. It does not independently prove that either provider's declared derivatives are correct.

37.5 Backend-isolated probes

JAX and PyTorch availability is tested in bounded child interpreters before a provider is constructed. The resulting discovery record distinguishes an installed distribution, a successful import, a working JVP primitive, and a user function that is actually traceable. A failed probe never silently selects finite differences or another backend. Applications that make backend availability a requirement should inspect `ad_framework_diagnostics`, then construct the selected provider explicitly.

37.5.1 Cross-provider comparison example

Use

$$F(x_1, x_2) = (x_1^3 + x_1 x_2,\ x_2^2)$$

at $x = (2, 3)$, with directions $u = (1, 2)$, $v = (-1, 4)$, and $w = (3, -2)$. The cross-provider comparison residual is

$$\rho_r^{p,q} = \left\| D_p^r F(x)[V] - D_q^r F(x)[V] \right\|, \qquad r = 1, 2, 3.$$

The dense polynomial tensors use `T_2[0,0,1] = T_2[0,1,0] = 1`, `T_2[1,1,1] = 2`, and `T_3[0,0,0,0] = 6`.

```
from __future__ import annotations

import numpy as np
import sympy as sp

from komorebi_math import Exactness
from komorebi_math.nonlinear import (
    CallableDerivativeProvider,
    FiniteDifferenceDerivativeProvider,
    PolynomialDerivativeProvider,
    SympyDerivativeProvider,
)

t2 = np.zeros((2, 2, 2), dtype=object)
t2[0, 0, 1] = t2[0, 1, 0] = 1
t2[1, 1, 1] = 2
t3 = np.zeros((2, 2, 2, 2), dtype=object)
t3[0, 0, 0, 0] = 6

polynomial = PolynomialDerivativeProvider(
    {2: t2, 3: t3},
    exactness=Exactness.EXACT,
)
x, y = sp.symbols("x y")
symbolic = SympyDerivativeProvider((x**3 + x*y, y**2), (x, y))

point = np.array([2, 3], dtype=object)
directions = (
    np.array([1, 2], dtype=object),
    np.array([-1, 4], dtype=object),
    np.array([3, -2], dtype=object),
)

print("value:", polynomial.value(point).tolist())
for order in range(1, 4):
    dense = polynomial.derivative(order, point, directions[:order])
    exact = symbolic.derivative(
        order,
        sp.Matrix(point),
        tuple(sp.Matrix(v) for v in directions[:order]),
    )
```

```
    print(f"D{order} polynomial:", dense.tolist(), "sympy:", list(exact))

numerical = FiniteDifferenceDerivativeProvider(
    lambda z: np.array([z[0]**3 + z[0]*z[1], z[1]**2]),
    source_dimension=2,
    target_dimension=2,
    step=2e-4,
    max_order=2,
)
print(
    "D2 finite difference:",
    np.round(
        numerical.derivative(2, point, directions[:2]).astype(float),
        8,
    ).tolist(),
)
```

Observed output is:

```
value: [Fraction(14, 1), Fraction(9, 1)]
D1 polynomial: [Fraction(19, 1), Fraction(12, 1)] sympy: [19, 12]
D2 polynomial: [Fraction(-10, 1), Fraction(16, 1)] sympy: [-10, 16]
D3 polynomial: [Fraction(-18, 1), Fraction(0, 1)] sympy: [-18, 0]
D2 finite difference: [-10.00000001, 15.99999993]
```

The exact cross-provider residuals are zero. The finite-difference discrepancy is numerical and step-dependent.

This negative example separates the gating symmetry residual from the non-gating Taylor diagnostic.

```
wrong_asymmetric = CallableDerivativeProvider(
    function=lambda z: np.array([z[0]**3 + z[0]*z[1], z[1]**2]),
    derivatives={
        2: lambda z, d: np.array([d[0][0] * d[1][1], 0.0]),
    },
    source_dimension=2,
    target_dimension=2,
)
bad = wrong_asymmetric.validation_certificate(point, directions[:2])
print("asymmetric valid:", bad.valid)
print("symmetry residual:", bad.residuals["derivative_symmetry"])

wrong_symmetric = CallableDerivativeProvider(
    function=lambda z: np.array([z[0]**3 + z[0]*z[1], z[1]**2]),
    derivatives={
        1: lambda z, d: np.zeros(2),
        2: lambda z, d: np.zeros(2),
    },
    source_dimension=2,
    target_dimension=2,
)
diagnostic = wrong_symmetric.validation_certificate(
    point,
    directions[:2],
    check_taylor=True,
    increment=np.array([1.0, -1.0]),
)
print("symmetric-wrong valid:", diagnostic.valid)
print("Taylor diagnostic:", diagnostic.residuals["truncated_taylor"])
```

Observed output is:

```
asymmetric valid: False
symmetry residual: 6.0
symmetric-wrong valid: True
Taylor diagnostic: 19.6468827043885
```

This is not a contradiction. `PSC-III-D02` certifies selected permutation symmetries. It does not certify that arbitrary declared callables are globally the derivatives of `function`.

38. Packet jets and Faà di Bruno composition

A packet jet is one block of a multilinear derivative after projecting each source direction into a named packet and projecting the output into a named target packet. Packet jets expose sparsity, permit exact derivative reconstruction, and provide the finite building blocks for packet-aware composition.

Read the objects in this order. A provider supplies the derivative. A family fixes its base point, order, and packet systems. An address selects one output packet and an ordered tuple of input packets. A support record classifies which addresses were tested, and a snapshot stores evaluated coefficients for one fixed address. These objects serve different purposes: support discovery does not itself execute a family, and a snapshot cannot be moved to a new base point without recapture.

Let the source and target packet systems satisfy

$$I_X = \sum_{a \in A} P_a, \qquad I_Y = \sum_{b \in B} Q_b.$$

For theorem-level exact reconstruction, these identities must hold exactly in the selected backend. A numerical `PacketSystem` validates them within its tolerance. Packet systems require pairwise-annihilating idempotents, but not necessarily self-adjoint Hilbert-space orthogonal projectors. `hilbert_certificate()` is the separate self-adjointness check. The formulas in this chapter are finite-dimensional. They do not claim convergence of an infinite jet, an analytic Taylor series, or a continuum decomposition.

The recommended imports are `PacketSystem` and `Exactness` from `komorebi_math`, followed by nonlinear objects from `komorebi_math.nonlinear`. Low-level record types such as `PacketJetAddress`, `PacketJetSupport`, `PacketTaylorResult`, `FaaDiBrunoResult`, and `PacketJetCoefficient` are available from the nonlinear namespace even when they are not re-exported by the root package.

38.1 Jet addresses, supports, families, and snapshots

This section establishes the address space used by packet jets. Supports, families, and portable snapshots retain those addresses so a coefficient can be traced back to one output packet, an ordered input-packet tuple, and a derivative order.

38.1.1 Jet addresses and blocks

The public type alias and construction records are:

```
PacketLabel = int | str

PacketJetAddress(
    output: str,
    inputs: tuple[str, ...],
)

PacketJet(
    provider: DerivativeProvider,
    point: Any,
    source: PacketSystem,
    target: PacketSystem,
    output_index: int,
    input_indices: tuple[int, ...],
)
```

```
PacketJetFamily(
    provider: DerivativeProvider,
    point: Any,
    source: PacketSystem,
    target: PacketSystem,
    order: int,
)
```

For order r, the address space is

$$\mathcal{A}_r = B \times A^r, \qquad |\mathcal{A}_r| = |B||A|^r, \qquad \alpha = (b; a_1, \dots, a_r).$$

The corresponding block is

$$J^{(r)}_{b;a_1,\dots,a_r}(x)[v_1, \dots, v_r] = Q_b D^r F(x)[P_{a_1} v_1, \dots, P_{a_r} v_r].$$

`PacketJetAddress` is a frozen, slotted record. Its `order` property is `len(inputs)`, and `to_dict()` returns `order`, `output`, and `inputs`.

`PacketJet` is also frozen and slotted. Its public members are:

- `order -> int`, the number of input packet indices.
- `address -> PacketJetAddress`, using packet names rather than integer indices.
- `exactness -> Exactness`, equal to `EXACT` only when the provider and both packet backends are exact. Conditional, heuristic, or planned provider labels are preserved. Other combinations are numerical.
- `evaluate(directions) -> Any`, also available through `jet(directions)`, projects directions, calls the provider, and projects the result.
- `norm_bound(derivative_norm: float) -> float`, the projector-product bound.
- `symmetry_certificate(directions, *, tolerance=None) -> Certificate`, theorem record `PSC-III-D06`.
- `to_dict() -> dict[str, Any]`, a structural metadata record. It does not serialize the provider callable.

The universal operator-norm statement is

$$\|J^{(r)}_{b;\mathbf{a}}\| \le \|Q_b\| \, \|D^r F(x)\| \prod_{j=1}^{r} \|P_{a_j}\|.$$

Thus, if $\|D^r F(x)\| \le M_r$, the same right-hand side is bounded by $\|Q_b\| M_r \prod_j \|P_{a_j}\|$.

`norm_bound` computes the right-hand side from the caller's declared `derivative_norm`. It does not estimate M_r, validate that the supplied value is a finite nonnegative upper bound, or return a certificate. A negative input can therefore produce a meaningless negative result.

For a symmetric derivative, packet symmetry pairs direction permutations with address permutations:

$$J_{b;a_{\sigma(1)},\dots,a_{\sigma(r)}}[v_{\sigma(1)}, \dots, v_{\sigma(r)}] = J_{b;a_1,\dots,a_r}[v_1, \dots, v_r].$$

The symmetry certificate evaluates all $r!$ paired permutations. It leaves global correctness of a user-supplied provider unchecked.

`PacketJetFamily` fixes a provider, point, source system, target system, and derivative order. Its members are:

- `jet(output, inputs) -> PacketJet`, accepting packet names or integer labels.
- `addresses() -> tuple[PacketJetAddress, ...]`, in deterministic output-major, product-lexicographic input order.
- `reconstruct(directions) -> Any`, the sum over every address.
- `reconstruction_certificate(directions, *, tolerance=None) -> Certificate`.
- `to_dict() -> dict[str, Any]`, including the address count.

Source and target packet systems must use the same backend. Provider dimensions must equal packet-system dimensions. The provider must support the requested order. Invalid labels, wrong direction counts, and wrong base-point dimensions fail explicitly.

Cost. One jet evaluation performs r source projector-vector products, one provider derivative evaluation, and one target projector-vector product. For dense $d_X \times d_X$ and $d_Y \times d_Y$ projectors this adds $O(rd_X^2 + d_Y^2)$ arithmetic around the provider. Sparse or symbolic backends have backend-specific costs.

38.2 Multilinear derivative storage

A packet family stores projected blocks of a multilinear derivative rather than one opaque dense tensor. Exact reconstruction and conservative support discovery are the two structural checks needed before composition.

38.2.1 Reconstruction theorem

Multilinearity and packet completeness give

$$D^r F(x)[V] = \sum_{b \in B} \sum_{\mathbf{a} \in A^r} J^{(r)}_{b;\mathbf{a}}(x)[V].$$

The certificate residual is

$$\rho_{\text{rec}} = \left\| D^r F(x)[V] - \sum_{\alpha \in \mathcal{A}_r} J_\alpha(x)[V] \right\|.$$

`PacketJetFamily.reconstruction_certificate` compares a direct provider evaluation with the reconstructed sum. The theorem record is `PSC-III-T07`, whose checked assumptions are complete input packets, complete output packets, and multilinearity. The certificate reports order, address count, provider name, and residual.

For an exact provider and exact packet backend, only zero residual passes. Otherwise the threshold is the maximum source and target packet tolerance unless the caller supplies `tolerance`.

The reconstruction enumerates all $|B||A|^r$ addresses and does not consult support data. Its cost is therefore exponential in derivative order when the packet count exceeds one:

$$C_{\text{reconstruct}} = |B||A|^r C_J,$$

where C_J is one packet-jet evaluation. This direct path is a transparent reference calculation. Section 38.2.2 classifies support, and later execution APIs compile selected batches, but support does not alter `PacketJetFamily.reconstruct` itself.

38.2.2 Support discovery

`packet_jet_support` exhaustively tests each packet block on bases for the corresponding source packet ranges.

```
PacketJetSupport(
    order: int,
    nonzero: tuple[PacketJetAddress, ...],
    zero: tuple[PacketJetAddress, ...],
    untested: tuple[PacketJetAddress, ...],
    evaluations: int,
    certificate: Certificate,
)

packet_jet_support(
    family: PacketJetFamily,
    *,
    tolerance: float | None = None,
    max_evaluations: int = 100_000,
) -> PacketJetSupport
```

For packet-range bases $\mathcal{B}_a$, a block is certified zero when

$$J_\alpha[e_1, \dots, e_r] = 0 \quad \forall (e_1, \dots, e_r) \in \mathcal{B}_{a_1} \times \cdots \times \mathcal{B}_{a_r}.$$

The resulting partition is

$$\mathcal{A}_r = \mathcal{A}_r^{\neq 0} \sqcup \mathcal{A}_r^{0} \sqcup \mathcal{A}_r^{?}.$$

An exact SymPy backend obtains each packet-range basis from `columnspace()` and tests exact zero. A numerical backend obtains the range basis from an SVD of each source projector. Its rank threshold is the larger of the absolute tolerance and that tolerance times the leading singular value.

The record's `complete` property is true exactly when `untested` is empty. `contains(output, inputs)` tests membership in `nonzero` only. A false result means *not certified nonzero*. It does not distinguish certified zero from untested. Inspect `zero` and `untested` when that distinction matters.

The global `max_evaluations` budget is checked while addresses are processed. Once exhausted, the current and all remaining addresses are placed in `untested`. The certificate remains valid because it truthfully records the finite classification, but its exactness changes to `CONDITIONAL` and its unchecked assumptions mention the untested addresses. An untested address must never be pruned.

Let $k_a = \dim \operatorname{range} P_a$. Apart from basis construction, exhaustive work is bounded by

$$N_{\text{support}} \le \sum_{b \in B} \sum_{(a_1, \dots, a_r) \in A^r} \prod_{j=1}^{r} k_{a_j} = |B| \left(\sum_{a \in A} k_a \right)^r = |B| d_X^r.$$

Nonzero blocks may terminate early after the first nonzero basis value. Zero blocks require their full basis product. `max_evaluations` caps jet evaluations but does not cap SVD or symbolic basis construction.

The theorem record is `PSC-III-C08`. The exact claim is finite multilinear basis classification. Numerical zero is tolerance-dependent and must not be described as structural exact zero.

38.3 Faà di Bruno formula

The finite composition law is organized by set partitions. The packet Taylor construction below fixes the directional and projection conventions before the classical and packet-decorated Faà di Bruno sums are evaluated.

38.3.1 Packet Taylor polynomial

The public result and function are:

```
PacketTaylorResult(
    approximation: Any,
    observed: Any,
    truncation_residual: float,
    order_certificates: tuple[Certificate, ...],
    certificate: Certificate,
)

packet_taylor(
    provider: DerivativeProvider,
    point: Any,
    increment: Any,
    source: PacketSystem,
    target: PacketSystem,
    order: int,
    *,
    tolerance: float | None = None,
) -> PacketTaylorResult
```

It assembles

$$T_nF(x;h) = F(x) + \sum_{r=1}^{n} \frac{1}{r!} \sum_{\alpha \in \mathcal{A}_r} J_\alpha(x)[h^r].$$

The observed diagnostic is

$$\rho_n(x,h) = \|F(x+h) - T_nF(x;h)\|.$$

For every retained order, the implementation constructs a `PacketJetFamily`, obtains its reconstruction certificate, and separately reconstructs the derivative. `certificate.valid` is the conjunction of the retained-order reconstruction certificates. It does not depend on ρ_n. The residual is stored as `observed_truncation_residual`, and the certificate leaves the omitted Taylor remainder and global correctness of user derivatives unchecked.

Order zero is valid and returns `provider.value(point)` as the approximation, with no order certificates. Negative, Boolean, or nonintegral orders fail. Positive orders construct a packet family and therefore enforce provider dimensions and backend compatibility. At order zero no family is constructed, so callers should verify target dimension and backend compatibility explicitly rather than relying on that path as a structural validator.

The theorem record is `PSC-III-C09`. The exact assertion is that the retained Taylor terms were assembled from reconstructed packet derivatives. Equality with $F(x+h)$ occurs for a polynomial when the retained order reaches its degree, but it is not a general certificate condition.

The implementation computes each retained reconstruction twice, once inside its certificate and once for the term. Consequently the transparent cost is approximately

$$2\sum_{r=1}^{n} |B||A|^r C_{J_r} + 2C_F,$$

plus vector additions and factorial scaling. This is a reference implementation rather than a reuse-optimized Taylor compiler.

38.3.2 Formula and partition structure

38.3.2.1 Canonical set partitions and counts

The public combinatoric surface is:

```
Partition = tuple[tuple[int, ...], ...]

set_partitions(order: int) -> tuple[Partition, ...]
stirling_second(order: int, blocks: int) -> int

labeled_composition_term_count(
    order: int,
    intermediate_packets: int,
) -> int
```

`set_partitions(n)` returns a cached deterministic enumeration of partitions of `range(n)`. Entries within a block and blocks within a partition follow their least elements. It returns `((),)` at order zero. The first Bell counts are 1, 1, 2, 5, 15, 52, and 203 for orders zero through six.

The counts are

$$|\Pi_n| = \sum_{k=0}^{n} S(n,k), \qquad N_{\text{labeled}}(n,m) = \sum_{k=1}^{n} S(n,k)m^k.$$

`labeled_composition_term_count` requires positive integer n and m. `set_partitions` strictly validates a nonnegative integer order. `stirling_second` returns zero for negative arguments or $k > n$, but in this release it converts argu-

ments with `int()` without the same strict nonintegral and Boolean guard. Treat integer input as part of its public precondition.

`set_partitions(n)` materializes every partition and retains the immutable tuple in an unbounded process-local cache. Its output storage is $\Theta(B_n n)$ integer positions up to tuple overhead. `stirling_second(n, k)` builds an $(n+1) \times (k+1)$ dynamic-programming table, taking $O(nk)$ time and storage. `labeled_composition_term_count` calls that routine separately for each $k = 1, \ldots, n$, so the current transparent implementation uses $O(n^3)$ aggregate table work and $O(n^2)$ peak table storage before big-integer costs.

38.3.2.2 Classical finite-dimensional composition

For $H = F \circ G$,

$$D^n(F \circ G) = \sum_{\pi \in \Pi_n} D^{|\pi|}F(G) \prod_{B \in \pi} D^{|B|}G.$$

Writing every multilinear argument explicitly gives

$$D^n H(x)[V] = \sum_{\pi \in \Pi_n} D^{|\pi|}F(G(x)) \left[D^{|B|}G(x)[v_i]_{i \in B}\right]_{B \in \pi}.$$

The public records and calls are:

```
FaaDiBrunoTerm(
    partition: Partition,
    intermediate_packets: tuple[str, ...],
    value: Any,
    pruned: bool = False,
    reason: str = "",
)

FaaDiBrunoResult(
    value: Any,
    terms: tuple[FaaDiBrunoTerm, ...],
    raw_term_count: int,
    evaluated_term_count: int,
    pruned_term_count: int,
    certificate: Certificate,
)

faa_di_bruno(
    outer: DerivativeProvider,
    inner: DerivativeProvider,
    point: Any,
    directions: Sequence[Any],
    *,
    direct_provider: DerivativeProvider | None = None,
    tolerance: float = 1e-9,
    retain_terms: bool = True,
) -> FaaDiBrunoResult

ComposedDerivativeProvider(
    outer: DerivativeProvider,
    inner: DerivativeProvider,
    *,
    name: str | None = None,
)
```

At least one direction is required. The inner target dimension must equal the outer source dimension, and both providers must supply *every* derivative order from one through n. Requiring lower orders is essential because a partition can contain blocks of every size through n.

`retain_terms=False` avoids storing term records but does not reduce evaluation work. The raw and evaluated term counts are both the Bell number $|\Pi_n|$, with zero pruned terms.

Without `direct_provider`, the result's certificate has no direct-comparison residual. Its validity records successful finite set-partition assembly, and global correctness of the declared providers remains unchecked. With a compatible direct provider for $F \circ G$, the certificate compares the assembled value with the direct order-n derivative. The exactness is combined across providers. The theorem record is `PSC-III-T10`.

`ComposedDerivativeProvider` exposes the same assembly through the provider protocol. `supports_order(n)` requires all component orders through n. `value(x)` computes `outer.value(inner.value(x))`, and `derivative` delegates to `faa_di_bruno(..., retain_terms=False)`.

Classical composition evaluates one inner derivative per partition block and one outer derivative per partition. Term count grows as a Bell number. Retaining results adds $O(B_n)$ record storage, excluding the potentially large stored values.

38.3.2.3 Packet-decorated composition

For output packet c, source labels a_i, intermediate packet set M, and label map $\lambda : \pi \to M$, the packet identity is

$$Q_c D^n (F \circ G)(x)[P_{a_1} v_1, \dots, P_{a_n} v_n]$$

$$= \sum_{\pi \in \Pi_n} \sum_{\lambda : \pi \to M} J^F_{c;(\lambda(B))_{B \in \pi}} \left[J^G_{\lambda(B);(a_i)_{i \in B}} [v_i]_{i \in B} \right]_{B \in \pi}.$$

The public call is:

```
packet_faa_di_bruno(
    outer: DerivativeProvider,
    inner: DerivativeProvider,
    point: Any,
    directions: Sequence[Any],
    source: PacketSystem,
    intermediate: PacketSystem,
    target: PacketSystem,
    *,
    input_packets: Sequence[PacketLabel],
    output_packet: PacketLabel,
    inner_support: Mapping[int, PacketJetSupport] | None = None,
    outer_support: Mapping[int, PacketJetSupport] | None = None,
    tolerance: float | None = None,
    retain_terms: bool = True,
    max_terms: int = 1_000_000,
) -> FaaDiBrunoResult
```

All three packet systems must share one backend. Provider dimensions must match their source, intermediate, and target spaces. Exactly one source packet is supplied per direction.

The raw labeled count $N_{\text{labeled}}(n, |M|)$ is compared with `max_terms` *before* any support pruning. If it exceeds the limit, the call raises `ValidationError`. Certified zero outer jets prune a term. Certified zero inner jets also prune a term. Missing support, incomplete support, nonzero support, and untested addresses never justify pruning.

The result compares the decorated sum with the target projection of a classical Faà di Bruno evaluation on source-projected directions. Its reconstruction residual gates certificate `PSC-III-T11A`. Diagnostics report raw, evaluated, and pruned terms.

The current over-budget error text suggests supplying structural support or raising the limit. The implementation still rejects on raw count before consulting support, so only reducing order or intermediate packet count, or explicitly raising `max_terms`, can pass that guard. This wording mismatch is documented here rather than hidden.

When `retain_terms=True`, pruned terms are retained with `value=None`, `pruned=True`, and reason `zero outer packet jet` or `zero inner packet jet`. When false, only counts remain. The worst-case evaluation and record count is exactly $N_{\text{labeled}}(n, |M|)$.

38.4 Packet composition and Taylor expansion

`packet_faa_di_bruno` combines the projected inner and outer blocks described above, while `packet_taylor` assembles a finite repeated-direction polynomial. Both are finite identities with explicit support, term-budget, residual, and exactness records. Neither asserts convergence of an infinite analytic expansion.

38.5 Sparse and portable jet records

Dense derivative tensors are not required. Orbit-sparse symmetric tensors and portable coefficient snapshots provide two bounded representations for storage, transfer, digest checking, and later execution.

38.5.1 Sparse symmetric tensors

Dense derivative tensors repeat equal coefficients across every permutation of symmetric source indices. The sparse representation stores one coefficient per nondecreasing orbit.

```
SparseTensorEntry(
    output: int,
    inputs: tuple[int, ...],
    value: Any,
)

SparseSymmetricTensor(
    order: int,
    source_dimension: int,
    target_dimension: int,
    entries: tuple[SparseTensorEntry, ...] = (),
)
```

For a stored orbit $(o; i_1 \le \cdots \le i_r, c)$, contraction is

$$T[v_1, \dots, v_r]_o = \sum_{(o,\mathbf{i},c)} c \sum_{\sigma \in \mathrm{Orb}(\mathbf{i})} \prod_{j=1}^{r} (v_j)_{i_{\sigma(j)}}.$$

The size measures are

$$N_{\mathrm{dense}} = d_Y d_X^r, \qquad \rho_{\mathrm{storage}} = N_{\mathrm{stored}} / N_{\mathrm{dense}}.$$

`SparseSymmetricTensor` exposes:

- `from_mapping(order, source_dimension, target_dimension, entries)`, where keys are `(output, *sorted_inputs)`.
- `from_dense(tensor, *, source_dimension=None, tolerance=0.0, validate_symmetry=True)`.
- `stored_entry_count`, `dense_entry_count`, `expanded_nonzero_count`, and `storage_ratio` properties.
- `contract(vectors, *, exact=False) -> np.ndarray`.
- `to_dense(*, dtype=None) -> np.ndarray`.
- `certificate(*, tolerance=0.0) -> Certificate`, record `PSC-III-D04S`.
- `to_dict() -> dict[str, Any]`.

Construction removes exactly zero stored coefficients, sorts entries, and rejects duplicate orbit keys, out-of-range indices, wrong orbit lengths, and decreasing input tuples. `from_dense` validates all distinct permutations of each representative when `validate_symmetry=True`. A positive tolerance can omit small dense coefficients and accept approximate symmetry, so that compression is numerical.

`SparseTensorEntry` normalizes indices with `int()`. The surrounding tensor validates ranges and ordering but does not separately reject every nonintegral value before conversion. Supply genuine integers rather than relying on coercion.

Contraction cost is

$$O\left(r \sum_{e \in E} |\operatorname{Orb}(e)|\right),$$

with at most $r!$ distinct permutations per stored orbit. `to_dense` writes `expanded_nonzero_count` entries and allocates $d_Y d_X^r$ elements.

The sparse polynomial provider applies the same factorial convention as Section 37.2.2:

```
SparsePolynomialDerivativeProvider(
    tensors: Mapping[
        int,
        SparseSymmetricTensor | Mapping[tuple[int, ...], Any] | Any,
    ],
    *,
    source_dimension: int | None = None,
    target_dimension: int | None = None,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float = 1e-10,
    name: str = "sparse polynomial derivative provider",
)
```

Its public surface includes:

- `from_dense_provider(provider, *, tolerance=None, name=...)`.
- `degree`, `stored_entry_count`, `dense_entry_count`, and `storage_ratio`.
- `supports_order`, `value`, and `derivative`.
- `to_dense_provider() -> PolynomialDerivativeProvider`.
- `storage_certificate(points=(), directions=(), *, max_order=None, tolerance=None) -> Certificate`.
- `to_dict() -> dict[str, Any]`.

`storage_certificate` compares sparse and dense values and derivatives only at supplied probes. With no point probes, its zero residual certifies structural conversion machinery but does not test a function value. With probes, it leaves global equality beyond those probes unchecked. Exact providers require zero residual. Numerical providers use the selected tolerance. The record is `PSC-III-D04P`.

Sparse storage is beneficial only when orbit count is substantially below dense size. A tensor can be symmetric yet dense in orbit coordinates. `storage_ratio` is a representation statistic, not a runtime-speed certificate. Orbit expansion, Python-level iteration, object arithmetic, and dtype conversions can outweigh saved multiplication for small dense problems.

38.5.2 Finite snapshots

A `PacketJet` contains executable provider state and is not safely reconstructible from JSON. A snapshot evaluates one fixed block on the ambient standard basis and stores its nonzero coefficient vectors.

```
PacketJetCoefficient(
    indices: tuple[int, ...],
    value: tuple[Any, ...],
)

PacketJetSnapshot(
    address: PacketJetAddress,
    source_dimension: int,
    target_dimension: int,
    provider_name: str,
    exactness: Exactness,
    point: tuple[Any, ...],
    coefficients: tuple[PacketJetCoefficient, ...],
    capture_certificate: Certificate,
)
```

```
snapshot_packet_jet(
    jet: PacketJet,
    *,
    tolerance: float | None = None,
    max_evaluations: int = 100_000,
) -> PacketJetSnapshot
```

The captured coefficient is

$$c_{o;i_1,\dots,i_r} = (J[e_{i_1},\dots,e_{i_r}])_o,$$

and snapshot evaluation is

$$J[v_1,\dots,v_r]_o = \sum_{i_1,\dots,i_r} c_{o;i_1,\dots,i_r} \prod_{j=1}^{r} (v_j)_{i_j}.$$

`PacketJetSnapshot` exposes:

- `order`, `nnz`, and `dense_coefficient_count` properties.
- `coefficient(indices)`, returning an explicit zero target vector when an address is unstored.
- `evaluate(directions)`, also available through `snapshot(directions)`.
- `to_dense(*, max_elements=10_000_000)`.
- `comparison_certificate(jet, directions, *, tolerance=None)`.
- `to_dict()`.

Capture requires d_X^r jet evaluations and checks this count against `max_evaluations` before starting. Exact snapshots omit only exact zero coefficient vectors. Numerical snapshots omit coefficient vectors whose norm is at most the declared tolerance and record the maximum omitted basis norm.

The largest omitted basis norm is not a uniform error bound for arbitrary large directions. Direction products can amplify many omitted coefficients. The snapshot remains a tolerance-compressed numerical representation whose intended accuracy should be checked at application-relevant probes.

Stored coefficient payload is $O(d_Y \,\mathrm{nnz})$, while dense expansion allocates $d_Y d_X^r$ scalar elements. `to_dense` compares that full element count with `max_elements`. Capture's `max_evaluations` controls basis addresses only and does not multiply the budget by d_Y.

`comparison_certificate` requires matching packet address and dimensions, then compares one supplied probe. Its `assumptions_unchecked` text says that probes were not supplied even though the method does receive directions. That diagnostic wording is a known record defect in `1.0.0b4`. The actual residual is computed from the supplied directions.

The capture record is `PSC-III-D58`. A snapshot fixes order, packet address, dimensions, provider name, exactness, base point, and coefficients. It does not carry executable provider logic and cannot be moved to another base point.

Portable persistence is supplied by `komorebi_math.export.persistence`:

```
dumps_portable(value: Any, *, indent: int | None = 2, max_depth: int = 128) -> str
loads_portable(text: str | bytes, *, max_depth: int = 128) -> Any
portable_digest(value: Any, *, max_depth: int = 128) -> str
```

The portable envelope verifies a SHA-256 payload digest and reconstructs only registered codecs. Digest equality is an integrity statement. It is not a signature, authorship proof, or authenticity claim.

38.5.3 Example ladder

38.5.3.1 Exact packet reconstruction, support, and Taylor assembly

```
import sympy as sp

from komorebi_math import PacketSystem
from komorebi_math.nonlinear import (
    PacketJetFamily,
    SympyDerivativeProvider,
    packet_jet_support,
    packet_taylor,
)

x, y = sp.symbols("x y")
provider = SympyDerivativeProvider((x**2, y**2), (x, y))
packets = PacketSystem(
    (sp.diag(1, 0), sp.diag(0, 1)),
    names=("x", "y"),
    backend="sympy",
)
point = sp.Matrix([1, 2])
directions = (sp.Matrix([2, 3]), sp.Matrix([-1, 4]))

family = PacketJetFamily(provider, point, packets, packets, order=2)
family.reconstruction_certificate(directions).require()
support = packet_jet_support(family)
partial = packet_jet_support(family, max_evaluations=1)
taylor = packet_taylor(
    provider,
    point,
    sp.Matrix([3, -1]),
    packets,
    packets,
    2,
)

print("address count:", len(family.addresses()))
print("nonzero:", support.nonzero)
print("zero blocks:", len(support.zero), "complete:", support.complete)
print(
    "partial evaluations:", partial.evaluations,
    "untested:", len(partial.untested),
    "exactness:", partial.certificate.exactness.value,
)
print(
    "Taylor approximation:", list(taylor.approximation),
    "residual:", taylor.truncation_residual,
)
```

Observed output is:

```
address count: 8
nonzero: (PacketJetAddress(output='x', inputs=('x', 'x')), PacketJetAddress(output='y', inputs=('y', 'y')))
zero blocks: 6 complete: True
partial evaluations: 1 untested: 7 exactness: conditional
Taylor approximation: [16, 1] residual: 0.0
```

The partial support record is valid and conditional. It does not promote its seven untested addresses to zero.

38.5.3.2 Exact Faà di Bruno composition and partition counts

The shipped `examples/nonlinear_jets_composition.py` uses the factorial tensor convention for

$$F(u) = u^2, \qquad G(x) = x + x^2,$$

at $x = 2$ in directions 3 and 4.

```
import numpy as np

from komorebi_math import Exactness
from komorebi_math.nonlinear import (
    PolynomialDerivativeProvider,
    faa_di_bruno,
)
from komorebi_math.nonlinear.composition import set_partitions

outer = PolynomialDerivativeProvider(
    {2: np.array([[[2]]], dtype=object)},
    exactness=Exactness.EXACT,
)
inner = PolynomialDerivativeProvider(
    {
        1: np.array([[1]], dtype=object),
        2: np.array([[[2]]], dtype=object),
    },
    exactness=Exactness.EXACT,
)
result = faa_di_bruno(
    outer,
    inner,
    np.array([2], dtype=object),
    (np.array([3], dtype=object), np.array([4], dtype=object)),
)
result.certificate.require()

print("Bell counts order 0..4:", [len(set_partitions(n)) for n in range(5)])
print("second directional derivative:", result.value[0])
print("set-partition terms:", result.raw_term_count)
```

Observed output is:

```
Bell counts order 0..4: [1, 1, 2, 5, 15]
second directional derivative: 888
set-partition terms: 2
```

The focused exact test suite independently compares classical and packet Faà di Bruno composition through order four with direct SymPy derivatives.

38.5.3.3 Exact sparse contraction

```
from fractions import Fraction

import numpy as np

from komorebi_math import Exactness
from komorebi_math.nonlinear import SparsePolynomialDerivativeProvider

tensor = np.zeros((1, 2, 2), dtype=object)
tensor[0, 0, 0] = Fraction(2, 3)
tensor[0, 0, 1] = tensor[0, 1, 0] = Fraction(1, 5)
```

```
provider = SparsePolynomialDerivativeProvider(
    {2: tensor},
    source_dimension=2,
    exactness=Exactness.EXACT,
)
value = provider.derivative(
    2,
    np.array([0, 0], dtype=object),
    (
        np.array([Fraction(1, 2), Fraction(2, 3)], dtype=object),
        np.array([Fraction(3, 4), Fraction(1, 7)], dtype=object),
    ),
)
provider.storage_certificate(
    points=(np.array([0, 0], dtype=object),),
    directions=(
        np.array([Fraction(1, 2), Fraction(2, 3)], dtype=object),
        np.array([Fraction(3, 4), Fraction(1, 7)], dtype=object),
    ),
).require()

print("sparse exact D2:", value[0])
print(
    "stored/dense:",
    f"{provider.stored_entry_count}/{provider.dense_entry_count}",
)
```

Observed output is:

```
sparse exact D2: 51/140
stored/dense: 2/4
```

38.5.3.4 Snapshot roundtrip, digest, and tamper rejection

```
import json

import numpy as np

from komorebi_math import PacketSystem
from komorebi_math.exceptions import ValidationError
from komorebi_math.export.persistence import (
    dumps_portable,
    loads_portable,
    portable_digest,
)
from komorebi_math.nonlinear import (
    PacketJetFamily,
    PolynomialDerivativeProvider,
    snapshot_packet_jet,
)

packets = PacketSystem(
    (np.diag([1.0, 0.0]), np.diag([0.0, 1.0])),
    names=("x", "y"),
)
tensor = np.zeros((2, 2, 2))
tensor[0, 0, 0] = 2.0
tensor[1, 1, 1] = 2.0
provider = PolynomialDerivativeProvider(
    {2: tensor},
    source_dimension=2,
```

```
    target_dimension=2,
)
jet = PacketJetFamily(
    provider,
    np.zeros(2),
    packets,
    packets,
    2,
).jet("x", ("x", "x"))

snapshot = snapshot_packet_jet(jet)
restored = loads_portable(dumps_portable(snapshot))
probe = (np.array([2.0, 3.0]), np.array([-1.0, 4.0]))
snapshot.comparison_certificate(jet, probe).require()

print("snapshot nnz:", snapshot.nnz)
print("roundtrip:", restored == snapshot)
print("value:", restored.evaluate(probe).tolist())
print("digest:", portable_digest(snapshot))

envelope = json.loads(dumps_portable(snapshot))
envelope["payload_sha256"] = "0" * 64
try:
    loads_portable(json.dumps(envelope))
except ValidationError as exc:
    print("tamper rejection:", type(exc).__name__, str(exc))
```

Observed output is:

```
snapshot nnz: 1
roundtrip: True
value: [(-4+0j), 0j]
digest: 7fbe4ca3a9e166083e4621c3d39a5fc71db307b395a8b159fbbef0d076e170fb
tamper rejection: ValidationError portable payload SHA256 mismatch
```

The digest is deterministic for this exact serialized record and this release's codec. It is not a security signature.

38.5.3.5 Verification and source-truth ledger

The Chapter 37 through 38 focused replay executed:

- `tests/test_nonlinear_jets_composition.py`.
- `tests/test_nonlinear_sparse_autodiff.py`.
- `tests/test_nonlinear_snapshots_persistence.py`.
- `examples/nonlinear_jets_composition.py`.
- Every new code path whose observed output appears above.

The result was **21 passed and 2 skipped**. The skipped cases were isolated JAX and PyTorch adapter tests because neither optional framework was installed in the reference environment. Their skips confirm the optional-backend contract and do not qualify either external runtime.

These source boundaries remain visible:

- Symmetry probes do not establish global derivative correctness.
- Taylor residuals are diagnostics and do not gate provider or packet-Taylor certificates.
- `Exactness.EXACT` relies on genuinely exact caller data.
- Numerical support depends on SVD rank and zero tolerances.
- Untested support addresses are not zero addresses.
- Raw packet-composition term limits are enforced before pruning.
- Sparse storage ratios are not performance benchmarks.
- Snapshot omission tolerance is not an arbitrary-direction error bound.

- Portable digests establish integrity only.
- Several tolerance-bearing low-level certificate calls accept a caller-supplied float without a uniform finite, non-negative guard. Production callers should validate tolerances before passing them.

These boundaries are part of the interface contract. They prevent a finite computation record from being misreported as a global analytic theorem, a backend qualification, or an authenticity claim.

39. Nonlinear trees and graded operations

The finite nonlinear layer turns two familiar infinite-looking constructions into bounded, inspectable computations. Ordered rooted trees encode finite Picard iterates of polynomial fixed-point equations. Finite abelian labels encode packet-selection rules for multilinear operations and finite Maurer-Cartan expressions. The implementation does not infer convergence, multilinearity, grading, or algebraic identities from a successful run. Those hypotheses remain visible in the certificates that use them.

The complete Chapter 39 surface is exported by `komorebi_math.nonlinear`:

```
from komorebi_math.nonlinear import (
    FiniteAbelianGroup,
    GradedPacketOperation,
    OrderedRootedTree,
    PolynomialFixedPointProblem,
    majorant_convergence,
    maurer_cartan_packets,
    packet_tree_reconstruction,
)
```

The principal problem classes and constructor functions are also re-exported from `komorebi_math`, but result records such as `TreeExpansionResult`, `GradingCertificate`, and `MaurerCartanResult` belong to the broader research namespace. None of these names is in the curated `komorebi_math.stable` or `komorebi_math.beta` surface in version `1.0.0b4`. Pin the package version when these signatures form an application contract.

The claim labels used below are:

- **E** for exact finite algebra or combinatorics.
- **N** for a finite numerical identity accepted at a stated tolerance.
- **C** for a conclusion conditional on declared, unchecked hypotheses.
- **M** for a work or storage model rather than a timed benchmark.
- **I** for provenance or digest integrity rather than mathematical truth.

The namespace control card is `FEATURE_KEY = "nonlinear"`. `status() -> FeatureSpec` reports the feature as implemented and `require() -> None` is the implemented-feature compatibility no-op. The registry summary explicitly leaves infinite completion and analytic convergence conditional on supplied hypotheses.

39.1 Ordered rooted trees

An ordered rooted tree is either a leaf or an internal root with an ordered tuple of subtrees:

$$\tau ::= \bullet \mid B_r(\tau_1, \dots, \tau_r), \qquad r \in \mathcal{R} \subset \{2, 3, \dots\}.$$

The order of the children matters. Thus $B_2(\bullet, B_2(\bullet, \bullet))$ and $B_2(B_2(\bullet, \bullet), \bullet)$ are distinct. An internal vertex with zero or one child is not in this grammar.

`OrderedRootedTree` is a frozen, slotted, orderable dataclass with one field:

```
OrderedRootedTree(
    children: tuple[OrderedRootedTree, ...] = (),
)
```

Its finite structural record is:

- `leaf() -> OrderedRootedTree` constructs •.
- `is_leaf -> bool` tests whether `children` is empty.
- `arity -> int` returns the root arity, with zero for a leaf.
- `height -> int` returns zero for a leaf and one plus the maximum child height otherwise.
- `leaf_count -> int`, `internal_count -> int`, and `vertex_count -> int` count the corresponding vertices.
- `arity_profile() -> dict[int, int]` counts internal vertices by arity.
- `prefix() -> str` writes a leaf as `s` and an internal tree as `Br(child,...)`.
- `to_dict() -> dict[str, Any]` recursively records `arity`, `height`, `leaves`, and `children`.

The runtime coerces `children` to a tuple and rejects a non-tree child or an internal root of arity one. These metadata are exact finite combinatorics. **E**

Height-bounded families

For a fixed allowed arity set $\mathcal{R}$, let N_h count all ordered trees of height at most h. The implementation uses the exact recurrence

$$N_0 = 1, \qquad N_h = 1 + \sum_{r \in \mathcal{R}} N_{h-1}^r.$$

The leading one is the leaf. Each other term chooses an allowed root arity and an ordered subtree of height at most $h - 1$ in every child slot.

```
ordered_tree_count(
    max_height: int,
    arities: Sequence[int],
) -> int

ordered_rooted_trees(
    max_height: int,
    arities: Sequence[int],
    *,
    max_trees: int = 100000,
) -> tuple[OrderedRootedTree, ...]
```

`arities` is normalized to a sorted duplicate-free tuple. Every entry must be an integer at least two, booleans are rejected, and the normalized set must be nonempty. The height must be a nonnegative integer. Enumeration first computes the exact count and raises `ValidationError` before materialization when the count exceeds `max_trees`. The returned tuple is cached by height and normalized arity set. **E**

For binary trees the first height-bounded counts are

$$(N_0, N_1, N_2, N_3) = (1, 2, 5, 26).$$

The family therefore grows far faster than its small-height examples suggest. The explicit count guard is a mathematical resource boundary, not a claim that height four or greater is intrinsically unsafe.

Leaf-bounded families and Catalan numbers

The alternative enumerator fixes the number of leaves:

```
ordered_trees_with_leaves(
    leaves: int,
    arities: Sequence[int],
    *,
    max_trees: int = 100000,
) -> tuple[OrderedRootedTree, ...]

catalan_number(index: int) -> int
```

For every allowed root arity r, the routine enumerates every positive composition

$$n = n_1 + \cdots + n_r, \qquad n_j \geq 1,$$

then takes the Cartesian product of the recursively generated child families. For the binary family with n leaves, the exact count is

$$C_{n-1} = \frac{1}{n}\binom{2n-2}{n-1}, \qquad C_k = \frac{1}{k+1}\binom{2k}{k}.$$

The leaf count must be a positive integer and the Catalan index a nonnegative integer.

Before requesting a large family, choose whether height or leaf count is the intended constraint and compute the corresponding count. They describe different finite sets. For evaluating a fixed number of Picard iterations, follow the height convention used by `tree_expansion`; a leaf-count cutoff is not a substitute for that iteration depth.

Unlike `ordered_rooted_trees`, the leaf-bounded routine checks `max_trees` after its cached family has been generated. The limit prevents an oversized result from being returned, but it is not a pre-allocation memory guard for this path. This source-level distinction matters in automated workloads. **E/M**

Minimal structural example

```
from komorebi_math.nonlinear import (
    OrderedRootedTree,
    catalan_number,
    ordered_tree_count,
)

leaf = OrderedRootedTree.leaf()
tree = OrderedRootedTree((leaf, OrderedRootedTree((leaf, leaf))))

print(tuple(ordered_tree_count(h, (2,)) for h in range(4)))
print(tuple(catalan_number(n) for n in range(7)))
print(
    tree.prefix(),
    tree.height,
    tree.leaf_count,
    tree.internal_count,
    tree.vertex_count,
)
```

Observed output:

```
(1, 2, 5, 26)
(1, 1, 2, 5, 14, 42, 132)
B2(s,B2(s,s)) 2 3 2 5
```

39.2 Polynomial fixed-point trees

`PolynomialFixedPointProblem` represents the finite-dimensional equation

$$u = s + \sum_{r \in \mathcal{R}} B_r(u, \dots, u) =: \Phi(u), \qquad u_0 = 0, \qquad u_{m+1} = \Phi(u_m).$$

Every operation is supplied as a callable accepting one tuple of r arguments. The public typing alias is

```
MultilinearOperation = Callable[[tuple[Any, ...]], Any]
```

It describes the expected calling convention. The runtime checks arity and vector dimensions, but it does not prove that a supplied callable is multilinear.

The tree valuation is recursive:

$$\mathrm{val}(\bullet) = s, \qquad \mathrm{val}(B_r(\tau_1, \dots, \tau_r)) = B_r(\mathrm{val}\,\tau_1, \dots, \mathrm{val}\,\tau_r).$$

Distributing each finite Picard iterate gives the exact finite identity

$$u_m = \sum_{h(\tau) < m} \mathrm{val}(\tau).$$

This identity is about a particular finite depth. It neither takes a limit nor asserts that u_m converges.

Problem reference

```
PolynomialFixedPointProblem(
    seed: Any,
    operations: Mapping[int, MultilinearOperation],
    *,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float = 1e-10,
    name: str = "polynomial fixed-point problem",
)
```

The constructor determines one vector dimension from `seed`, normalizes the operation keys to integer arities at least two, requires at least one callable, and rejects a nonfinite or negative tolerance.

Its callable surface is:

- `operation(arity: int, arguments: Sequence[Any]) -> Any` validates the declared arity, argument count, input dimensions, and output dimension.
- `map(value: Any) -> Any` evaluates $\Phi(value)$.
- `residual(value: Any) -> Any` returns $value - \Phi(value)$.
- `picard(iterations: int, *, initial: Any | None = None) -> Any` iterates from the zero-like seed unless an initial value is supplied.
- `tree_value(tree: OrderedRootedTree) -> Any` evaluates one tree recursively.
- `tree_expansion(depth: int, *, max_trees: int = 100000, retain_terms: bool = True) -> TreeExpansionResult` sums all trees of height less than `depth` and compares the sum with the matching Picard iterate.
- `convergence_certificate(operation_norms, radius, *, seed_norm=None) -> MajorantConvergence` delegates to the scalar majorant in Section 39.3.

`depth=0` returns the zero-like seed and compares it to the zeroth Picard iterate. For positive depth, the enumerated family has maximum height `depth - 1`. `retain_terms=False` avoids storing the individual result records, but every tree is still enumerated and evaluated.

The returned frozen, slotted records are:

- `TreeTerm(tree: OrderedRootedTree, value: Any)` for one contribution.
- `TreeExpansionResult(value, picard_value, terms, depth, certificate)` for the finite comparison.

The certificate residual is

$$r_{\text{tree}} = \left\| \sum_{h(\tau)<m} \operatorname{val}(\tau) - u_m \right\|_2 .$$

With `Exactness.EXACT`, validity requires `r_tree == 0.0`. Otherwise it requires `r_tree <= tolerance`. Exactness is caller-declared rather than inferred from the value types. The certificate checks enumeration and recursive evaluation, and explicitly leaves convergence beyond the finite depth unchecked. **E/N**

Work and storage model

Let $T_m = N_{m-1}$ for $m > 0$. The expansion stores T_m tree objects and, when `retain_terms=True`, T_m result records. Each call to `tree_value` recursively evaluates its own tree. Common subtrees across different terms are not memoized at the value level. Consequently a useful structural work model is

$$W_m = \sum_{h(\tau)<m} V(\tau)c(\tau),$$

where $V(\tau)$ is the vertex count and $c(\tau)$ represents the cost of the corresponding multilinear operations. The Picard comparison adds m applications of the polynomial map. This is a model of calls, not a wall-clock guarantee. **M**

39.3 Majorant convergence certificates

Suppose callers have established bounds

$$\|s\| \le a, \qquad \|B_r(x_1, \dots, x_r)\| \le b_r \prod_{j=1}^{r} \|x_j\|.$$

Define the scalar majorant

$$\phi(t) = a + \sum_r b_r t^r.$$

On a declared ball of radius $R > 0$, the runtime checks

$$\phi(R) \le R, \qquad q = \sum_r r b_r R^{r-1} < 1.$$

When the actual operation bounds are valid and the ambient space is complete, the contraction argument supplies the tail estimate

$$\|u - u_m\| \le \frac{q^m a}{1-q}.$$

The conditions and scalar arithmetic are finite numerical checks. Applying them to the nonlinear problem is conditional because the implementation does not measure the multilinear operator norms or prove completeness. **N/C**

```
majorant_convergence(
    seed_norm: float,
    operation_norms: Mapping[int, float],
    radius: float,
    *,
    tolerance: float = 1e-12,
) -> MajorantConvergence
```

All norms and bounds must be finite and nonnegative, the radius finite and positive, every operation label an integer arity at least two, and the operation map nonempty. The tolerance must be finite and nonnegative.

`MajorantConvergence` stores:

- `seed_norm: float` and the normalized `operation_norms: dict[int, float]`.
- `radius: float`.
- `image_bound: float`, equal to $\phi(R)$.
- `contraction: float`, equal to q.
- `certificate: Certificate`.
- `scalar_map(value: float) -> float`.
- `scalar_iterates(iterations: int) -> tuple[float, ...]`, beginning with $t_0 = 0$.
- `picard_tail_bound(iterate: int) -> float`, which first requires the certificate and then evaluates the displayed bound.

The certificate accepts the ball condition with additive tolerance, `image_bound <= radius + tolerance`, but it requires the contraction inequality strictly, `contraction < 1.0`. Thus $q = 1$ is invalid even though the stored `contraction_excess` residual is zero. This is the correct strict boundary for the contraction theorem.

Quadratic Catalan majorant

For

$$u = s + B(u, u), \qquad \|B(x, y)\| \le b\|x\|\|y\|,$$

the small scalar fixed point is

$$R = \frac{1 - \sqrt{1 - 4ab}}{2b}, \qquad 4ab < 1.$$

```
quadratic_catalan_majorant(
    seed_norm: float,
    bilinear_norm: float,
    *,
    tolerance: float = 1e-12,
) -> MajorantConvergence
```

When $a, b > 0$ and $1 - 4ab \le 0$, the function returns a result with candidate radius $1/(2b)$ and an explicitly invalid certificate whose theorem ID is `PSC-III-C15`. It does not raise merely because the strict Catalan condition fails. The cases $a = 0$ or $b = 0$ are handled separately and can produce a valid contraction record.

```
import numpy as np

from komorebi_math.nonlinear import (
    PolynomialFixedPointProblem,
    majorant_convergence,
    quadratic_catalan_majorant,
)

problem = PolynomialFixedPointProblem(
    np.array([0.1]),
```

```
    {2: lambda values: np.array([values[0][0] * values[1][0]])},
)
expansion = problem.tree_expansion(4)
majorant = majorant_convergence(0.1, {2: 1.0}, 0.2)

print(expansion.value.tolist(), expansion.picard_value.tolist())
print(expansion.certificate.valid)
print(majorant.image_bound, majorant.contraction)
print(majorant.picard_tail_bound(4))
print(quadratic_catalan_majorant(1.0, 1.0).certificate.valid)
```

Observed output:

```
[0.11256641000000002] [0.11256641]
True
0.14 0.4
0.004266666666666668
False
```

The shipped `examples/nonlinear_trees_elimination.py` begins with the same tree sum and tail bound before continuing into the correction and elimination APIs documented in Chapter 41.

39.4 Finite abelian gradings

Let Λ be a finite abelian group and let a packet system decompose

$$X = \bigoplus_{g \in \Lambda} X_g.$$

An r-linear operation is grade respecting when

$$\ell_r(X_{g_1}, \dots, X_{g_r}) \subseteq X_{g_1 + \cdots + g_r}.$$

For packet components x_g, the output packet has the finite convolution form

$$(\ell_r \star x)_g = \sum_{g_1 + \cdots + g_r = g} \ell_r(x_{g_1}, \dots, x_{g_r}).$$

The package represents both the group and the packet decomposition explicitly. It does not encode a group label in an array position without checking that the two ordered label sets agree.

Explicit group tables

```
FiniteAbelianGroup(
    labels: Sequence[str],
    addition: Mapping[tuple[str, str], str],
    *,
    zero: str,
    validate: bool = True,
)
```

Labels are stringified, nonempty, and unique. The identity label must be in the label set. The addition mapping must contain every ordered label pair exactly once and every result must remain in the label set. With the default `validate=True`, construction calls an exhaustive certificate that checks:

- left and right identity for every label.
- Existence of a two-sided inverse for every label.
- Commutativity for every ordered pair.
- Associativity for every ordered triple.

The check is exact. For group order q, the table occupies q^2 entries and the exhaustive validation performs $O(q^3)$ additions. **E/M**

The cyclic constructor has the signature

```
cyclic(
    order: int,
    *,
    prefix: str = "",
) -> FiniteAbelianGroup
```

It creates labels `prefix0` through `prefix(order - 1)` and addition modulo the positive integer `order`. The remaining public methods are:

- `add(left: str, right: str) -> str`.
- `sum(labels: Sequence[str]) -> str`, beginning at the declared identity.
- `inverse(label: str) -> str`, found by finite search.
- `certificate() -> Certificate`.
- `to_dict() -> dict[str, Any]`, whose addition keys have the form `g+h`.

`validate=False` permits construction from a closed but otherwise unchecked table. Such an object should not be called a group until `certificate()` has been inspected. `add` raises `ValidationError` for a label outside the table.

Graded operations and finite basis probes

The module-visible callable aliases are:

```
GradedOperationCallable = Callable[[tuple[Any, ...]], Any]
LinearOperation = Callable[[Any], Any]
BracketOperation = Callable[[Any, Any], Any]
```

They are typing conventions in `komorebi_math.nonlinear.graded`, not additional runtime classes and not entries in that module's `__all__` list.

```
GradedPacketOperation(
    group: FiniteAbelianGroup,
    packets: PacketSystem,
    arity: int,
    operation: GradedOperationCallable,
    *,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float | None = None,
    name: str = "graded packet operation",
)
```

The arity is a positive integer. `packets.names` must equal `group.labels` in the same order, and the operation must be callable. `evaluate(arguments)` requires exactly the declared number of vectors and checks every input and the output against the packet dimension.

```
grading_certificate(
    *,
```

```
    max_evaluations: int = 100000,
) -> GradingCertificate
```

This method constructs a basis for every packet range. An exact SymPy backend uses each projector's exact column space. A numerical backend uses left singular vectors whose singular values exceed a tolerance-scaled threshold. For every entered input-label tuple $(g_1, \dots, g_r)$, products of range-basis vectors are evaluated until the budget is exhausted, and every output packet other than $g_1 + \cdots + g_r$ is projected away. The recorded residual is

$$\rho_{\mathrm{grade}} = \max_{\substack{(g_1,\dots,g_r) \\ h \neq g_1+\cdots+g_r}} \|P_h \ell_r(e_1, \dots, e_r)\| .$$

`GradingCertificate` stores:

- `arity: int`.
- `tested_input_labels: int`.
- `forbidden_residual: float`.
- `certificate: Certificate`.

When the finite basis scan completes, this is an exhaustive finite-dimensional multilinearity test provided the callable really is multilinear. If `max_evaluations` stops the scan, `certificate.exactness` becomes `CONDITIONAL` and `complete=False` appears in diagnostics. `tested_input_labels` counts tuples whose scan was entered. The final counted tuple can be only partially evaluated. The record does not identify tuple values individually and reports the remaining work only through a generic unchecked-assumption string. An incomplete valid prefix is not a global grading proof. **E/N/C**

For packet-range dimensions d_g, a complete arity-r scan evaluates

$$N_{\mathrm{basis}} = \sum_{(g_1,\dots,g_r)\in\Lambda^r} \prod_{j=1}^{r} d_{g_j} = \left(\sum_g d_g\right)^r$$

operation calls, with projections onto up to $q-1$ forbidden output packets per call. `max_evaluations` caps operation calls, not projection work. **M**

Packet convolution record

```
GradedPacketOperation.packet_convolution(
    arguments: Sequence[Any],
    output_label: str,
) -> GradedConvolutionResult
```

The method analyzes every full argument into all packet components, enumerates all q^r input-label tuples, retains exactly those whose sum is the requested output label, evaluates and projects those terms, then compares their sum with the same output packet of a direct full-vector evaluation.

For a group, each choice of the first $r-1$ labels determines the last, so there are exactly q^{r-1} retained label terms. The code still enumerates all q^r tuples. The frozen records are:

- `GradedConvolutionTerm(input_labels, value)`.
- `GradedConvolutionResult(output_label, value, direct_value, terms, certificate)`.

The reconstruction residual is

$$\rho_g = \left\| P_g \ell_r(x_1, \dots, x_r) - \sum_{g_1+\cdots+g_r=g} P_g \ell_r(P_{g_1} x_1, \dots, P_{g_r} x_r) \right\| .$$

The certificate checks the finite packet identity at the supplied arguments. It explicitly leaves global grade preservation unchecked. With an exact backend and caller-declared exactness, equality must be exact. Otherwise the declared tolerance is used. **E/N**

39.5 Maurer-Cartan and divided-square packets

For a finite grading and a packet-decomposed element

$$\eta = \sum_{g \in \Lambda} \eta_g,$$

the ordinary finite Maurer-Cartan expression is

$$\mathrm{MC}(\eta) = d\eta + \tfrac{1}{2}[\eta, \eta].$$

Its output packet is assembled as

$$\mathrm{MC}_g = d\eta_g + \tfrac{1}{2} \sum_{a+b=g} [\eta_a, \eta_b].$$

```
maurer_cartan_packets(
    group: FiniteAbelianGroup,
    components: Mapping[str, Any],
    differential: LinearOperation,
    bracket: BracketOperation,
    *,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float = 1e-10,
) -> MaurerCartanResult
```

`components` must contain every group label exactly once. The routine forms each packet equation, sums those equations, independently forms `differential(eta) + bracket(eta, eta)/2`, and compares them. For `Exactness.EXACT`, division by two uses `fractions.Fraction(1, 2)`. For other exactness values it uses the floating scalar `0.5`.

The record `MaurerCartanResult(equations, reconstructed, direct, certificate)` contains both sides. Its certificate checks finite label convolution at the supplied components and leaves linearity of d, bilinearity and grading of the bracket, and any broader differential graded Lie-algebra axioms unchecked. It does not test $d^2 = 0$, graded antisymmetry, or a Jacobi identity. **E/N/C**

Higher finite truncations

For a finite family of declared operations, the implemented expression is

$$\mathrm{MC}^{(R)}(\eta) = \sum_{r=1}^{R} \frac{1}{r!} \ell_r(\eta, \dots, \eta).$$

```
higher_maurer_cartan_packets(
    group: FiniteAbelianGroup,
    components: Mapping[str, Any],
    operations: Mapping[int, GradedOperationCallable],
    *,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float = 1e-10,
) -> HigherMaurerCartanResult
```

Operation labels must be positive integer orders and the mapping must be nonempty. The direct side performs one operation call per declared order. The packet side enumerates q^r ordered label tuples for order r, scales each term by $1/r!$, and places it in the packet indexed by the label sum. The result stores `equations`, `reconstructed`, `direct`, `max_order`, and `certificate`.

This is a finite truncation. It neither supplies nor checks an infinite tail. The certificate lists multilinearity, grading, and convergence of any omitted series as unchecked assumptions. **E/N/C**

Characteristic-sensitive divided squares

When division by two is not appropriate, the package exposes a separate finite polarization path. The caller supplies a map q intended to satisfy

$$q(x+y) = q(x) + q(y) + [x, y].$$

The equation is

$$d\eta + q(\eta).$$

For output grade g, the implementation adds:

$$d\eta_g, \qquad q(\eta_a) \quad \text{when } a + a = g, \qquad [\eta_a, \eta_b] \quad \text{when } a < b \text{ and } a + b = g.$$

The label order used by the final sum is the declared `group.labels` order. Each unordered cross-label pair therefore appears once.

```
divided_square_packets(
    group: FiniteAbelianGroup,
    components: Mapping[str, Any],
    differential: LinearOperation,
    bracket: BracketOperation,
    divided_square: LinearOperation,
    *,
    exactness: Exactness = Exactness.NUMERICAL,
    tolerance: float = 1e-10,
) -> DividedSquareResult
```

`DividedSquareResult` stores `equations`, `reconstructed`, `direct`, and the certificate. The package does not verify the displayed polarization identity or grading compatibility. A successful reconstruction is evidence only at the supplied finite components. **E/N/C**

Exact finite grading example

```
from fractions import Fraction

from komorebi_math import Exactness
from komorebi_math.nonlinear import (
    FiniteAbelianGroup,
    divided_square_packets,
    higher_maurer_cartan_packets,
    maurer_cartan_packets,
)

group = FiniteAbelianGroup.cyclic(3)
components = {"0": Fraction(1), "1": Fraction(2), "2": Fraction(3)}

mc = maurer_cartan_packets(
    group,
    components,
    lambda x: 2 * x,
    lambda x, y: x * y,
    exactness=Exactness.EXACT,
)
higher = higher_maurer_cartan_packets(
    group,
    components,
    {
        1: lambda values: values[0],
```

```
        2: lambda values: values[0] * values[1],
    },
    exactness=Exactness.EXACT,
)
square = divided_square_packets(
    group,
    components,
    lambda x: 3 * x,
    lambda x, y: 2 * x * y,
    lambda x: x * x,
    exactness=Exactness.EXACT,
)

print(group.add("2", "2"), group.inverse("1"), group.certificate().valid)
print(mc.equations, mc.reconstructed, mc.direct, mc.certificate.valid)
print(higher.max_order, higher.reconstructed, higher.direct, higher.certificate.valid)
print(square.reconstructed, square.direct, square.certificate.valid)
```

Observed output:

```
1 2 True
{'0': Fraction(17, 2), '1': Fraction(21, 2), '2': Fraction(11, 1)} 30 30 True
2 24 24 True
54 54 True
```

This example checks exact reconstruction. It is not a claim that the chosen scalar product is a Lie bracket. The distinction illustrates why the result records separate finite reconstruction from unchecked algebraic structure.

Packet-tree reconstruction

The bridge between the tree and grading viewpoints inserts a complete packet identity on every edge of one evaluated tree:

$$\operatorname{val}(\tau) = \sum_{\text{packet labelings } \ell} \operatorname{val}(\tau, \ell).$$

```
packet_tree_reconstruction(
    problem: PolynomialFixedPointProblem,
    tree: OrderedRootedTree,
    packets: PacketSystem,
    *,
    zero_support: Mapping[int, PacketJetSupport] | None = None,
    tolerance: float | None = None,
) -> PacketTreeResult
```

At a leaf, the seed is projected into every packet. At an internal vertex of arity r, the routine recursively obtains packet values for each child, enumerates every input label tuple and every output label, evaluates B_r, and projects the result. A `PacketJetAddress` listed in the supplied `PacketJetSupport.zero` set is skipped. No `unknown` or `untested` address is used for pruning.

`PacketTreeResult` stores `value`, the final `packet_values`, `evaluated_blocks`, `pruned_blocks`, and `certificate`. The certificate compares the synthesized packet value with `problem.tree_value(tree)`. Exactness is `EXACT` only when both the problem declares exactness and the packet backend is exact. It records global correctness of the declared multilinear operations as unchecked. The routine also trusts that any supplied zero-support record is appropriate to the same operation and packet system. It does not verify that provenance relationship itself.

For p packets and an internal vertex of arity r, an unpruned local evaluation performs p^{r+1} projected operation calls. The total depends on the arity profile of the tree. `evaluated_blocks` and `pruned_blocks` provide the realized finite counts. **E/N/M**

40. Defects, obstruction, lifting, and holonomy

One finite diagnostic pattern appears in four settings:

1. Compare a fine nonlinear map with its coarse counterpart.
2. Project a linear correction defect to a cokernel.
3. Solve the residual equation one prime-power layer at a time.
4. Transport local packet fibers around finite graph cycles.

In every setting, a certificate says what was computed and compared. A valid certificate need not say that the computed defect is zero. Solvability is carried by a separate field such as `vanishes`, `lifts`, or the validity of a specific gluing certificate.

The complete records live in `komorebi_math.nonlinear`. The most common constructors are also re-exported from `komorebi_math`:

```
from komorebi_math import (
    LinearLiftProblem,
    LinearObstructionProblem,
    NonlinearPacketMap,
    NonlinearRefinementDefect,
    PolynomialLiftProblem,
    TransportEdge,
    TransportGraph,
    build_lift_tree,
    solve_mod_prime,
)
```

Use the research namespace when type annotations need `ObstructionResult`, `LiftStepResult`, `ModularLinearSolution`, `FundamentalHolonomy`, or `IntertwiningResult`.

40.1 Nonlinear packet maps and refinement defects

This section separates packet-coordinate conjugation, whose certificate checks a reconstructed finite evaluation, from refinement comparison, whose computed defect can be valid evidence without vanishing.

Packet coordinate conjugation

Let source and target packet systems provide analysis and synthesis maps A_X, S_X, A_Y, S_Y. A nonlinear map $F : X \to Y$ has packet-coordinate form

$$\widehat{F} = A_Y \circ F \circ S_X.$$

`NonlinearPacketMap` evaluates precisely this finite conjugation:

```
NonlinearPacketMap(
    function: Callable[[Any], Any],
    source: PacketSystem,
    target: PacketSystem,
    name: str = "nonlinear packet map",
)
```

Source and target must use the same backend name. The method signatures are:

```
__call__(
    coordinates: PacketCoordinates,
) -> PacketCoordinates

apply(vector: Any) -> Any

certificate(vector: Any) -> Certificate

iterate(
    coordinates: PacketCoordinates,
    count: int,
) -> PacketCoordinates

fixed_point_residual(
    coordinates: PacketCoordinates,
) -> ComputationResult[Any]
```

`__call__` reconstructs source coordinates, evaluates the function, validates the target dimension, and analyzes the output. `apply` performs the ambient function evaluation after source and target dimension checks. `certificate` compares direct ambient evaluation with packet-coordinate evaluation. `iterate` and `fixed_point_residual` require equivalent source and target systems.

The coordinate-conjugacy residual is

$$\rho_{\mathrm{coord}} = \left\| F(x) - S_Y \widehat{F}(A_X x) \right\|.$$

It is exact for an exact backend and numerical otherwise, using the larger of the source and target packet tolerances. **E/N**

The fixed-point method returns

$$r = \widehat{F}(\hat{x}) - \hat{x}$$

after reconstruction to ambient coordinates. Its `certificate.valid` is always `True` once the residual has been computed. The norm is stored under `fixed_point_residual_norm`. Validity does not assert $r = 0$ and does not assert that the input is a fixed point.

Refinement defect

For fine and coarse maps

$$F_f : X_f \to Y_f, \qquad F_c : X_c \to Y_c,$$

with linear coarsening maps $C_X : X_f \to X_c$ and $C_Y : Y_f \to Y_c$, the pointwise defect is

$$\delta_{C_X, C_Y}(F)(x) = C_Y F_f(x) - F_c(C_X x).$$

```
NonlinearRefinementDefect(
    fine_map: Callable[[Any], Any],
    coarse_map: Callable[[Any], Any],
    coarsen_source: Any,
    coarsen_target: Any,
)
```

A coarsening map may be callable or matrix-like. The implementation converts the final difference to a NumPy array.

- `evaluate(point: Any) -> np.ndarray` returns the defect vector.

- `norm(point: Any) -> float` returns its Euclidean norm.
- `composition_identity(...) -> ComputationResult[np.ndarray]` evaluates the finite composition law and compares it with an independently evaluated composite defect.
- `iterated_orbit_bound(...) -> float` computes the declared orbit estimate.
- `fixed_point_bound(...) -> float` computes the declared fixed-point estimate.

Their complete signatures are:

```
composition_identity(
    outer_fine: Callable[[Any], Any],
    outer_coarse: Callable[[Any], Any],
    outer_coarsen_target: Any,
    point: Any,
) -> ComputationResult[np.ndarray]

iterated_orbit_bound(
    point: Any,
    *,
    iterations: int,
    coarse_lipschitz: float,
) -> float

fixed_point_bound(
    fine_fixed_point: Any,
    *,
    coarse_contraction: float,
    verify_fixed_point: bool = True,
    tolerance: float = 1e-10,
) -> float
```

For the composition $G \circ F$, the code evaluates

$$\delta(G \circ F)(x) = \delta(G)(F_f(x)) + G_c(F_c(C_X x) + \delta(F)(x)) - G_c(F_c(C_X x))$$

and compares it pointwise with the direct composite defect. The returned certificate is always numerical with tolerance 10^{-10}. This is a finite identity at one point, not a regularity theorem. **N**

For the implemented orbit and fixed-point bounds, take endomaps with a common coarsening $C_X = C_Y =: C$, and write $\delta_C = \delta_{C,C}$. If F_c is L-Lipschitz and

$$\varepsilon_j = \|\delta_C(F)(F_f^j(x))\|,$$

then

$$\|CF_f^n(x) - F_c^n(Cx)\| \le \sum_{j=0}^{n-1} L^{n-1-j}\varepsilon_j.$$

`iterated_orbit_bound` returns exactly the right-hand finite sum. It rejects a negative iteration count or negative declared Lipschitz constant, but it does not test the Lipschitz inequality. **C**

If x_f is a fine fixed point and F_c contracts by $q < 1$, then for a coarse fixed point x_c,

$$\|Cx_f - x_c\| \le \frac{\|\delta_C(F)(x_f)\|}{1-q}.$$

`fixed_point_bound` requires $0 \le q < 1$. By default it checks $\|F_f(x_f) - x_f\| \le$ `tolerance` and raises `ValidationError` when that finite fixed-point test fails. Setting `verify_fixed_point=False` skips that check and makes the conclusion explicitly dependent on the caller's claim. It does not find x_c, test global contraction, or prove uniqueness. **C**

```
import numpy as np

from komorebi_math.nonlinear import NonlinearRefinementDefect

defect = NonlinearRefinementDefect(
    fine_map=lambda x: np.asarray(x),
    coarse_map=lambda y: 0.5 * np.asarray(y),
    coarsen_source=np.array([[1.0, 1.0]]),
    coarsen_target=np.array([[1.0, 1.0]]),
)
point = np.array([2.0, 4.0])

print(defect.evaluate(point).tolist())
print(defect.fixed_point_bound(point, coarse_contraction=0.5))
```

Observed output:

```
[3.0]
6.0
```

40.2 Linear obstruction problems

Given a finite linear correction map $D : X \to Y$ and defect $\delta \in Y$, the correction problem is

$$Du = -\delta.$$

Its obstruction class is the image of δ in the cokernel:

$$\mathrm{ob}(\delta) = \pi_{\operatorname{coker} D}(\delta).$$

Finite-dimensional linear algebra gives

$$\mathrm{ob}(\delta) = 0 \iff \delta \in \operatorname{im} D, \qquad u = u_0 + \ker D.$$

```
LinearObstructionProblem(
    correction_map: Any,
    defect: Any,
    *,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float = 1e-10,
)
```

The correction map is converted to a backend matrix, the defect to a backend vector, and their codomain dimensions must agree. `solve() -> ObstructionResult` dispatches to an exact SymPy path when the backend name is `"sympy"`. Other backends use the numerical least-squares path.

`ObstructionResult` is a frozen, slotted record with:

- `vanishes: bool` for the actual finite solvability decision.
- `obstruction_coordinates: tuple[Any, ...]` in a computed left-nullspace basis.
- `cokernel_dimension: int`.
- `correction: Any | None`, present only when `vanishes` is true.
- `kernel_basis: tuple[Any, ...]`.
- `residual: float`.
- `certificate: Certificate`.
- `require_correction() -> Any`, which requires the certificate and then rejects a nonzero obstruction.

Exact SymPy branch

The exact branch compares

$$\operatorname{rank} D \quad \text{and} \quad \operatorname{rank}[D \mid -\delta].$$

It computes a basis z_j for $\ker D^{\mathsf{T}}$ and stores

$$c_j = z_j^{\mathsf{T}} \delta.$$

When solvable, SymPy's parametric Gauss-Jordan result is specialized by setting all free parameters to zero, yielding one correction. The separately stored kernel basis describes the remaining affine freedom. The exact certificate requires equivalence between zero obstruction coordinates and the rank decision, plus zero correction residual. **E**

The obstruction coordinates depend on the basis returned by the backend. Their individual values are not canonical invariants, while the vanishing of all coordinates is.

Numerical branch

The numerical branch computes a least-squares correction, sets

$$r = \|Du + \delta\|_2, \qquad \texttt{vanishes} \iff r \le \tau,$$

and obtains numerical kernel and left-nullspace bases through the selected backend. It records

$$c_{\max} = \max_j |\langle z_j, \delta \rangle|.$$

The certificate verifies that `c_max <= 10 * tolerance` agrees with the least-squares vanishing decision. It can therefore be invalid when the two numerical rank diagnostics disagree near a threshold. A successful certificate records consistency of the finite numerical diagnostics. It does not prove rank stability under perturbation. **N**

Obstruction squares

A correction square consists of horizontal maps $D_s : X_s \to Y_s$ and $D_t : X_t \to Y_t$, together with vertical maps $C_X : X_s \to X_t$ and $C_Y : Y_s \to Y_t$.

It induces a map of obstruction classes only when

$$C_Y D_s = D_t C_X.$$

```
ObstructionSquare(
    source_correction: Any,
    target_correction: Any,
    source_map: Any,
    target_map: Any,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float = 1e-10,
)
```

This is a frozen, slotted record. `certificate()` checks all four matrix dimensions and computes

$$\rho_{\square} = \|C_Y D_s - D_t C_X\|.$$

`transport_defect(defect)` first requires that certificate, then returns $C_Y \delta$. An invalid square therefore cannot silently transport a defect. The exact backend requires zero residual. A numerical backend uses the stored tolerance. **E/N**

Exact obstruction example

```
import sympy as sp

from komorebi_math.nonlinear import LinearObstructionProblem

obstructed = LinearObstructionProblem(
    sp.Matrix([[1, 0], [0, 0]]),
    sp.Matrix([0, 1]),
    backend="sympy",
).solve()
solvable = LinearObstructionProblem(
    sp.Matrix([[1, 0], [0, 0]]),
    sp.Matrix([1, 0]),
    backend="sympy",
).solve()

print(obstructed.vanishes, obstructed.obstruction_coordinates)
print(solvable.vanishes, tuple(solvable.require_correction()))
```

Observed output:

```
False (1,)
True (-1, 0)
```

40.3 Linear and polynomial lift problems

Prime-power lifting replaces one large congruence by a sequence of exact correction problems over the residual field $\mathbb{F}_p$. The package requires `prime` to be mathematically prime. Composite moduli are rejected rather than passed to row reduction with noninvertible pivots.

Linear systems over a prime field

```
solve_mod_prime(
    matrix: Any,
    rhs: Any,
    prime: int,
) -> ModularLinearSolution
```

The inputs are converted to exact integral object arrays and reduced modulo p. Nonintegral entries are rejected. Exact Gauss-Jordan elimination then describes

$$Au = b \pmod{p}.$$

When it is solvable, the output has affine form

$$u = u_0 + \sum_{j=1}^{\nu} c_j k_j, \qquad c_j \in \mathbb{F}_p, \qquad N_{\mathrm{sol}} = p^{\nu}.$$

The frozen record

```
ModularLinearSolution(
    prime: int,
    solvable: bool,
    particular: tuple[int, ...] | None,
    kernel_basis: tuple[tuple[int, ...], ...],
    pivot_columns: tuple[int, ...],
```

```
    obstruction_rows: tuple[int, ...],
)
```

also exposes `nullity -> int`, `solution_count -> int`, and `enumerate(*, limit: int = 100000) -> tuple[tuple[int, ...], ...]`. An inconsistent reduced row is recorded in `obstruction_rows`. In that case `particular` is `None`, the kernel record is empty, `solution_count` is zero, and enumeration returns an empty tuple.

For a solvable system, enumeration rejects a solution count above the explicit limit, then traverses all coefficient tuples in lexicographic product order. The row reduction cost is the usual finite dense elimination cost, while full enumeration has unavoidable output size p^{ν}. **E/M**

One linear lift step

Suppose

$$Ax_k = b \pmod{p^k}.$$

Every child modulo p^{k+1} has the form

$$x_{k+1} = x_k + p^k u,$$

and the divided residual is

$$r_k = \frac{Ax_k - b}{p^k} \pmod{p}.$$

Substitution gives the residual-field equation

$$Au = -r_k \pmod{p}.$$

```
LinearLiftProblem(
    matrix: Any,
    rhs: Any,
    point: Any,
    *,
    prime: int,
    depth: int,
)

.step(*, enumerate_limit: int = 100000) -> LiftStepResult
```

Dimensions must agree, the prime must pass the primality guard, and the depth must be positive. `step` first verifies the current congruence modulo p^k. It solves the correction equation, enumerates its affine solution space, constructs all children in canonical residues modulo p^{k+1}, and directly verifies every child.

`LiftStepResult` stores:

- `prime`, `depth`, and the current `point`.
- `residual`, the divided residual modulo p.
- `correction_space: ModularLinearSolution`.
- `children: tuple[tuple[int, ...], ...]`.
- `certificate: Certificate`.
- `lifts -> bool`, an alias for `correction_space.solvable`.

An obstructed step can have no children and still have a valid certificate: the exact certificate says that the complete empty lift space was computed correctly. `lifts`, not certificate validity alone, answers the existence question. **E**

Polynomial one-step law

For an integer polynomial-like callable F and a supplied Jacobian J_F, assume

$$F(x_k) = 0 \pmod{p^k}.$$

The first-order congruence is

$$F(x_k + p^k u) \equiv F(x_k) + p^k J_F(x_k) u \pmod{p^{k+1}}.$$

Therefore the correction equation is

$$J_F(x_k) u = -\frac{F(x_k)}{p^k} \pmod{p}.$$

```
PolynomialLiftProblem(
    function: Callable[[tuple[int, ...]], Iterable[int]],
    jacobian: Callable[[tuple[int, ...]], Any],
    point: Any,
    *,
    prime: int,
    depth: int,
)

.step(
    *,
    enumerate_limit: int = 100000,
    linearization_limit: int = 100000,
    assume_valid_jacobian: bool = False,
) -> LiftStepResult
```

The current function value must be divisible by p^k, and the Jacobian shape must be `number_of_equations x number_of_variables`. Let d be the number of variables. By default the method exhaustively checks the supplied first-order law for all p^d residual corrections. For every $u \in \{0, \dots, p-1\}^d$, it verifies both congruence preservation through depth k and

$$\frac{F(x_k + p^k u) - F(x_k)}{p^k} \equiv J_F(x_k) u \pmod{p}.$$

This exhaustive finite check is exact. A wrong Jacobian or a callable that fails the required congruence law raises `ValidationError` before the lift space is returned. **E**

When $p^d >$ `linearization_limit`, the default path raises `ValueError` and reports the required correction count. Setting `assume_valid_jacobian=True` allows the step to continue. Every computed child is still checked directly modulo p^{k+1}, but the result exactness becomes `CONDITIONAL` and the full Jacobian law appears in `assumptions_unchecked`. This flag is a visible trust boundary, not a faster exact proof. **C**

Lift behavior example

```
import numpy as np

from komorebi_math.nonlinear import PolynomialLiftProblem, solve_mod_prime

affine = solve_mod_prime(
    [[1, 1, 0], [0, 1, 1]],
    [1, 0],
    3,
)
unique = PolynomialLiftProblem(
```

```
    lambda x: (x[0] * x[0] - 2,),
    lambda x: [[2 * x[0]]],
    [3],
    prime=7,
    depth=1,
).step()
branching = PolynomialLiftProblem(
    lambda x: (x[0] * x[0],),
    lambda x: [[2 * x[0]]],
    [0],
    prime=2,
    depth=1,
).step()
conditional = PolynomialLiftProblem(
    lambda x: tuple(x),
    lambda x: np.eye(len(x), dtype=int),
    [0] * 8,
    prime=3,
    depth=1,
).step(
    linearization_limit=100,
    assume_valid_jacobian=True,
)

print(affine.solution_count, affine.enumerate())
print(unique.children, branching.children)
print(
    conditional.certificate.exactness.value,
    conditional.certificate.diagnostics["residual_correction_count"],
)
```

Observed output:

```
3 ((1, 0, 0), (2, 2, 1), (0, 1, 2))
((10,),) ((0,), (2,))
conditional 6561
```

The first polynomial has one lift from $3 \pmod 7$ to $10 \pmod{49}$. The singular binary example branches. The eight-variable identity example shows the explicit conditional boundary without pretending that 6,561 Jacobian tests were executed.

40.4 Prime-power lift trees

Repeated one-step lifting produces a finite rooted forest whose level k contains congruence classes modulo p^k. The data structures are intentionally finite:

```
LiftTreeNode(
    value: tuple[int, ...],
    depth: int,
    parent_index: int | None,
)

FiniteLiftTree(
    prime: int,
    levels: tuple[tuple[LiftTreeNode, ...], ...],
)
```

Every stored node depth must be positive and the tree prime must pass the primality guard. `FiniteLiftTree.max_depth -> int` returns the depth of the first node in the final stored level when that level is nonempty, and zero when

the final stored level is empty. `terminal_branches() -> tuple[tuple[LiftTreeNode, ...], ...]` follows the parent indices of every node in the last level back to a root.

```
build_lift_tree(
    problem_factory: Callable[
        [tuple[int, ...], int],
        LinearLiftProblem | PolynomialLiftProblem,
    ],
    roots: Iterable[tuple[int, ...]],
    *,
    prime: int,
    start_depth: int,
    max_depth: int,
    max_nodes: int = 100000,
) -> FiniteLiftTree
```

The start depth must be positive, the maximum depth cannot precede it, and the node limit must be positive. For each current node the factory receives the node value and depth. Its returned problem must use the same prime. The builder requires the one-step certificate, appends every child with its parent index, and stops early when a level is empty. It raises before returning a forest whose cumulative node count exceeds `max_nodes`.

If a node has correction nullity ν, it can produce p^{ν} children. For level sizes n_k, storage is

$$N_{\text{nodes}} = \sum_{k} n_k,$$

and the exact work includes one residual-field solve plus explicit child verification for every expanded node. `max_nodes` caps stored nodes and is also passed as the per-step correction enumeration limit. **E/M**

The finite conclusion is intentionally narrow:

> A nonempty tree through depth K proves that the displayed residue classes lift through p^K. It does not prove that any branch continues through all depths, converges to a p-adic solution, or is unique beyond the finite tree.

```
from komorebi_math.nonlinear import (
    PolynomialLiftProblem,
    build_lift_tree,
)

F = lambda x: (x[0] * x[0] - 1,)
J = lambda x: [[2 * x[0]]]

tree = build_lift_tree(
    lambda point, depth: PolynomialLiftProblem(
        F, J, point, prime=3, depth=depth
    ),
    [(1,), (2,)],
    prime=3,
    start_depth=1,
    max_depth=4,
)

print(tuple(len(level) for level in tree.levels))
print(len(tree.terminal_branches()))
```

Observed output:

```
(2, 2, 2, 2)
2
```

The shipped `examples/obstruction_lifting.py` extends this calculation through depth five and prints:

```
obstruction coordinates: (1,)
lift levels: 5
terminal branches: 2
```

40.5 Transport graphs and finite holonomy

A `TransportGraph` attaches one finite-dimensional model fiber to every vertex of a connected finite graph. An oriented edge $e : v \to w$ carries an invertible matrix

$$T_e : X_v \to X_w.$$

The graph uses edge orientations for matrix transport but treats each edge as traversable in both directions while finding a spanning tree. Reverse traversal uses T_e^{-1}.

The primary records are:

```
TransportEdge(
    source: str,
    target: str,
    matrix: Any,
    name: str = "",
)

FundamentalHolonomy(
    edge_index: int,
    source: str,
    target: str,
    matrix: Any,
)

IntertwiningResult(
    intertwiners: Mapping[str, Any],
    edge_residuals: Mapping[str, float],
    cycle_residuals: Mapping[str, float],
    certificate: Certificate,
)
```

`TransportEdge.reversed_name() -> str` returns the explicit edge name when present and otherwise the string `target->source`. Certificate keys do not use that helper. They use `TransportGraph.edge_label(index)`, which returns `name[index]` or `edge[index]`. The index keeps parallel or duplicate-named edges distinct.

```
TransportGraph(
    vertices: Iterable[str],
    edges: Iterable[TransportEdge],
    *,
    backend: str | LinearAlgebraBackend | None = None,
    tolerance: float = 1e-10,
)
```

Vertex names are stringified and deduplicated in first-occurrence order. The set must be nonempty. Every edge endpoint must be known, every transport must be square and invertible in the chosen backend, all edge matrices

must share one dimension, and the underlying undirected multigraph must be connected. A single vertex with no edges is accepted with model dimension one. A graph with multiple vertices and no edges is rejected.

Spanning-tree normalization

Choose a root r. Breadth-first traversal produces a parent relation and a tuple of tree-edge indices. Let

$$S_v : X_r \to X_v$$

be the ordered product of edge transports or inverses along the tree path. Then:

- `spanning_tree(root=None)` returns the parent mapping and tree-edge tuple.
- `tree_transports(root=None) -> dict[str, Any]` returns all S_v.
- `tree_gauge(root=None) -> dict[str, Any]` returns S_v^{-1}, which normalizes every tree transport to the identity.

For vertex gauges G_v, `gauge_transform(gauges)` requires one invertible matrix of the common fiber dimension at every vertex and applies

$$T_e \longmapsto G_w T_e G_v^{-1}.$$

The returned graph is a new validated `TransportGraph`. The original is not mutated. **E/N**

Fundamental cycles and gluing

Every non-tree edge $e : v \to w$ closes one based fundamental cycle. Its holonomy at the root is

$$H_e = S_w^{-1} T_e S_v.$$

```
TransportGraph.fundamental_holonomies(
    root: str | None = None,
) -> tuple[FundamentalHolonomy, ...]
```

For a connected multigraph, the number of returned cycles is

$$\beta_1 = |E| - |V| + 1.$$

Parallel edges and self-loops are retained as distinct edges and therefore can contribute cycles. `gluing_certificate(root=None)` compares every fundamental holonomy with the identity:

$$\rho_e = \|H_e - I\|, \qquad \text{glues} \iff \rho_e = 0 \text{ for all non-tree } e.$$

The equality is exact for an exact backend and tolerance-based otherwise. A tree has no non-tree edges, so the empty residual mapping is valid and $\beta_1 = 0$. For a fixed root and traversal tree, the criterion is finite and complete for this transport graph. **E/N**

Under the displayed gauge action, based holonomy transforms by conjugation:

$$H_e \longmapsto G_r H_e G_r^{-1}.$$

Thus identity holonomy and the gluing decision are gauge invariant, although the matrix entries of a nontrivial holonomy depend on the root gauge.

Intertwining two systems

Suppose T_e and T'_e use the same ordered graph, backend, and fiber dimension. Given a root map $R : X_r \to X'_r$, the tree paths propagate vertex maps

$$R_v = S'_v R S_v^{-1}.$$

Global intertwining requires

$$R_w T_e = T'_e R_v$$

on every edge. On the fundamental cycles it equivalently requires

$$R H_e = H'_e R.$$

```
TransportGraph.intertwine(
    other: TransportGraph,
    root_intertwiner: Any,
    *,
    root: str | None = None,
) -> IntertwiningResult
```

The method checks identical ordered vertices, edge counts and orientations, backend names, and dimensions. It stores both per-edge and per-cycle residuals. The certificate is valid only when both sets pass exact or numerical comparison. A root map need not be invertible. It is an intertwiner, not a gauge. **E/N**

Holonomy example

```
import numpy as np

from komorebi_math import TransportEdge, TransportGraph

A = np.array([[1.0, 1.0], [0.0, 1.0]])
B = np.array([[1.0, 0.0], [1.0, 1.0]])
C = B @ A

graph = TransportGraph(
    ("a", "b", "c"),
    (
        TransportEdge("a", "b", A, "ab"),
        TransportEdge("b", "c", B, "bc"),
        TransportEdge("a", "c", C, "ac"),
    ),
)
gauges = {
    "a": np.eye(2),
    "b": np.diag([2.0, 1.0]),
    "c": np.diag([1.0, 3.0]),
}
transformed = graph.gauge_transform(gauges)

broken = TransportGraph(
    ("a", "b", "c"),
    (
        TransportEdge("a", "b", A, "ab"),
        TransportEdge("b", "c", B, "bc"),
        TransportEdge("a", "c", 2.0 * C, "ac"),
    ),
)
```

```
print(len(graph.fundamental_holonomies()), graph.gluing_certificate().valid)
print(transformed.gluing_certificate().valid)
print(broken.gluing_certificate().residuals)
```

Observed output:

```
1 True
True
{'bc[1]': 0.7071067811865476}
```

The non-tree edge is `bc[1]` for the breadth-first spanning tree selected from the root `a`. `ac` is a tree edge in that traversal. The broken cycle is still detected. A fundamental-cycle label describes the chosen tree presentation, not a claim that the named edge alone caused the inconsistency.

The shipped `examples/holonomy.py` exercises the same gluing, gauge, and broken cycle paths and prints:

```
fundamental cycles: 1
gauge invariant gluing: True
broken cycle detected: True
```

40.6 Failure behavior and certificate reading

The most important negative paths are deliberate and typed:

- `ValidationError`: malformed tree arity, invalid group table, a composite declared prime, mismatched packet labels, wrong source coordinates, a non-fixed fine point, a nonzero obstruction passed to `require_correction`, a noncommuting obstruction square, a current point that is not a solution at its declared depth, a bad Jacobian law, a lift-tree prime mismatch, an edge referencing an unknown graph vertex, a disconnected graph, a multivertex graph with no edges, or an incomplete gauge mapping.
- `DimensionError`: nonlinear output dimension mismatch, obstruction codomain mismatch, correction-square shape mismatch, lift matrix/vector mismatch, Jacobian shape mismatch, nonsquare or inconsistent transport dimensions, or a wrong root-intertwiner shape.
- `ValueError`: nonpositive lift depth, an enumerated affine space above its limit, an unverified polynomial linearization above its limit, an invalid depth interval or node limit, a graph with no vertices, or a noncontractive fixed-point bound.
- `KeyError`: an unknown root passed to the spanning-tree routines.
- Backend linear-algebra failure: singular transport or gauge matrices are rejected when the backend inverse is attempted.
- `Certificate.require()`: an invalid finite tree comparison, majorant, grading test, reconstruction, obstruction consistency check, lift-child verification, gluing condition, or intertwining condition raises through the common certificate mechanism.

Several result fields answer questions that certificate validity does not:

- `MajorantConvergence.certificate.valid` says whether the scalar contraction checks pass, still conditional on the declared operator bounds.
- `ComputationResult` from `fixed_point_residual` is valid because the residual was computed, not because it is zero.
- `ObstructionResult.certificate.valid` checks the obstruction computation, while `vanishes` decides solvability.
- `LiftStepResult.certificate.valid` checks the computed child set, while `lifts` decides whether that set is nonempty.
- `TransportGraph.gluing_certificate().valid` itself is the zero-holonomy decision because that particular certificate is defined around vanishing cycle residuals.

40.7 Public records and import tiers

For compact reference, the Chapter 39 records are:

- trees: `OrderedRootedTree`, `TreeTerm`, `TreeExpansionResult`, `MajorantConvergence`, and `PacketTreeResult`.
- Gradings: `FiniteAbelianGroup`, `GradingCertificate`, `GradedConvolutionTerm`, and `GradedConvolutionResult`.
- Maurer-Cartan: `MaurerCartanResult`, `HigherMaurerCartanResult`, and `DividedSquareResult`.

The Chapter 40 records are:

- coordinates and defects: `NonlinearPacketMap` and `NonlinearRefinementDefect`.
- Obstruction: `LinearObstructionProblem`, `ObstructionResult`, and `ObstructionSquare`.
- Lifting: `ModularLinearSolution`, `LiftStepResult`, `LinearLiftProblem`, `PolynomialLiftProblem`, `LiftTreeNode`, and `FiniteLiftTree`.
- Transport: `TransportEdge`, `FundamentalHolonomy`, `IntertwiningResult`, and `TransportGraph`.

Every Chapter 40 record and operation is research-only in `1.0.0b4`. None is in the curated `komorebi_math.beta` or `komorebi_math.stable` manifest. Pin the package version when any of these signatures forms an application contract.

Use these import tiers:

```
# Preferred complete research surface
from komorebi_math import nonlinear

# Convenient promoted constructors
from komorebi_math import PolynomialFixedPointProblem, TransportGraph

# Module-specific typing aliases or implementation-focused inspection
from komorebi_math.nonlinear import graded, lifting, trees
```

`komorebi_math.nonlinear` is the supported broad namespace for this edition. Importing private helpers such as `_normalize_arities`, `_as_int_vector`, or `_oriented_adjacency` binds an application to implementation details and is not recommended.

40.8 Cost and storage summary

These are structural models, not performance promises:

- height-bounded tree enumeration stores N_h trees with $N_h = 1 + \sum_r N_{h-1}^r$.
- A binary leaf-bounded family stores C_{n-1} trees.
- A retained tree expansion stores one result per enumerated tree and reevaluates common subtrees across distinct terms.
- An unpruned packet-tree vertex of arity r over p packets performs p^{r+1} projected operation evaluations.
- A finite group table stores q^2 additions and its exhaustive certificate performs $O(q^3)$ table operations.
- A complete graded basis probe performs d^r operation evaluations for total packet dimension d, plus forbidden-packet projections.
- Higher Maurer-Cartan assembly enumerates q^r label tuples at every retained order r.
- Numerical obstruction uses dense least squares and nullspaces, while the exact path uses symbolic ranks, nullspaces, and a parametric solve.
- One lift step uses finite-field elimination plus up to p^ν explicit children. Polynomial Jacobian validation uses p^d residual corrections.
- A lift tree stores every generated node through the declared depth.
- Spanning-tree transport uses $|V|-1$ tree edges, and fundamental holonomy computes $|E|-|V|+1$ cycle matrices with dense matrix inversions and products.

For large workloads, the decisive controls are `max_trees`, `max_evaluations`, `enumerate_limit`, `linearization_limit`, and `max_nodes`. They guard different stages and are not interchangeable.

40.9 Version-specific source observations

These observations describe version `1.0.0b4`. They are not expanded input contracts:

1. Provenance identifiers collide across modules. `PSC-III-D13` labels both the ordered-tree definition and the linear obstruction datum, while `PSC-III-T14` labels both majorant convergence and the cokernel criterion. Attached `PSC-III-T41` records both nonlinear Schur elimination and the fundamental-holonomy intertwining criterion. Emitted runtime identifiers also collide at `PSC-III-T40` and `PSC-III-T41` between elimination and holonomy. The computations and test suites remain distinct, but consumers should qualify a theorem string by its emitting symbol rather than use the string alone as a globally unique evidence key.
2. `NonlinearPacketMap.iterate` rejects a negative count but does not perform the explicit integral/boolean normalization used by the tree APIs. A nonintegral value therefore reaches Python's `range` behavior, and a boolean acts as zero or one. Pass a genuine nonnegative integer.
3. `NonlinearRefinementDefect` relies on NumPy operations and does not perform a complete constructor-time dimension or finiteness audit. Validate custom callables, matrix shapes, Lipschitz constants, and sampled outputs at the application boundary.
4. `LinearObstructionProblem`, graded constructors, Maurer-Cartan helpers, and `TransportGraph` do not uniformly reject every nonfinite or negative tolerance at construction. Use a finite nonnegative tolerance.
5. The lifting conversion accepts values according to Python's integral equality test, so booleans can pass as zero or one. The lift-problem depth is checked for positivity and then converted with `int`, rather than being guarded with the strict integer check used by tree depth. Supply genuine integers for coefficients, points, and depths.
6. `PolynomialLiftProblem` converts values returned by `function` with `int` without first checking equality with the original values. A nonintegral callable result can therefore be truncated before congruence tests. Ensure that the callable returns genuine integer values.
7. `terminal_branches()` follows only nodes in the final stored level. A branch that dies while another branch continues is not returned. If all branches die, `build_lift_tree` appends an empty final level, `FiniteLiftTree.max_depth` reports zero, and `terminal_branches()` returns no branches even though earlier levels contain nodes. Inspect `levels` and one-step child sets directly when terminal failures are part of the analysis.
8. `ordered_trees_with_leaves` enforces `max_trees` after generating its cached family. Use an independently computed Catalan or recurrence bound before a large leaf request.
9. Exactness on polynomial tree and graded/Maurer-Cartan APIs is caller declared. Marking floating data as `Exactness.EXACT` does not turn it into exact arithmetic or verify multilinearity.
10. A supplied packet zero-support record is used for pruning by matching addresses. The tree routine does not prove that the record was generated from the same operation, point, and packet system.
11. `TransportGraph` chooses a deterministic breadth-first spanning tree from the stored vertex and edge order. Fundamental holonomy matrices and their edge labels can change with this presentation, while the trivial-holonomy gluing decision remains invariant.

Treat these as narrow source-audit notes. Future releases may strengthen the guards without preserving the weak behaviors.

40.10 Executed verification ledger

The chapter was checked against the shipped source rather than only against the symbolic topology.

- Focused tests executed: `test_nonlinear_trees.py`, `test_nonlinear_graded.py`, `test_nonlinear_coordinates_defects.py`, `test_nonlinear_obstruction.py`, `test_lifting.py`, and `test_holonomy.py`.
- Result: **41 passed in 2.99 seconds**.
- Shipped examples executed successfully: `nonlinear_trees_elimination.py`, `obstruction_lifting.py`, and `holonomy.py`.
- The exact and numerical panels printed in this chapter were rerun under CPython `3.12.13`, NumPy `2.5.2`, SymPy `1.14.0`, and pytest `9.1.1`.
- No optional JAX, PyTorch, or CuPy path is required by Chapters 39 through 40.

This evidence establishes parity with the finite shipped implementation on the executed platform. It does not turn the conditional majorant, Lipschitz, Jacobian-trust, or infinite-lift hypotheses into verified global theorems.

41. Correction and elimination

A nonlinear equation can be reduced through four certified routes. The routes are different by design. A Hilbert obstruction projector asks whether a linear defect lies in an image. A right inverse supplies a contraction map for a nonlinear correction. Lyapunov-Schmidt reduction separates kernel and cokernel coordinates near a root. Nonlinear Schur elimination solves a hidden equation and substitutes its local branch into a retained equation. They share matrix operations, but they do not share the same hypotheses or the same meaning of success.

What you know	Route	What remains to be checked
A linear correction map and a defect	Hilbert obstruction projector	Whether `vanishes` is true
A right inverse and a justified Lipschitz bound	Right-inverse correction	The ball hypothesis and returned equation residual
A root and its derivative, possibly rank deficient	Lyapunov-Schmidt reduction	The reduced obstruction after solving the range equation
Retained and hidden equations with an invertible hidden derivative	Nonlinear Schur elimination	The hidden solve and the retained reduced equation

Choose the route from the available hypotheses before choosing a solver. For example, solving the range equation in Lyapunov-Schmidt reduction removes one part of the problem; the remaining obstruction is still an equation to solve, not an error message to suppress.

The implementation is finite-dimensional. Its numerical paths use NumPy complex arrays and singular-value or Newton computations. Its exact Schur path is available when both derivative providers are exact and SymPy is installed. The routines never establish a global implicit branch, a global Lipschitz bound, or rank stability merely by returning a valid finite certificate.

The primary imports are:

```
from komorebi_math.nonlinear import (
    HilbertObstructionProjector,
    LyapunovSchmidtReduction,
    NonlinearSchurElimination,
    RightInverseCorrectionProblem,
)
```

Those four operational classes are also re-exported from `komorebi_math`. Their result-record classes are exported from `komorebi_math.nonlinear`, while the defining modules are `komorebi_math.nonlinear.correction` and `komorebi_math.nonlinear.elimination`. None of the Chapter 41 objects belongs to the curated `komorebi_math.beta` or `komorebi_math.stable` namespace in version `1.0.0b4`. They are implemented research APIs, so applications should pin the package version if reflected signatures are part of their contract.

The chapter uses the common Part VII claim labels:

- **E** means an exact finite algebraic identity.
- **N** means a finite numerical identity accepted relative to a tolerance.
- **C** means a conclusion that still depends on displayed local or analytic assumptions.
- **O** means an optional backend path.
- **I** means integrity or reproducibility evidence, not authorship.

41.1 Hilbert obstruction projectors

This first correction route isolates the component of a declared defect outside the numerically resolved image and reports solvability separately from the validity of the projection computation.

41.1.1 Image, cokernel, and least-norm correction

Let $D : X \to Y$ be represented by an $m \times n$ complex matrix. A full singular-value decomposition resolves a numerical rank r:

$$D = U\Sigma V^*, \qquad U_r = U[:, 0 : r].$$

The implementation forms the orthogonal image and cokernel projectors

$$\Pi_{\text{im}} = U_r U_r^*, \qquad \Pi_{\text{coker}} = I - \Pi_{\text{im}}, \qquad o = \Pi_{\text{coker}}\delta.$$

Here I is the codomain identity I_Y. The obstruction norm is the distance from $-\delta$ to the image of D:

$$\|o\| = \operatorname{dist}(-\delta, \operatorname{im} D), \qquad u_* = -D^+\delta \quad (\|o\| \le \varepsilon).$$

If the resolved obstruction vanishes, the least-norm correction is

$$u_* = -D^+\delta, \qquad Du_* + \delta \approx 0.$$

Here D^+ is NumPy's Moore-Penrose pseudoinverse. The finite-dimensional projection identities are classical. The runtime claim is **N** because the rank, pseudoinverse, and residuals depend on floating singular values and a declared threshold.

`HilbertObstructionProjector` sets

$$\tau_{\text{rank}} = \max\{\tau, \tau\sigma_1\}$$

when singular values exist, and counts values strictly above that threshold. It stores the full `U` and `V` bases because `numpy.linalg.svd` is called with `full_matrices=True`. Consequently, both the kernel and cokernel bases remain available even for a rectangular map.

41.1.2 Result semantics

The result makes obstruction and certificate validity separate facts:

- `vanishes` means $\|o\|_2 \le \tau$.
- `least_norm_correction` is an array only when `vanishes` is true.
- `correction_residual` is $\|Du_* + \delta\|_2$ in the solvable case and $\|o\|_2$ in the obstructed case.
- `certificate.valid` checks the orthogonal distance identity and, when a correction exists, its residual.

An obstructed problem can therefore have a valid certificate. That certificate means that the obstruction was computed consistently. It does not mean that the obstruction vanishes. Code that tests only `result.certificate.valid` will misclassify an honestly certified obstruction as solvable.

The certificate uses theorem identifier `PSC-III-T31`. It records numerical exactness, `correction_residual`, `distance_identity`, the resolved rank, kernel dimension, cokernel dimension, and obstruction norm. Rank stability below the singular-value threshold remains unchecked.

41.1.3 Runnable projection example

```
from komorebi_math.nonlinear import HilbertObstructionProjector

projector = HilbertObstructionProjector(
    [[1.0, 0.0], [0.0, 0.0]],
    tolerance=1e-10,
)

obstructed = projector.solve([0.0, 1.0])
removable = projector.solve([2.0, 0.0])

print(
    obstructed.vanishes,
    obstructed.obstruction_norm,
    obstructed.least_norm_correction,
    obstructed.certificate.valid,
)
print(
    removable.vanishes,
    removable.obstruction_norm,
    removable.least_norm_correction,
    removable.certificate.valid,
)
```

Observed with NumPy `2.5.2`:

```
False 1.0 None True
True 0.0 [-2.+0.j  0.+0.j] True
```

The first line is the important one. The calculation is valid and the equation is obstructed.

41.1.4 Construction and failure boundary

Construction rejects a nonmatrix correction map with `DimensionError`, a negative or nonfinite tolerance with `ValidationError`, and `solve` rejects a defect whose flattened vector dimension is not m. A row or column vector with one singleton axis is flattened. Other two-dimensional shapes are not. Nonfinite defect entries are rejected.

The object does not check that the supplied matrix is a derivative of any nonlinear map. It solves only the displayed finite linear obstruction problem. It also cannot distinguish a true zero singular value from a numerically small one without the caller's rank-scale judgment.

41.2 Right-inverse corrections

41.2.1 Quantitative contraction problem

`RightInverseCorrectionProblem` addresses

$$Dx + N(x) = y,$$

where $D : X \to Y$, $R : Y \to X$, and $N : X \to Y$. Its fixed-point map is

$$\Phi(x) = R(y - N(x)), \qquad x_{m+1} = \Phi(x_m), \qquad x_0 = 0.$$

The constructor receives a radius $R_0 > 0$ and a declared Lipschitz bound $L_N \geq 0$. The hypothesis certificate checks

$$DR = I, \qquad q = \|R\|L_N < 1, \qquad \|R(y - N(0))\| \le (1 - q)R_0.$$

The last inequality places the center displacement inside the contraction ball. The code checks the inequality only at the center. The assertion that L_N bounds N throughout the whole ball is explicitly unchecked, so the existence and uniqueness conclusion remains **C** even though the residual arithmetic is **N**.

The reported target stability estimate is

$$\|x(y) - x(\tilde{y})\| \le \frac{\|R\|}{1 - q}\|y - \tilde{y}\|.$$

`target_stability_bound(target_distance)` evaluates the right-hand side for a caller-supplied nonnegative scalar distance. It does not solve a second target problem or independently verify the distance.

41.2.2 Hypothesis and solution certificates

`hypothesis_certificate()` uses theorem identifier `PSC-III-T32`. Its residual ledger contains:

- `right_inverse`: $\|DR - I_Y\|_2$
- `invariant_ball_excess`: $\max(0, \|R(y - N(0))\|_2 - (1 - q)R_0)$

Its diagnostics include the right-inverse norm, declared Lipschitz bound, contraction factor, center norm, and radius. The certificate is invalid if the right-inverse residual exceeds 10τ, $q \ge 1$, or the ball excess exceeds τ.

`solve(max_iterations=10000)` first calls that certificate's `require()`. Each accepted iterate must remain within $R_0 + 10\tau$. The resulting `RightInverseCorrectionResult` stores the solution, iteration count, contraction factor, equation residual, fixed-point residual, and a second certificate. Reaching the iteration cap does not itself raise an exception. It returns a result whose certificate is invalid when convergence residuals do not pass.

41.2.3 Runnable scalar correction

For

$$x + 0.2x^2 = 0.1,$$

the root near zero is

$$x_* = \frac{-1 + \sqrt{1.08}}{0.4}.$$

```python
import numpy as np

from komorebi_math.nonlinear import RightInverseCorrectionProblem

problem = RightInverseCorrectionProblem(
    np.eye(1),
    np.eye(1),
    lambda x: 0.2 * x * x,
    [0.1],
    radius=0.2,
    lipschitz_bound=0.08,
    tolerance=1e-13,
)

hypotheses = problem.hypothesis_certificate()
result = problem.solve()

print(hypotheses.valid, hypotheses.diagnostics["contraction_factor"])
print(result.solution.tolist())
```

```
print(result.iterations, f"{result.equation_residual:.3e}")
print(problem.target_stability_bound(0.01))
```

Observed output:

```
True 0.08
[0.09807621135331551]
10 4.441e-16
0.010869565217391304
```

41.2.4 Failure example

```
import numpy as np

from komorebi_math.exceptions import ValidationError
from komorebi_math.nonlinear import RightInverseCorrectionProblem

bad = RightInverseCorrectionProblem(
    np.eye(1),
    np.eye(1),
    lambda x: 0.7 * x,
    [0.1],
    radius=1.0,
    lipschitz_bound=1.0,
)

print(bad.hypothesis_certificate().valid)
try:
    bad.solve()
except ValidationError as error:
    print(type(error).__name__, str(error))
```

The certificate is false because $q = 1$. `solve` then raises `ValidationError` with the certificate message. This is an assumption failure, not evidence that the equation has no solution by another method.

41.3 Lyapunov-Schmidt reduction

41.3.1 SVD splitting at a root

Let $F : X \to Y$, let x_0 satisfy $F(x_0) = 0$, and put

$$L = DF(x_0).$$

The numerical singular-value decomposition supplies orthonormal splittings

$$X = \ker L \oplus X_1, \qquad Y = \operatorname{im} L \oplus C.$$

Write the corresponding basis matrices as K, X_1, R, and C. For kernel coordinates κ and complement coordinates ξ, the ambient point is

$$x = x_0 + K\kappa + X_1\xi.$$

The range equation is

$$\Pi_{\mathrm{im}} F(x_0 + K\kappa + X_1\xi) = 0.$$

In the stored orthonormal range coordinates, this is equivalently

$$R^*F(x_0 + K\kappa + X_1\xi) = 0.$$

When a local implicit branch exists, solving it gives

$$\xi = \psi(\kappa), \qquad \kappa_{\text{red}}(\kappa) = \Pi_C F(x_0 + K\kappa + X_1\psi(\kappa)).$$

The stored obstruction coordinates are $C^*F(x_0 + K\kappa + X_1\psi(\kappa))$.

At the base point the resolved kernel and cokernel identities imply

$$D\psi(0) = 0, \qquad D\kappa_{\text{red}}(0) = 0.$$

The identities are classical. This implementation is **N/C** because it resolves rank numerically and assumes that rank and the local branch remain well behaved away from the base point.

41.3.2 Constructor state

`LyapunovSchmidtReduction(provider, base_point, tolerance=1e-10)` requires a positive-dimensional provider with first derivatives. It evaluates the base value and rejects the point unless

$$\|F(x_0)\|_2 \le 10\tau.$$

It constructs a Jacobian by calling the provider once on each standard basis direction, then stores:

- `linearization`
- `rank`
- `kernel_basis` and `kernel_dimension`
- `complement_basis` and `complement_dimension`
- `range_basis`
- `obstruction_basis` and `obstruction_dimension`
- `decomposition`, a `LyapunovSchmidtDecomposition` record

The decomposition certificate has theorem identifier `PSC-III-T33`. It checks that R^*LX_1 is invertible on the resolved rank block. Its unchecked assumption is neighborhood rank stability.

41.3.3 Damped range solve

`solve_range` fixes κ, initializes ξ, and applies Newton's method to the range equation. At every iteration it builds the full provider Jacobian and restricts it to

$$R^*DF(x)X_1.$$

A backtracking factor begins at one and is halved at most twenty times until the range residual decreases. A singular restricted Jacobian or a step that cannot reduce the residual raises `ValidationError`. Exhausting the outer iteration limit returns a `LyapunovSchmidtPoint` with an invalid certificate if the final range residual exceeds 10τ.

The returned `reduced_obstruction` is the cokernel coordinate

$$C^*F(x).$$

It need not vanish. A valid point certificate means the range equation was eliminated. Solutions of the original equation are precisely the computed branch points for which this remaining reduced obstruction also vanishes.

`base_derivative_certificate()` checks the displayed base derivative identities from the SVD splitting. It does not finite-difference the computed branch. `reduced_second_derivative(left, right)` requires provider order two and returns

$$C^* D^2 F(x_0)[Kh, Kk]$$

inside `ComputationResult[np.ndarray]`. The provider's declared second derivative correctness remains unchecked. That result uses theorem identifier `PSC-III-C34`.

41.3.4 Quadratic obstruction example

Consider

$$F(x_1, x_2) = (x_2, x_1^2).$$

At the origin, the kernel is the x_1-axis and the obstruction space is the second target coordinate. The one-coordinate reduced equation is

$$\kappa_{\mathrm{red}}(\kappa) = \kappa^2.$$

```
import numpy as np

from komorebi_math import Exactness
from komorebi_math.nonlinear import (
    CallableDerivativeProvider,
    LyapunovSchmidtReduction,
)

provider = CallableDerivativeProvider(
    lambda x: np.array([x[1], x[0] ** 2]),
    {
        1: lambda x, d: np.array(
            [d[0][1], 2 * x[0] * d[0][0]]
        ),
        2: lambda x, d: np.array(
            [0.0, 2 * d[0][0] * d[1][0]]
        ),
    },
    source_dimension=2,
    target_dimension=2,
    exactness=Exactness.NUMERICAL,
)

reduction = LyapunovSchmidtReduction(
    provider,
    [0.0, 0.0],
    tolerance=1e-12,
)
point = reduction.solve_range([0.3])
quadratic = reduction.reduced_second_derivative([1.0], [1.0])

print(
    reduction.rank,
    reduction.kernel_dimension,
    reduction.obstruction_dimension,
)
print(point.complement_coordinates.tolist())
print(point.reduced_obstruction.tolist(), point.certificate.valid)
print(quadratic.value.tolist(), quadratic.certificate.valid)
```

Observed output:

```
1 1 1
[0.0]
[0.09] True
[2.0] True
```

The valid point at $\kappa = 0.3$ is not a root. It lies on the eliminated range branch and retains the nonzero scalar obstruction 0.09.

41.4 Nonlinear Schur elimination

41.4.1 Retained and hidden equations

Split a variable as $x = (u, v)$, where $u \in \mathbb{K}^{d_P}$ is retained and $v \in \mathbb{K}^{d_Q}$ is hidden. Split the equation as

$$F(u, v) = (F_P(u, v), F_Q(u, v)).$$

At a base point (u_0, v_0), require

$$F_Q(u_0, v_0) = 0, \qquad D_v F_Q(u_0, v_0) \text{ invertible.}$$

The local implicit branch $v = \phi(u)$ then satisfies

$$Dv = -(D_v F_Q)^{-1} D_u F_Q, \qquad F_{\text{red}}(u) = F_P(u, v(u)).$$

Writing that branch as $v = \phi(u)$, the first identity becomes

$$D\phi = -(D_v F_Q)^{-1} D_u F_Q.$$

The reduced retained map

$$F_{\text{red}}(u) = F_P(u, \phi(u))$$

has derivative

$$DF_{\text{red}} = D_u F_P + D_v F_P Dv.$$

Equivalently, in the ϕ notation,

$$DF_{\text{red}} = D_u F_P + D_v F_P D\phi = D_u F_P - D_v F_P (D_v F_Q)^{-1} D_u F_Q.$$

This is the nonlinear analogue of a Schur complement. The finite derivative formula is **E** when both providers are exact SymPy providers, and **N** for numerical providers. The assertion that these derivatives arise from a local branch remains **C**.

41.4.2 Second-order formula

For retained directions h, k, lift them to tangent directions on the branch:

$$\tilde{h} = (h, D\phi[h]), \qquad \tilde{k} = (k, D\phi[k]).$$

Differentiating the hidden equation twice gives

$$D^2 v[h,k] = -(D_v F_Q)^{-1} D^2 F_Q[(h, Dv[h]), (k, Dv[k])],$$

In the ϕ notation this is

$$D^2\phi[h,k] = -(D_v F_Q)^{-1} D^2 F_Q[\tilde{h}, \tilde{k}].$$

Therefore

$$D^2 F_{\text{red}}[h,k] = D^2 F_P[(h, Dv[h]), (k, Dv[k])] + D_v F_P D^2 v[h,k].$$

The equivalent lifted-direction form used by the implementation is

$$D^2 F_{\text{red}}[h,k] = D^2 F_P[\tilde{h}, \tilde{k}] + D_v F_P D^2\phi[h,k].$$

The implementation also assembles the equivalent displayed subtraction form and certifies that both finite expressions agree. This check cannot detect a shared error in the supplied second-derivative providers.

41.4.3 Exact and numerical modes

The constructor decides its mode from the two providers:

- if both providers declare `Exactness.EXACT`, inputs and derivatives are represented as SymPy matrices and the certificate exactness is `exact`
- otherwise, both blocks are evaluated through complex NumPy arrays and the certificate exactness is `numerical`

Both providers must use the concatenated source dimension $d_P + d_Q$. The hidden provider's target dimension must equal d_Q. The retained provider may have an arbitrary positive target dimension.

`first_derivatives()` returns the hidden Jacobian, its inverse, the implicit derivative, the reduced derivative, and a certificate with theorem identifier `PSC-III-T41`. `second_derivative(left, right)` returns the two lifted directions, the implicit second derivative, the reduced second derivative, and a certificate with theorem identifier `PSC-III-T42`.

`solve_hidden` is intentionally numerical only. For a fixed retained value it uses damped Newton iteration on $F_Q(u, v) = 0$, with at most twenty-four backtracking trials per outer iteration. Exact-mode callers must supply or manipulate a symbolic branch externally. `reduced_value` first requires a valid hidden solve and then evaluates F_P on that point. The numerical hidden-solve and reduced-value certificates use the historical theorem identifier `PSC-III-T40`.

41.4.4 Exact second-order example

This example requires the optional SymPy dependency.

```
import sympy as sp

from komorebi_math.nonlinear import (
    NonlinearSchurElimination,
    SympyDerivativeProvider,
)

u, v = sp.symbols("u v")
```

```
retained = SympyDerivativeProvider(
    (3 * u + 2 * v + u * v + v**2,),
    (u, v),
)
hidden = SympyDerivativeProvider(
    (v - 4 * u + u**2 + u * v,),
    (u, v),
)

problem = NonlinearSchurElimination(
    retained,
    hidden,
    1,
    1,
    sp.Matrix([0]),
    sp.Matrix([0]),
)

first = problem.first_derivatives()
second = problem.second_derivative(sp.Matrix([1]), sp.Matrix([1]))

print(list(first.implicit_derivative))
print(list(first.reduced_derivative))
print(list(second.implicit_second_derivative))
print(list(second.reduced_second_derivative))
print(first.certificate.exactness.value)
```

Observed with SymPy `1.14.0`:

```
[4]
[11]
[-10]
[20]
exact
```

41.4.5 Numerical hidden branch

For the same hidden equation, the branch is available explicitly as

$$v(u) = \frac{4u - u^2}{1 + u}$$

near zero. The focused package test evaluates `solve_hidden([0.05])` and matches this expression to absolute tolerance 10^{-12}. A valid numerical certificate checks only the returned hidden residual. It leaves uniqueness, the size of the implicit neighborhood, and absence of remote solutions unchecked.

41.5 Public signature ledger

These signatures are the reflected version `1.0.0b4` contracts. Type annotations are descriptive runtime annotations, not automatic validators.

41.5.1 Correction surface

```
HilbertObstructionProjector(
    correction_map: Any,
    *,
    tolerance: float = 1e-10,
)
    .solve(defect: Any) -> HilbertObstructionResult
```

```
RightInverseCorrectionProblem(
    linear_map: Any,
    right_inverse: Any,
    nonlinear: Callable[[np.ndarray], Any],
    target: Any,
    *,
    radius: float,
    lipschitz_bound: float,
    tolerance: float = 1e-10,
)
    .hypothesis_certificate() -> Certificate
    .solve(
        *,
        max_iterations: int = 10000,
    ) -> RightInverseCorrectionResult
    .target_stability_bound(
        target_distance: float,
    ) -> float
```

```
LyapunovSchmidtReduction(
    provider: DerivativeProvider,
    base_point: Any,
    *,
    tolerance: float = 1e-10,
)
    .solve_range(
        kernel_coordinates: Any,
        *,
        initial_complement: Any | None = None,
        max_iterations: int = 50,
    ) -> LyapunovSchmidtPoint
    .base_derivative_certificate() -> Certificate
    .reduced_second_derivative(
        left: Any,
        right: Any,
    ) -> ComputationResult[np.ndarray]
```

41.5.2 Elimination surface

```
NonlinearSchurElimination(
    retained_provider: DerivativeProvider,
    hidden_provider: DerivativeProvider,
    retained_dimension: int,
    hidden_dimension: int,
    base_retained: Any,
    base_hidden: Any,
    *,
    tolerance: float = 1e-10,
)
    .first_derivatives() -> SchurDerivativeResult
    .second_derivative(
        left: Any,
        right: Any,
    ) -> SchurSecondDerivativeResult
    .solve_hidden(
        retained_value: Any,
        *,
        initial_hidden: Any | None = None,
        max_iterations: int = 50,
```

```
    ) -> HiddenSolveResult
    .reduced_value(
        retained_value: Any,
        *,
        initial_hidden: Any | None = None,
        max_iterations: int = 50,
    ) -> ComputationResult[np.ndarray]
```

41.6 Result-record ledger

All named records below are frozen, slotted dataclasses. Their NumPy arrays remain mutable objects, so `frozen=True` prevents field reassignment but does not make array storage immutable.

- `HilbertObstructionResult`
  - `obstruction`
  - `obstruction_norm`
  - `vanishes`
  - `least_norm_correction`
  - `correction_residual`
  - `certificate`
- `RightInverseCorrectionResult`
  - `solution`
  - `iterations`
  - `contraction_factor`
  - `equation_residual`
  - `fixed_point_residual`
  - `certificate`
- `LyapunovSchmidtDecomposition`
  - `linearization`
  - `kernel_basis`
  - `complement_basis`
  - `range_basis`
  - `obstruction_basis`
  - `rank`
  - `certificate`
- `LyapunovSchmidtPoint`
  - `kernel_coordinates`
  - `complement_coordinates`
  - `point`
  - `reduced_obstruction`
  - `range_residual`
  - `iterations`
  - `certificate`
- `SchurDerivativeResult`
  - `hidden_jacobian`
  - `hidden_inverse`
  - `implicit_derivative`
  - `reduced_derivative`
  - `certificate`
- `SchurSecondDerivativeResult`
  - `lifted_left`

    - `lifted_right`
    - `implicit_second_derivative`
    - `reduced_second_derivative`
    - `certificate`
- `HiddenSolveResult`
    - `hidden`
    - `point`
    - `residual`
    - `iterations`
    - `certificate`

There are no registered package portable codecs for these Chapter 41 records in this release. If they must cross a process boundary, serialize a deliberate schema containing array dtype, shape, real and imaginary components, theorem identifier, and certificate fields. A raw dataclass conversion is not by itself a stable persistence contract.

41.7 Error and certificate interpretation

41.7.1 Exception families

- `DimensionError` reports array dimensionality, vector length, or concatenated-domain shape disagreement.
- `ValidationError` reports nonfinite values, invalid tolerances, missing derivative orders, an uncertified contraction, a bad base root, a singular numerical Jacobian, a failed damped step, or an exact-mode request for the numerical hidden solver.
- Calling `.require()` on an invalid `Certificate` also raises `ValidationError` with the certificate message.
- SymPy is optional. Exact provider construction without it follows that provider's `BackendUnavailableError` path.

An iteration limit is not uniformly an exception boundary. Both the right-inverse solver and the two Newton solvers may return an invalid result certificate after reaching the cap. Singular linear systems and failed backtracking steps raise immediately.

41.7.2 Certificate decision sequence

For safe use, test the facts in this order:

1. Require or inspect the computational certificate.
2. Inspect the semantic flag or residual that represents the mathematical question, such as `vanishes` or `reduced_obstruction`.
3. Inspect `assumptions_unchecked` before promoting a local calculation to a local existence statement.
4. Preserve theorem identifiers and tolerance metadata with reported results.

Neither a valid obstruction certificate nor a valid range-elimination certificate asserts that the original nonlinear equation is solved.

41.8 Cost and storage model

Let $D \in \mathbb{C}^{m\times n}$, let d_X and d_Y be provider dimensions, let r be a resolved rank, and let d_Q be the hidden dimension.

- Hilbert obstruction construction performs one full SVD and one pseudoinverse. Dense arithmetic is on the order of $O(mn\min(m,n))$, while full bases and projectors require $O(m^2+n^2+mn)$ storage.
- One Hilbert `solve` applies dense projectors and, when solvable, the pseudoinverse. It is $O(m^2+mn)$ with the stored matrices.
- A right-inverse hypothesis check takes dense operator norms and matrix products. Each fixed-point iteration performs one nonlinear evaluation and one multiplication by R. Runtime therefore scales linearly with the observed iteration count, apart from the user callback.
- Lyapunov-Schmidt construction calls the first derivative once per source basis vector and performs a full SVD of a $d_Y \times d_X$ Jacobian. Each Newton iteration rebuilds that Jacobian, solves an $r \times r$ system, and may perform up to twenty extra value evaluations for damping.

- First-order Schur assembly makes $d_P + d_Q$ directional derivative calls for each equation provider and inverts a $d_Q \times d_Q$ matrix. The dense inversion cost is $O(d_Q^3)$.
- Second-order Schur assembly adds one second-derivative call per equation block and dense feedback products.
- A numerical hidden solve rebuilds d_Q hidden Jacobian columns per outer iteration, solves one $d_Q \times d_Q$ system, and may make up to twenty-four damping evaluations.

No Chapter 41 routine is sparse-aware. Passing a sparse mathematical problem through these APIs materializes dense NumPy or SymPy matrices.

41.9 Version-specific source observations

These boundaries were reproduced against version `1.0.0b4` and should be treated as source observations rather than desired future guarantees:

1. `HilbertObstructionProjector` permits `tolerance=0`. Its internal distance comparison still uses a 10^{-14} numerical floor, while the emitted certificate tolerance is zero.
2. Obstructed Hilbert and filtered correction results can carry valid certificates. This is intentional but easy to misuse if `vanishes` is not checked.
3. A right-inverse Lipschitz bound is declared, not sampled or proved. The target stability helper accepts a scalar distance and does not compare two solved targets.
4. `base_derivative_certificate()` constructs $D\psi(0) = 0$ from the resolved splitting. It does not differentiate the numerical branch returned by `solve_range`.
5. Schur exactness is selected only when both providers declare exactness. Automatic hidden solving is unavailable in that mode.
6. A singular exact SymPy hidden derivative currently exposes SymPy's `NonInvertibleMatrixError`, while the numerical path normalizes a singular inverse to `ValidationError`.
7. None of the local numerical solvers establishes global uniqueness or finds disconnected solution branches.

41.10 Verification record

The focused correction and elimination test module passed **5/5** tests in the recorded guide qualification environment. The shipped `nonlinear_trees_elimination.py` example also passed and printed:

```
finite tree sum: 0.11256641000000002

```

The installed advanced nonlinear verifier passed its correction, Lyapunov-Schmidt, and nonlinear Schur checks. These are finite regression results. They do not replace the unchecked local hypotheses displayed above.

42. Filtered lifting and finite spectral sequences

Chapter 42 moves from numerical Hilbert spaces to exact linear algebra over a prime field. A finite decreasing filtration records successive depths of information. A correction problem solves one associated-graded equation. A branch verifier checks compatibility through a finite terminal depth. A filtered cochain complex exposes exact spectral-sequence pages. Only the final projective-limit helper crosses beyond finite data, and it does so through a `ConditionalResult` whose infinite hypotheses remain explicit.

The primary operational imports are:

```
from komorebi_math.nonlinear import (
    FilteredCorrectionProblem,
    FilteredVectorSpace,
    FiniteFilteredCochainComplex,
    conditional_projective_limit_completion,
    verify_finite_filtered_branch,
)
```

All five names are also available from `komorebi_math`. Result records and page records are exported from `komorebi_math.nonlinear`, with definitions in `komorebi_math.nonlinear.filtered`. These objects are not included in the curated beta or stable namespace in version `1.0.0b4`.

All finite filtration, correction, branch, and cochain computations in this chapter use exact row reduction modulo a validated prime p. Their **E** label refers to that finite field computation. It does not mean that an integer, rational, p-adic, or topological object has been reconstructed beyond the explicit finite model.

Keep the two depths separate. A filtration depth identifies a level of the supplied finite space. A spectral-sequence page identifies a stage of the associated cohomology calculation. The examples start with small spaces so both can be inspected directly. Retain the actual basis and differential matrices as well as the displayed dimensions; dimensions alone do not reconstruct the computation.

42.1 Filtered vector spaces

42.1.1 Finite decreasing filtration

A `FilteredVectorSpace` represents

$$V = F^0V \supseteq F^1V \supseteq \cdots \supseteq F^NV = 0, \qquad \mathrm{gr}^k V = F^kV/F^{k+1}V.$$

over $\mathbf{F}_p$. Every level is supplied as an ambient-coordinate basis matrix. Construction reduces its columns to a basis by modular row reduction, then verifies:

- depths are contiguous from zero
- $F^0V = V$
- every $F^{k+1}V$ is contained in F^kV
- the final declared level is the zero subspace
- p is prime

Because quotient elements are represented computationally, the runtime chooses a deterministic complement basis inside the supplied column ordering. It extends a basis of $F^{k+1}V$ with independent columns from F^kV. The resulting `graded_basis(k)` consists of ambient representatives of a quotient basis. It is not a canonical basis independent of the input coordinates and column order.

For $v \in F^k V$, `graded_coordinates(v, k)` solves

$$v = G_k c + B_{k+1} b \pmod{p},$$

where G_k is the selected graded complement and B_{k+1} is a basis of the deeper level. It returns c. Conversely,

$$\text{lift_graded}(c, k) = G_k c \pmod{p}.$$

The lift is a selected representative. Adding any vector from $F^{k+1} V$ represents the same graded class.

42.1.2 Weight constructor

`FilteredVectorSpace.from_weights(weights, prime=p)` assigns a nonnegative integer weight w_i to each coordinate and constructs

$$F^k V = \text{span}\{e_i : w_i \geq k\}.$$

The terminal depth is

$$N = 1 + \max_i w_i,$$

with the empty-coordinate default producing a zero-dimensional space with terminal depth one. The constructor requires every weight to be an actual nonnegative integer and rejects booleans.

For weights `(0, 1)` over $\mathbf{F}_5$,

$$\dim F^0 V = 2, \qquad \dim F^1 V = 1, \qquad \dim F^2 V = 0,$$

and both graded pieces have dimension one.

```
from komorebi_math.nonlinear import FilteredVectorSpace

space = FilteredVectorSpace.from_weights([0, 1], prime=5)

print(tuple(space.dimension_at(k) for k in range(3)))
print(tuple(space.graded_dimension(k) for k in range(2)))
print(space.graded_coordinates([3, 4], 0).tolist())
print(space.graded_coordinates([0, 4], 1).tolist())
print(space.lift_graded([3], 0).tolist())
print(space.lift_graded([4], 1).tolist())
print(space.certificate().exactness.value)
```

Observed output:

```
(2, 1, 0)
(1, 1)
[3]
[4]
[3, 0]
[0, 4]
exact
```

42.1.3 Depth behavior

`basis(depth)` returns a copy. Depths at or below zero select F^0V, while depths at or above the terminal depth select the zero space. Consequently `dimension_at` and `contains` use the same clamped behavior. By contrast, `graded_basis(depth)` returns a zero-column basis outside $0 \le k < N$.

`certificate()` uses theorem identifier `PSC-III-D50`. It has exactness `exact`, no tolerance, and diagnostics for the prime, ambient dimension, terminal depth, and all level dimensions.

42.2 Filtered correction problems

42.2.1 One-depth obstruction equation

Let $D : V \to W$ preserve the relevant filtration levels, and let

$$\delta \in F^k W.$$

A depth-k correction seeks a graded class $[u] \in \mathrm{gr}^k V$ such that

$$\mathrm{gr}^k D([u]) = -[\delta], \qquad \delta + Du \in F^{k+1}W.$$

For any lifted representative $u \in F^k V$, this is equivalent to the second relation in the display.

`FilteredCorrectionProblem` first checks filtration preservation at both depths k and $k+1$:

$$D(F^j V) \subseteq F^j W, \qquad j \in \{k, k+1\}.$$

It then constructs the induced matrix between the selected graded bases, computes the defect's graded coordinates, and calls exact modular row reduction to solve the affine equation.

42.2.2 Correction coset

The solution is a `ModularLinearSolution`:

$$c = c_0 + \sum_{i=1}^{\nu} a_i z_i, \qquad a_i \in \mathbf{F}_p.$$

Its nullity is ν, and its solution count is

$$N_{\mathrm{corr}} = \begin{cases} 0, & \text{if obstructed,} \\ p^{\nu}, & \text{if solvable.} \end{cases}$$

`solve(enumerate_limit=100000)` enumerates the entire correction coset only when this count does not exceed the guard. Every class is lifted to an ambient tuple, and every enumerated representative is checked to improve the defect by one level.

The result's property

```
DepthObstructionResult.vanishes
```

is exactly `correction_space.solvable`. As in Chapter 41, an obstructed result can carry a valid certificate. Its valid certificate means the finite obstruction and empty correction set were computed consistently.

The certificate uses theorem identifier `PSC-III-T51` and records the depth, obstruction status, kernel dimension, solution count, and a child-verification residual.

42.2.3 Solvable and obstructed example

```
import numpy as np

from komorebi_math.nonlinear import (
    FilteredCorrectionProblem,
    FilteredVectorSpace,
)

source = FilteredVectorSpace.from_weights([0, 1], prime=5)
target = FilteredVectorSpace.from_weights([0, 1], prime=5)

blocked = FilteredCorrectionProblem(
    source,
    target,
    np.diag([1, 0]),
    [0, 1],
    1,
).solve()

solved = FilteredCorrectionProblem(
    source,
    target,
    np.eye(2, dtype=int),
    [0, 1],
    1,
).solve()

print(blocked.vanishes, blocked.correction_representatives)
print(blocked.certificate.valid)
print(solved.vanishes, solved.correction_representatives)
print(solved.certificate.valid)
```

Observed output:

```
False ()
True
True ((0, 4),)
True
```

The representative `(0, 4)` changes the defect `(0, 1)` to zero modulo five. The obstructed result is still an exact and valid description of the failed graded equation.

42.2.4 Failure boundary

Construction rejects different source and target primes, a correction matrix with the wrong shape, a defect with the wrong dimension, and a depth outside the common associated-graded range. `induced_map()` raises `ValidationError` when D does not preserve the two required levels. `solve()` raises when the defect is not in its declared depth.

The enumeration guard currently comes from `ModularLinearSolution.enumerate`. If p^{ν} exceeds the limit, it raises built-in `ValueError` rather than the package's `ResourceLimitError`. A caller that expects large correction spaces should inspect `correction_space.solution_count` through a lower-level solve or choose a safe guard explicitly rather than requesting accidental exhaustive enumeration.

42.3 Finite filtered cochain complexes

42.3.1 Complex and filtration contract

A `FiniteFilteredCochainComplex` represents a bounded finite cochain complex

$$\cdots \xrightarrow{d^{n-1}} C^n \xrightarrow{d^n} C^{n+1} \to \cdots, \qquad d^{n+1}d^n = 0, \qquad d(F^pC^n) \subseteq F^pC^{n+1}.$$

The complex is over one prime field and carries a common finite decreasing filtration in every declared degree. Each differential must preserve every filtration level as displayed.

The constructor accepts explicit degree dimensions, any supplied differentials, and one `FilteredVectorSpace` per degree. A missing differential is interpreted as the appropriately shaped zero map when queried through `differential(degree)`.

It rejects inconsistent dimensions, absent filtrations, mixed primes, unequal terminal depths, differential shapes that disagree with adjacent dimensions, failure of $d^2 = 0$, and any filtration-nonpreserving differential.

42.3.2 Implemented finite subquotients

Let the total cochain degree be $n = p + q$. The implementation defines

$$Z_r^{p,n} = \{x \in F^pC^n : dx \in F^{p+r}C^{n+1}\}, \qquad B_r^{p,n} = F^pC^n \cap d(F^{p-r}C^{n-1}).$$

At page zero,

$$E_0^{p,q} = F^pC^{p+q}/F^{p+1}C^{p+q}.$$

For $r \geq 1$, the source implements the finite subquotient

$$E_r^{p,q} = Z_r^{p,p+q} \Big/ \left(Z_{r-1}^{p+1,p+q} + B_{r-1}^{p,p+q}\right).$$

The page differential has bidegree

$$d_r : E_r^{p,q} \to E_r^{p+r,q-r+1}.$$

All subspaces, intersections, preimages, images, quotients, and ranks are computed by exact modular row reduction. The implementation raises `ArithmeticError` if an internally assembled quotient denominator is not contained in its numerator. That exception signals an invariant failure in the page construction, not ordinary user input validation.

42.3.3 Page certificate

For every bidegree, the page checks

$$\dim E_{r+1}^{p,q} = \dim E_r^{p,q} - \operatorname{rank} d_r^{p,q} - \operatorname{rank} d_r^{p-r,q+r-1}.$$

`SpectralSequencePage` stores all nonzero or incident entries, its total dimension, the sum of outgoing differential ranks, and an exact certificate. `page.entry(p, q)` returns the matching entry. If no stored entry exists, it returns a synthetic zero-dimensional entry on that page rather than `None`.

The page certificate uses theorem identifier `PSC-III-S54`. It records the number of failed page-cohomology relations and diagnostics for page number, entry count, total dimension, and total differential rank.

42.3.4 Finite convergence

The runtime constructs pages

$$E_0, E_1, \dots, E_N$$

through the common terminal filtration depth. It computes ordinary cohomology dimensions as

$$\dim H^n(C) = \dim C^n - \operatorname{rank} d^n - \operatorname{rank} d^{n-1},$$

using the already validated relation $d^n d^{n-1} = 0$. The terminal check is

$$\sum_{p+q=n} \dim E_\infty^{p,q} = \dim H^n(C), \qquad \operatorname{rank} d_\infty = 0.$$

In the finite implementation, E_N supplies the limiting page. The `FilteredSpectralSequenceResult` certificate is valid only when every page certificate is valid, all terminal differential ranks vanish, and limiting dimensions match ordinary cohomology dimensions.

This is an exact theorem about the explicit bounded finite filtered complex. It does not claim convergence of an unbounded or topological spectral sequence.

42.3.5 Nonzero differential example

This two-term complex has a nonzero d_1 cancellation.

```
import numpy as np

from komorebi_math.nonlinear import (
    FilteredVectorSpace,
    FiniteFilteredCochainComplex,
)

c0 = FilteredVectorSpace(
    1,
    {
        0: np.eye(1, dtype=int),
        1: np.zeros((1, 0), dtype=int),
        2: np.zeros((1, 0), dtype=int),
    },
    prime=5,
)
c1 = FilteredVectorSpace.from_weights([1], prime=5)

complex_ = FiniteFilteredCochainComplex(
    {0: 1, 1: 1},
    {0: [[1]]},
    {0: c0, 1: c1},
    prime=5,
)

result = complex_.spectral_sequence()

print(
    [
        (page.page, page.total_dimension, page.total_differential_rank)
        for page in result.pages
    ]
)
print(result.total_cohomology_dimensions)
print(result.limiting_dimensions)
print(result.certificate.valid)
```

Observed output:

```
[(0, 2, 0), (1, 2, 1), (2, 0, 0)]
{0: 0, 1: 0}
{0: 0, 1: 0}
True
```

The page-zero rank is zero because d_0 preserves filtration degree. The nonzero map appears at d_1, after which both classes cancel.

42.4 Branch verification

This section verifies a caller-supplied finite branch one filtration level at a time. It does not construct the branch or promote a finite terminal check to an infinite convergence claim.

42.4.1 Finite compatible branches

Given a map $F : V \to W$, a finite branch beginning at depth k_0 is a sequence

$$x_{k_0}, x_{k_0+1}, \dots, x_{k_1}$$

that should satisfy

$$F(x_k) \in F^k W, \qquad x_{k+1} - x_k \in F^k V.$$

`verify_finite_filtered_branch` evaluates the supplied `map_function` at every point. It counts depth failures and compatibility failures exactly modulo the common prime. Its result uses theorem identifier `PSC-III-T52`.

If the last verified depth reaches the target's terminal depth N, then

$$F^N W = 0$$

forces

$$F(x_N) = 0.$$

Accordingly, the certificate is invalid when a terminal branch ends with a nonzero defect. For a prefix ending before N, certificate validity means only that the displayed finite prefix is compatible. The unchecked assumptions explicitly record continuation beyond that prefix.

42.4.2 Runnable terminal branch

```
from komorebi_math.nonlinear import (
    FilteredVectorSpace,
    verify_finite_filtered_branch,
)

source = FilteredVectorSpace.from_weights([0, 1], prime=5)
target = FilteredVectorSpace.from_weights([0, 1], prime=5)

result = verify_finite_filtered_branch(
    source,
    target,
    lambda point: (point[0] - 1, point[1] - 2),
    [(0, 0), (1, 0), (1, 2)],
)

print(result.approximations)
```

```
print(result.limit)
print(result.exact_solution)
print(result.certificate.valid)
print(result.certificate.diagnostics)
```

Observed core output:

```
((0, 0), (1, 0), (1, 2))
(1, 2)
True
True
{'start_depth': 0, 'final_depth': 2, 'terminal_depth': 2, 'terminal_reached': True}
```

The word `limit` in `FiniteFilteredBranchResult` means the last point of this finite branch. It does not mean a topological inverse limit.

42.4.3 Invalid versus exceptional branches

The function raises `ValidationError` for different primes, a noncallable map, an empty approximation sequence, a negative or nonintegral start depth, or a branch extending beyond the finite terminal filtration. Wrong point or defect dimensions also raise.

A well-shaped branch with bad compatibility or defect depth returns a result whose certificate is false. This distinction lets a verifier retain the failed finite record without converting every mathematical counterexample into an exception.

42.5 Conditional projective-limit completion

42.5.1 Finite evidence is not infinite completion

An infinite filtered lifting argument requires more than arbitrarily many finite computations. The helper displays the external requirements as

$$\bigcap_k F^k V = 0, \qquad V \cong \varprojlim V/F^k V,$$

$$F \text{ continuous}, \quad (x_k)_k \text{ compatible and infinite.}$$

Only under those declarations may one conclude conditionally that

$$x = \lim_k x_k, \qquad F(x) = 0.$$

`conditional_projective_limit_completion` does not receive spaces, bonding maps, a topology, a map F, or the branch itself. It records four booleans:

- `separated`
- `complete`
- `continuous`
- `compatible_infinite_branch`

It returns `ConditionalResult[ProjectiveLimitRecord]`. The certificate uses exactness `conditional` and theorem identifier `PSC-III-T53`. A finite `verified_prefix_depth` is diagnostic metadata only. Increasing that integer cannot turn a finite prefix into proof of an infinite branch.

42.5.2 Truth-table example

```
from komorebi_math.nonlinear import (
    conditional_projective_limit_completion,
)

incomplete = conditional_projective_limit_completion(
    7,
    separated=True,
    complete=False,
    continuous=True,
    compatible_infinite_branch=True,
)

declared = conditional_projective_limit_completion(
    7,
    separated=True,
    complete=True,
    continuous=True,
    compatible_infinite_branch=True,
)

print(incomplete.certificate.valid)
print(incomplete.value.conclusion)
print(incomplete.certificate.assumptions_unchecked)
print(declared.certificate.valid)
print(declared.certificate.exactness.value)
print(declared.certificate.assumptions_unchecked)
```

Observed core output:

```
False
the inverse-limit conclusion is not licensed
('complete',)
True
conditional
('the declared infinite branch and topological hypotheses are external inputs, not established by the finite
   ↪  runtime',)
```

Even the all-true record retains the external-input warning. Its valid status means the caller declared every premise. It does not mean the runtime proved those premises.

42.6 Public signature ledger

42.6.1 Filtered spaces and corrections

```
FilteredVectorSpace(
    dimension: int,
    levels: Mapping[int, Any],
    *,
    prime: int,
)
    .from_weights(
        weights: Sequence[int],
        *,
        prime: int,
    ) -> FilteredVectorSpace
    .basis(depth: int) -> np.ndarray
    .dimension_at(depth: int) -> int
    .contains(vector: Any, depth: int) -> bool
```

```
    .graded_basis(depth: int) -> np.ndarray
    .graded_dimension(depth: int) -> int
    .graded_coordinates(
        vector: Any,
        depth: int,
    ) -> np.ndarray
    .lift_graded(
        coordinates: Any,
        depth: int,
    ) -> np.ndarray
    .certificate() -> Certificate
```

```
FilteredCorrectionProblem(
    source: FilteredVectorSpace,
    target: FilteredVectorSpace,
    correction_map: Any,
    defect: Any,
    depth: int,
)
    .induced_map() -> np.ndarray
    .solve(
        *,
        enumerate_limit: int = 100000,
    ) -> DepthObstructionResult
```

42.6.2 Branch and projective helpers

```
verify_finite_filtered_branch(
    source: FilteredVectorSpace,
    target: FilteredVectorSpace,
    map_function: Callable[
        [tuple[int, ...]],
        Sequence[int],
    ],
    approximations: Sequence[Sequence[int]],
    *,
    start_depth: int = 0,
) -> FiniteFilteredBranchResult
```

```
conditional_projective_limit_completion(
    verified_prefix_depth: int,
    *,
    separated: bool,
    complete: bool,
    continuous: bool,
    compatible_infinite_branch: bool,
) -> ConditionalResult[ProjectiveLimitRecord]
```

42.6.3 Filtered complex

```
FiniteFilteredCochainComplex(
    dimensions: Mapping[int, int],
    differentials: Mapping[int, Any],
    filtrations: Mapping[int, FilteredVectorSpace],
    *,
    prime: int,
```

```
)
    .differential(degree: int) -> np.ndarray
    .page(page: int) -> SpectralSequencePage
    .total_cohomology_dimensions() -> dict[int, int]
    .spectral_sequence() -> FilteredSpectralSequenceResult
```

```
SpectralSequencePage
    .entry(
        filtration_degree: int,
        complementary_degree: int,
    ) -> SpectralSequenceEntry
```

42.7 Result-record ledger

The filtered result records are frozen, slotted dataclasses. Their NumPy arrays remain mutable unless a caller copies or protects them.

- `DepthObstructionResult`
  - `depth`
  - `induced_correction_map`
  - `defect_coordinates`
  - `correction_space`
  - `correction_representatives`
  - `certificate`
  - property `vanishes`
- `FiniteFilteredBranchResult`
  - `approximations`
  - `limit`
  - `exact_solution`
  - `certificate`
- `ProjectiveLimitRecord`
  - `verified_prefix_depth`
  - `separated`
  - `complete`
  - `continuous`
  - `compatible_infinite_branch`
  - `conclusion`
- `SpectralSequenceEntry`
  - `page`
  - `filtration_degree`
  - `complementary_degree`
  - `total_degree`
  - `dimension`
  - `outgoing_rank`
  - `incoming_rank`
- `SpectralSequencePage`
  - `page`
  - `entries`
  - `total_dimension`
  - `total_differential_rank`
  - `certificate`

- `FilteredSpectralSequenceResult`
  - `pages`
  - `total_cohomology_dimensions`
  - `limiting_dimensions`
  - `certificate`

`ModularLinearSolution`, used inside `DepthObstructionResult`, stores `prime`, `solvable`, `particular`, `kernel_basis`, `pivot_columns`, and `obstruction_rows`. Its computed properties are `nullity` and `solution_count`, and its `enumerate(limit=100000)` method materializes every affine solution when allowed by the guard.

No Chapter 42 record has a registered package portable codec in this release. For durable storage, use a versioned application schema. Store the prime, ambient dimensions, terminal depth, basis matrices, degree keys, theorem identifiers, and certificates rather than only printed page dimensions.

42.8 Certificate and error map

The theorem identifier ledger is:

- `PSC-III-D50`: finite decreasing filtration definition
- `PSC-III-T51`: one-step associated-graded correction
- `PSC-III-T52`: finite compatible branch
- `PSC-III-T53`: conditional projective-limit completion
- `PSC-III-S54`: finite filtered spectral sequence

The exact finite certificates have no floating tolerance. Their residuals are integer failure counts encoded as floats for the shared certificate schema. Projective completion is the sole `Exactness.CONDITIONAL` result in this chapter.

Input failures are normally `ValidationError` or its `DimensionError` subclass. The principal categories are:

- a composite or otherwise invalid field modulus
- nonintegral modular matrix or vector entries
- noncontiguous, nonnested, incomplete, or nonzero-terminal filtrations
- dimensions or differential shapes that do not agree
- a correction map or differential that does not preserve filtration
- successive differentials with nonzero composition
- an invalid page or branch depth
- an enumeration count beyond its declared materialization limit

The exact modular runtime does not silently coerce a composite modulus into a field computation. `require_prime` rejects it before row reduction.

42.9 Cost and storage model

Let d bound ambient dimensions, N be terminal filtration depth, g the number of cochain degrees, and ν a correction-space nullity.

- Filtration construction row-reduces every supplied level basis and performs nested-subspace tests. With dense square-scale bases, a conservative model is $O(Nd^3)$ field operations and $O(Nd^2)$ stored integers.
- A graded basis or coordinate operation performs further exact rank or linear solves on ambient matrices. The implementation does not cache every quotient computation.
- One filtered correction builds an induced graded map and solves a modular system. Enumerating representatives adds exactly p^ν output vectors, so time and storage become exponential in nullity even though row reduction is polynomial.
- A branch of length L performs L map evaluations, L defect membership tests, and $L-1$ compatibility membership tests. User callback cost is additional.
- One spectral page visits each declared total degree and filtration degree, repeatedly constructing images, preimages, intersections, spans, and quotient complements. The source favors transparent exact recomputation over cached asymptotic optimization.

- `spectral_sequence()` materializes $N+1$ pages. The entry ledger has at most $O(N^2 g)$ bidegree slots across all pages, though zero unincident entries are omitted from stored tuples.
- Projective completion stores only a fixed-size record and performs no limit computation.

These methods use dense NumPy integer arrays for modular bases. They are not designed for very large sparse chain complexes.

42.10 Version-specific source observations

These behaviors were confirmed from the version `1.0.0b4` source and adversarial probes:

1. `FilteredVectorSpace.basis`, `dimension_at`, and related depth accessors call `int(depth)` without checking integrality. For example, depth `1.9` is treated as depth `1`. Constructors and page/branch entry points are stricter in several, but not all, locations.
2. `FiniteFilteredCochainComplex` converts declared dimension values with `int` and does not compare the result back to the input. A value such as `1.9` can be accepted as dimension `1` when the filtration agrees.
3. `conditional_projective_limit_completion` converts each premise with `bool`. A nonempty string such as `"False"` is therefore treated as true. Pass actual booleans only.
4. The filtered correction enumeration guard raises built-in `ValueError` rather than `ResourceLimitError`.
5. `DepthObstructionResult.certificate.valid` can be true while `vanishes` is false. Callers must test both the integrity of the computation and the obstruction status.
6. Quotient complements depend on supplied basis-column order. Dimensions and represented subspaces are invariant, but printed coordinate representatives should not be treated as canonical across arbitrary rebasings.
7. The projective-limit helper checks only declared truth flags. It has no runtime objects from which to establish separation, completeness, continuity, or an infinite compatible branch.

These are documentation boundaries, not invitations to depend on permissive validation. Future releases may reject inputs that this source coerces.

42.11 Integrated finite workflow

The finite correction pipeline can be summarized as

$$\begin{aligned} \delta_k &\longrightarrow [\delta_k] \in \mathrm{gr}^k W \longrightarrow \mathrm{gr}^k D[c_k] = -[\delta_k], \\ x_{k+1} = x_k + \tilde{c}_k &\longrightarrow \delta_{k+1} \in F^{k+1} W. \end{aligned}$$

At every depth, retain the complete `DepthObstructionResult`. If `vanishes=False`, the branch stops with an exact finite obstruction. If it vanishes, choose a representative explicitly, update the approximation, and verify the resulting branch independently. Reaching the terminal zero level gives a finite exact solution. Stopping earlier gives only a verified prefix.

A spectral sequence packages related finite cancellations across an entire cochain complex. It does not replace the branch computation for a nonlinear map. Conversely, a correction branch does not establish the cohomological page identities of a filtered complex unless the complex and its differentials are constructed explicitly.

42.12 Verification record

The focused filtered test module passed **7/7** tests in the recorded guide qualification environment. Together with Chapter 41, the two focused modules passed **12/12**. The installed nonlinear verifier passed all **14/14** checks, including finite filtered lifting and filtered spectral-sequence checks.

The shipped `filtered_transport.py` example also passed. Its Chapter 42 output was:

```
page 0 dimension 2 rank 0
page 1 dimension 2 rank 1
page 2 dimension 0 rank 0
```

The same example continues into Chapter 44 and reported a coarse-to-fine Kato transport difference of approximately 4.54×10^{-15}. That later numerical transport result is independent of the exact finite-field status of the spectral-sequence pages.

42.13 Chapter checklist

Before relying on a filtered computation:

1. Confirm the modulus is prime and every modular entry is integral.
2. Inspect the filtration certificate and level dimensions.
3. Check both `certificate.valid` and the semantic obstruction flag.
4. Bound correction-coset enumeration before materializing it.
5. Preserve the chosen graded representative convention.
6. Verify every finite branch point and its terminal status.
7. Treat a finite prefix as finite even when many depths were checked.
8. Require every page certificate and the terminal convergence certificate.
9. Pass actual booleans to the projective-limit recorder.
10. State separation, completeness, continuity, and infinite compatibility as external assumptions whenever an inverse-limit conclusion is quoted.

43. Nonlinear execution, streaming, profiling, and GPU paths

The packet-jet definitions in Chapter 38 expose every target packet and every ordered source-packet tuple. That explicit family is mathematically useful, but a literal evaluator repeats work: for fixed input packets $(a_1, \dots, a_r)$, every target block begins with the same directional derivative. The execution layer compiles that shared work, the snapshot layer freezes one multilinear block into finite coefficient data, and the streaming layer moves the same data through a bounded-memory directory format.

For a first run, follow the execution ladder in Section 43.5.4.1 and use the small worked plan in Section 43.1.4. Introduce persistence after the direct and planned evaluations agree. Introduce profiling after the workload is fixed. This makes a failed computation, a storage problem, and a timing comparison easier to diagnose independently.

The chapter covers five different kinds of statement. They should not be collapsed into one performance claim:

- execution-plan and complexity fields are exact finite counts.
- Reconstruction certificates compare one retained packet sum with the direct derivative supplied by the same provider.
- Snapshots and streams are finite persisted coefficient records.
- Profile timings and Python allocation peaks are local observations.
- CuPy classes are optional numerical paths whose availability and parity must be established on the machine that executes them.

Most of the CPU execution, snapshot, stream, and profile names in this chapter are part of the curated `komorebi_math.beta` surface in version `1.0.0b4`. They are also available from `komorebi_math.nonlinear` and, for compatibility, many are re-exported at the package root. The CuPy execution names remain on the research surface. None of these names belongs to the smaller frozen `komorebi_math.stable` surface.

The nonlinear feature record is obtained with

```
from komorebi_math import nonlinear

assert nonlinear.FEATURE_KEY == "nonlinear"
assert nonlinear.status().status.value == "implemented"
```

That registry status means the finite implementation is present. It does not assert that an optional CUDA runtime exists or that an arbitrary derivative callable is correct.

43.1 Projection-cached execution

Let the source packet system contain A projectors P_a, the target system contain B projectors Q_b, and the derivative order be r. The complete address family has

$$N_{\text{full}} = BA^r$$

members. For one ordered source tuple $\mathbf{a} = (a_1, \dots, a_r)$, define

$$w_{\mathbf{a}} = D^r F(x)[P_{a_1} v_1, \dots, P_{a_r} v_r].$$

Every active target block with those same inputs is then obtained by the cheap final projection

$$J_{b;\mathbf{a}}(x)[v_1, \dots, v_r] = Q_b w_{\mathbf{a}}.$$

`compile_packet_jet_plan` groups active addresses by the **ordered** tuple **a**. If G is the set of tuples represented by at least one active target address, the planned provider-call count is

$$N_{\text{calls}}^{\text{plan}} = |G|, \qquad N_{\text{calls}}^{\text{naive}} = BA^r.$$

The input order is not symmetrized during grouping. Even when the derivative is mathematically symmetric, `(left, right)` and `(right, left)` remain distinct groups because packet projection is attached to a direction slot.

43.1.1 Conservative support pruning

With no support record, every address stays active. With a supplied `PacketJetSupport`, compilation first requires its certificate, checks that its order agrees with the family, and checks that `nonzero`, `zero`, and `untested` partition the complete family address set. Only addresses in the certified `zero` tuple are removed:

$$\mathcal{A}_{\text{pruned}} \subseteq \mathcal{A}_r^0.$$

An `untested` block remains active. Consequently, an exhausted support search may reduce pruning efficiency, but it cannot justify dropping an untested contribution. `support_complete` records whether any such unresolved addresses remain.

The address ceiling is checked before compilation. For

```
compile_packet_jet_plan(
    family: PacketJetFamily,
    support: PacketJetSupport | None = None,
    *,
    max_addresses: int = 1_000_000,
) -> PacketJetExecutionPlan
```

`max_addresses` must be a positive, non-Boolean integer. The ceiling controls address enumeration. It is not a time or memory guarantee for the derivative provider itself.

43.1.2 Plan and group records

`PacketJetInputGroup(inputs, outputs)` is a frozen slotted record. `inputs` is the ordered tuple of source-packet indices. `outputs` must be a nonempty, sorted tuple of unique nonnegative target indices.

`PacketJetExecutionPlan` has these stored fields:

- `order`, `source_names`, and `target_names`.
- `groups: tuple[PacketJetInputGroup, ...]`.
- `active_addresses` and `pruned_addresses`.
- `support_was_supplied` and `support_complete`.
- `certificate`.

Its derived properties are:

- `active_address_count` and `pruned_address_count`.
- `full_address_count`.
- `derivative_call_count` and `naive_derivative_call_count`.
- `derivative_call_reduction`.

The last is

$$1 - \frac{N_{\text{calls}}^{\text{plan}}}{N_{\text{calls}}^{\text{naive}}},$$

with value one when the denominator is zero. `to_dict()` returns a report mapping.

The method

```
plan.matches(family: PacketJetFamily) -> bool
```

compares only derivative order, source packet names, and target packet names. It does **not** fingerprint the provider, point, packet projector matrices, backend, tolerance, or support proof. A plan is therefore a structural cache, not a self-authenticating executable artifact. Recompile it whenever any semantic input changes.

43.1.3 Execution and reconstruction

The two CPU entry points are

```
execute_packet_jet_plan(
    plan: PacketJetExecutionPlan,
    family: PacketJetFamily,
    directions: Sequence[Any],
    *,
    tolerance: float | None = None,
) -> PacketJetBatchResult

execute_packet_jets(
    family: PacketJetFamily,
    directions: Sequence[Any],
    *,
    support: PacketJetSupport | None = None,
    tolerance: float | None = None,
    max_addresses: int = 1_000_000,
) -> PacketJetBatchResult
```

The convenience form compiles and executes. The explicit form first requires the plan certificate and calls `plan.matches(family)`. Every direction is then converted through the source packet backend and projected once through every source packet. For each group, the provider is called once and the result is projected through the listed target packets.

If $\mathcal{A}_{\text{active}}$ is the retained address set, execution forms

$$\widetilde{D}^r F(x)[V] = \sum_{(b;\mathbf{a})\in\mathcal{A}_{\text{active}}} Q_b D^r F(x)[P_{a_1} v_1, \dots, P_{a_r} v_r]$$

and independently asks the same provider for

$$D^r F(x)[v_1, \dots, v_r].$$

The certificate residual is

$$\rho_{\text{plan}} = \left\| D^r F(x)[V] - \widetilde{D}^r F(x)[V] \right\|.$$

For exact families it must be zero. For numerical families it must not exceed the explicit tolerance, or the maximum source/target packet tolerance when no override is supplied. The certificate theorem identifier is `PSC-III-A10`. It checks the finite reconstruction on the supplied directions. Global correctness of the derivative provider remains unchecked.

`PacketJetEvaluation(address, value)` stores one active address result. `PacketJetBatchResult` stores:

- `evaluations`, `reconstructed`, and `direct`.
- `derivative_calls`, `input_projections`, and `output_projections`.
- `pruned_blocks`, `backend`, and `returned_to_host`.
- `certificate`.

`as_mapping()` creates an address-to-value dictionary. `value(address)` returns one active value and raises `KeyError` for a pruned or otherwise inactive address. `to_dict()` expands the complete report.

43.1.4 Numerical worked plan with exact structural counts

The repository example `examples/scalable_nonlinear.py` builds an exact quadratic provider with coordinate packets. The packet system uses the default NumPy backend, so execution values and certificates are numerical even though the provider coefficients and structural address counts are exact. The full order-two family contains eight blocks. Certified support leaves two:

```
from fractions import Fraction

import numpy as np

from komorebi_math import Exactness, PacketSystem
from komorebi_math.nonlinear import (
    PacketJetFamily,
    PolynomialDerivativeProvider,
    compile_packet_jet_plan,
    execute_packet_jet_plan,
    packet_jet_support,
)

tensor = np.zeros((2, 2, 2), dtype=object)
tensor[0, 0, 0] = Fraction(2)
tensor[1, 1, 1] = Fraction(-3)
provider = PolynomialDerivativeProvider(
    {2: tensor},
    exactness=Exactness.EXACT,
)
packets = PacketSystem(
    (
        np.diag([Fraction(1), Fraction(0)]),
        np.diag([Fraction(0), Fraction(1)]),
    ),
    names=("x", "y"),
)
family = PacketJetFamily(
    provider,
    np.array([Fraction(0), Fraction(0)], dtype=object),
    packets,
    packets,
    order=2,
)
support = packet_jet_support(family)
plan = compile_packet_jet_plan(family, support)

directions = (
    np.array([Fraction(2), Fraction(3)], dtype=object),
    np.array([Fraction(-1), Fraction(4)], dtype=object),
)
result = execute_packet_jet_plan(plan, family, directions)
result.certificate.require()

print(plan.active_address_count, plan.pruned_address_count)
```

```
print(result.derivative_calls)
print(result.reconstructed.tolist())
```

Observed output:

```
2 6
2
[(-4+0j), (-36+0j)]
```

The complex-looking scalars are NumPy's representation after backend normalization. They are numerically equal to integer values, but the resulting family, support, plan, and execution certificate have `Exactness.NUMERICAL`. The two calls are one per active input group. The example does not imply that every provider call has equal cost.

43.1.5 Complexity records

`estimate_packet_jet_complexity` converts a finite family and plan into a deterministic count record:

```
estimate_packet_jet_complexity(
    family: PacketJetFamily,
    support: PacketJetSupport | None = None,
    *,
    plan: PacketJetExecutionPlan | None = None,
    max_addresses: int = 1_000_000,
) -> PacketJetComplexityEstimate
```

When no plan is supplied, the function compiles one under `max_addresses`. When a plan is supplied, it requires that plan's certificate and uses the same name-and-order `matches` check described above.

For source dimension d_X, target dimension d_Y, source packet count A, target packet count B, and order r, the record includes

$$
\begin{aligned}
N_{\text{family}} &= BA^r, \\
N_{\text{basis}} &= d_X^r, \\
N_{\text{dense}} &= d_Y d_X^r, \\
N_{\text{input proj}} &= rA.
\end{aligned}
$$

Its fields are:

- `order`, `source_dimension`, and `target_dimension`.
- `source_packets`, `target_packets`, and `family_addresses`.
- `active_addresses`, `pruned_addresses`, and `input_groups`.
- `naive_derivative_calls` and `planned_derivative_calls`.
- `projected_input_vectors` and `output_projections`.
- `dense_basis_evaluations` and `dense_tensor_elements`.
- `certificate`.

`derivative_call_reduction` is a derived property and `to_dict()` produces the report mapping. The `PSC-III-A61` count certificate has `Exactness.EXACT`. That exactness applies to these structural counts, not to a runtime estimate. It leaves call cost, kernel fusion, caching, and transfer overhead unchecked.

For the three-coordinate sparse quadratic in the shipped example below,

```
examples/scalable_nonlinear_runtime.py
```

the observed ledger was:

```
active packet blocks: 4
pruned packet blocks: 23
planned derivative calls: 4
naive derivative calls: 27
```

The reduction from 27 to 4 provider calls is exact for that plan. A faster wall clock still depends on provider cost, projection cost, allocation, backend, and workload size.

43.2 Packet-jet snapshots and digest identity

A live `PacketJet` contains Python callables and packet-system objects. It is not reconstructed from JSON. `snapshot_packet_jet` instead evaluates one fixed packet block on every ordered ambient standard-basis tuple and stores the resulting coefficients.

For source basis $e_0, \dots, e_{d_X-1}$, address $\alpha = (b; a_1, \dots, a_r)$, and target coordinate o, define

$$c_{o;i_1,\dots,i_r} = \left(J_\alpha[e_{i_1}, \dots, e_{i_r}]\right)_o .$$

The frozen block evaluates as

$$J_\alpha[v_1, \dots, v_r]_o = \sum_{i_1,\dots,i_r} c_{o;i_1,\dots,i_r} \prod_{s=1}^{r} (v_s)_{i_s}.$$

The capture signature is

```
snapshot_packet_jet(
    jet: PacketJet,
    *,
    tolerance: float | None = None,
    max_evaluations: int = 100_000,
) -> PacketJetSnapshot
```

The safety check $d_X^r \le$ `max_evaluations` occurs before any basis evaluation. For exact backends, only coefficients exactly recognized as zero are omitted. For numerical backends, a coefficient vector is omitted when its norm does not exceed the selected tolerance. The capture certificate records the largest omitted norm. Thus numerical sparsification is a declared tolerance operation, not exact support discovery.

43.2.1 Snapshot records and methods

`PacketJetCoefficient(indices, value)` stores one input-index tuple and one target-coordinate tuple. The enclosing snapshot validates order, range, duplicates, target length, and lexicographically sorts the entries.

`PacketJetSnapshot` fields are:

- `address`, `source_dimension`, and `target_dimension`.
- `provider_name`, `exactness`, and `point`.
- `coefficients` and `capture_certificate`.

The derived properties `order`, `nnz`, and `dense_coefficient_count` return r, the stored coefficient-vector count, and d_X^r, respectively. Public methods are:

```
coefficient(indices: Sequence[int]) -> tuple[Any, ...]
evaluate(directions: Sequence[Any]) -> ndarray
to_dense(*, max_elements: int = 10_000_000) -> ndarray
comparison_certificate(
    jet: PacketJet,
    directions: Sequence[Any],
```

```
    *,
    tolerance: float | None = None,
) -> Certificate
to_dict() -> dict[str, Any]
```

`coefficient` returns an explicit zero target vector for an unstored valid index. `evaluate` and the `__call__` alias contract the sparse coefficients. `to_dense` enforces

$$d_Y d_X^r \leq \texttt{max_elements}$$

before allocation. `comparison_certificate` checks a matching address and dimensions, evaluates one supplied direction tuple through the live jet and snapshot, and records residual `snapshot_reconstruction` under theorem `PSC-III-D58`. It is sampled finite parity, not recovery of the live callable.

43.2.2 Portable envelope, digest, and adjacent migration

The portable codec for `PacketJetSnapshot` is version 2 under this tag:

```
nonlinear.packet_jet_snapshot
```

Version 2 names the provider field `provider` and records

```
coefficient_ordering = "lexicographic"
```

before decoding. The one committed adjacent migration transforms version 1 to version 2 by renaming `provider_name` to `provider` and adding the ordering field. A future version, a missing migration link, an unsupported ordering, an unknown codec, duplicate JSON keys, nonfinite JSON constants, or a payload digest mismatch fails closed.

The ordinary persistence path is:

```
from komorebi_math.export import dumps_portable, loads_portable, portable_digest

encoded = dumps_portable(snapshot)
restored = loads_portable(encoded)
assert portable_digest(restored) == portable_digest(snapshot)
```

The SHA-256 value binds canonical payload data. It detects an unchanged digest paired with changed content. It is not a signature, message-authentication code, timestamp, ownership record, or proof that the provider used during capture was mathematically correct.

The shipped `portable_nonlinear_state.py` example produced:

```
snapshot address: PacketJetAddress(output='x', inputs=('x', 'x'))
stored coefficients: 1
portable digest: dae6206f9b99acfa72649825253fd0b748c1e62236109f0a120872767ad97033
evaluation: [(-6+0j), 0j]
tampered payload: rejected
```

That digest is reproducible for this release and example data. It should not be used as a universal digest for all packet-jet snapshots.

43.3 Resumable streams and adjacent migrations

The ordinary portable envelope requires a complete finite snapshot in memory. The stream format stores coefficients in independently digested JSON chunks, commits progress after each completed chunk, and lets readers decode one chunk at a time.

The format constants are:

```
PACKET_JET_STREAM_SCHEMA = "komorebi-math.packet-jet-stream"
PACKET_JET_STREAM_SCHEMA_VERSION = 1
PACKET_JET_CHUNK_SCHEMA = "komorebi-math.packet-jet-stream.chunk"
PACKET_JET_CHUNK_SCHEMA_VERSION = 1
```

`StreamState = Literal["in_progress", "complete"]` and `CaptureMode = Literal["direct", "snapshot"]` are module-visible typing aliases in `komorebi_math.nonlinear.streaming`. They are not exported from the package-level nonlinear namespace. These layout constants are likewise implementation-visible rather than package exports:

- `STREAM_MANIFEST_NAME`.
- `STREAM_CHUNK_DIRECTORY`.
- `STREAM_PARTIAL_SUFFIX`.

For a destination named

```
run.kmstream
```

an interrupted write lives at

```
run.kmstream.partial
```

The directory contains:

- `manifest.json`.
- A `chunks` directory.
- Canonical members such as `chunk-00000000.json` and the successive numbered files.

The state transition is

$$\text{absent} \longrightarrow \texttt{destination.partial} \longrightarrow \text{verified staging} \longrightarrow \texttt{destination}.$$

Manifest and chunks each use the envelope

$$E = (\text{schema}, \text{schema version}, \text{SHA256}(\text{canonical payload}), \text{payload}).$$

Files are written to a same-directory temporary path, flushed, `fsync`ed, and atomically replaced. Promotion uses an operating-system replace operation. An explicit overwrite first moves an existing destination to a temporary backup and restores it if promotion fails. These steps limit torn local updates. They do not turn a multi-file directory into authenticated or adversary-resistant storage.

43.3.1 Direct capture, pause, and resume

```
capture_packet_jet_stream(
    jet: PacketJet,
    path: str | os.PathLike[str],
    *,
    tolerance: float | None = None,
    max_evaluations: int = 10_000_000,
    chunk_size: int = 1024,
    evaluation_budget: int | None = None,
    resume: bool = False,
    overwrite: bool = False,
) -> PacketJetStreamWriteResult
```

`max_evaluations` is a total safety ceiling. `evaluation_budget` is different: it limits only the additional basis evaluations performed by this call. A zero budget is valid and leaves an empty but structurally valid partial stream. If the budget

ends before d_X^r basis tuples have been visited, the write result is incomplete and the staging directory remains in place.

Resume verifies every committed prefix chunk and requires the same chunk size and metadata fingerprint. For direct capture that fingerprint contains

$$(\alpha, d_X, d_Y, n_F, e_F, x, \varepsilon),$$

where α is the packet address, n_F the provider name, e_F the exactness label, x the point, and ε the capture tolerance. It does **not** contain callable bytecode, closure state, packet projector matrices, package source, or a semantic provider hash. Resuming a live provider therefore assumes that all unrecorded behavior is unchanged.

When all basis tuples are complete, the final manifest gains a capture certificate, is reloaded and validated, and the staging directory is promoted. An incomplete write certificate is valid as a progress record but has `Exactness.CONDITIONAL`, residual `incomplete_stream = 1.0`, and an unchecked remaining-work assumption. Do not treat `certificate.valid` alone as proof that the stream is complete. Inspect `completed` or `manifest.complete`.

43.3.2 Streaming an existing snapshot

```
save_packet_jet_snapshot_stream(
    snapshot: PacketJetSnapshot,
    path: str | os.PathLike[str],
    *,
    chunk_size: int = 1024,
    coefficient_budget: int | None = None,
    resume: bool = False,
    overwrite: bool = False,
) -> PacketJetStreamWriteResult
```

Snapshot mode traverses the already stored nonzero coefficients, so `coefficient_budget` limits additional stored coefficient vectors rather than dense basis evaluations. Its resume fingerprint includes the complete ordered coefficient record and capture certificate. This is stronger than the direct callable fingerprint, although it remains an integrity identity rather than an authenticity proof.

Snapshot chunks initially carry coefficient progress. On finalization the last chunk is rewritten to close the complete dense-basis interval. Even a snapshot with zero stored coefficients receives a canonical empty chunk and can be round-tripped as complete.

43.3.3 Manifest and result records

`PacketJetStreamChunkRecord` stores:

- `index`, canonical `filename`, and `byte_count`.
- Half-open `basis_start:basis_stop`.
- Half-open `coefficient_start:coefficient_stop`.
- Lowercase `payload_sha256`.

Its `basis_count` and `coefficient_count` properties subtract the corresponding endpoints. `to_dict()` and `from_dict()` use an exact closed field schema.

`PacketJetStreamManifest` stores:

- `state`, `producer_version`, `capture_mode`, and `chunk_size`.
- Packet address, dimensions, provider name, exactness, point, and tolerance.
- `dense_coefficient_count` and `source_digest`.
- `metadata_sha256` and `stream_sha256`.
- Completed basis and coefficient counts and maximum omitted basis norm.
- The ordered chunk records and optional final capture certificate.

Its `complete` and `order` properties expose state and address order. `metadata_dict()`, `to_payload()`, and `from_payload()` enforce the closed version-1 schema. Chunk indices and ranges must be contiguous. A complete manifest must cover all d_X^r basis tuples and contain a capture certificate. An in-progress manifest must not contain that final certificate.

`PacketJetStreamWriteResult` reports:

- `destination` and `active_path`.
- `completed` and `resumed`.
- Chunk, evaluation, and coefficient counts written by the current call.
- Final `manifest` and `certificate`.

A completed result's active path is the destination. An incomplete result's active path is the `.partial` staging directory.

The stream schema is currently version 1 and has no stream-format migration path. The adjacent version-1-to-version-2 migration described in §43.2.2 is for the ordinary `nonlinear.packet_jet_snapshot` portable codec, not for a stream manifest or chunk. Stream schema/version mismatches are rejected.

43.3.4 Bounded reader, selections, and partial sums

The reader entry points are:

```
PacketJetSnapshotStreamReader(
    path,
    *,
    allow_incomplete: bool = False,
    verify_chunks: bool = False,
)

open_packet_jet_snapshot_stream(
    path,
    *,
    allow_incomplete: bool = False,
    verify_chunks: bool = False,
) -> PacketJetSnapshotStreamReader

load_packet_jet_snapshot_stream(
    path,
    *,
    max_coefficients: int = 1_000_000,
    verify_chunks: bool = True,
) -> PacketJetSnapshot
```

By default, opening an incomplete stream fails. With `allow_incomplete=True`, the reader may resolve the sibling `.partial` directory. `verify_chunks=True` immediately walks and requires the full stream integrity certificate.

Reader methods are:

```
iter_chunks()
iter_coefficients(*, start=0, stop=None)
select(*, start=0, stop=None, max_coefficients=100_000)
evaluate(directions, *, start=0, stop=None)
load_snapshot(*, max_coefficients=1_000_000)
verify()
```

Iteration holds at most one decoded chunk at a time. Selection and evaluation ranges are half-open ordinals in the **stored coefficient sequence**, not dense basis ordinals. If stored coefficients are $(c_0, \dots, c_{m-1})$, range $[a, b)$ evaluates

$$J_{[a,b)}[v_1, \dots, v_r] = \sum_{k=a}^{b-1} c_k \prod_{s=1}^{r} (v_s)_{i_s(k)}.$$

This is the complete snapshot value only when the stream is complete and $[a, b) = [0, m)$. Otherwise the certificate explicitly leaves coefficients outside the selected interval unchecked.

`PacketJetStreamSelection` stores the ordinal bounds, loaded coefficient tuple, `complete_snapshot`, and certificate. `StreamedPacketJetEvaluation` stores the result vector, bounds, total stored coefficient count, `complete_snapshot`, and certificate. `load_snapshot` refuses incomplete streams and enforces its materialization guard before constructing a conventional in-memory `PacketJetSnapshot`.

`verify()` checks manifest, metadata, and stream digests, every chunk envelope and manifest cross-reference, contiguous ranges, exact observed counts, and strict lexicographic coefficient order without duplicates. Its theorem identifier is `PSC-III-D60`. The certificate's unchecked assumptions state plainly that SHA-256 integrity does not establish authenticity or authorship.

43.3.5 Resume excerpt from the shipped example

The shipped example `examples/resumable_packet_jet_stream.py` pauses a quadratic block after two of four basis evaluations, resumes it, verifies every chunk, and evaluates the completed stream. Use this as the central resume excerpt. It assumes the shipped file's preceding imports and its definitions of `jet` and `directions`:

```
with tempfile.TemporaryDirectory() as directory:
    destination = Path(directory) / "quadratic.kmstream"
    partial = capture_packet_jet_stream(
        jet,
        destination,
        chunk_size=1,
        evaluation_budget=2,
    )
    complete = capture_packet_jet_stream(
        jet,
        destination,
        chunk_size=1,
        resume=True,
    )
    reader = open_packet_jet_snapshot_stream(
        destination,
        verify_chunks=True,
    )
    evaluation = reader.evaluate(directions)
    evaluation.certificate.require()

    print(partial.manifest.evaluations_completed)
    print(complete.resumed, len(reader.manifest.chunks))
    print(reader.manifest.coefficients_completed)
    print(evaluation.value.tolist())
```

Observed output:

```
2
True 4
4
[53.0]
```

The example uses a temporary directory. Applications should retain the `.partial` directory between processes if they intend to resume later.

43.4 Cost profiles and budget planners

The profiling module keeps deterministic counts separate from observations. `RuntimeProfileSample(duration_ns, traced_peak_bytes)` is one nonnegative pair. `profile_operation` returns a nonempty `RuntimeStageProfile(name, scope, warmup, samples)` and the record exposes:

- `repetitions`.
- Minimum, median, and maximum duration in nanoseconds.
- Median and maximum traced peak bytes.
- `to_dict()`.

The low-level observer is

```
profile_operation(
    name: str,
    operation: Callable[[], T],
    *,
    repetitions: int = 5,
    warmup: int = 1,
    scope: str =
        "Python call including allocations and synchronization performed by the callable",
) -> RuntimeStageProfile
```

`T` is a typing variable inside `nonlinear.profiling`. It is not a runtime operation exported by the nonlinear package. `repetitions` must be a positive integer, `warmup` a nonnegative integer, and both name and scope nonempty. Warmup results are discarded. Before each measured call, the implementation collects Python garbage, then records `time.perf_counter_ns()` and the `tracemalloc` peak. An already active `tracemalloc` session is preserved.

The complete packet runtime helper is

```
profile_packet_jet_runtime(
    family: PacketJetFamily,
    directions: Sequence[Any],
    *,
    support: PacketJetSupport | None = None,
    jet: PacketJet | None = None,
    repetitions: int = 5,
    warmup: int = 1,
    max_addresses: int = 1_000_000,
    max_snapshot_evaluations: int = 100_000,
    include_stream_write: bool = False,
    stream_chunk_size: int = 1024,
) -> PacketJetProfileReport
```

It always profiles:

- `address_enumeration`.
- `plan_compilation`.
- `plan_execution`.

When `jet` is supplied, it also profiles:

- `snapshot_capture`.
- `portable_serialization`.

When both a jet and stream-write inclusion are supplied, it adds `stream_snapshot_write` in a fresh temporary directory. The stream stage includes JSON encoding, per-chunk digests, flushes, manifest updates, and promotion. It does not profile direct live-provider resume.

`PacketJetProfileReport` contains the exact `estimate`, stage tuple, environment mapping, and a heuristic certificate. The environment records Python version and implementation, platform and processor strings, timer, memory observer, repetition count, and warmup. The certificate theorem is `PSC-III-A61`, with `Exactness.HEURISTIC`. It leaves

scheduler isolation, CPU frequency, cache state, thermals, cross-machine comparison, and native/device allocation visibility unchecked.

`tracemalloc` observes Python-managed allocations. It does not measure all NumPy buffers, linked-library workspaces, process resident memory, CUDA allocations, or device peaks. A callable that performs asynchronous device work must synchronize inside the measured scope if completion time is intended. The profiler does not insert a backend-specific synchronization.

43.4.1 Benchmark contracts are specifications

```
packet_jet_benchmark_contract(
    family: PacketJetFamily,
    *,
    backend: str,
    timing_scope: str = "kernel",
) -> BenchmarkContract
```

This function creates a matched workload description containing order, dimensions, packet counts, address count, provider name, expected output, timing scope, and backend. It does not run a benchmark. In particular,

$$\text{benchmark contract} \neq \text{speedup certificate}.$$

A defensible CPU/GPU comparison should use the same family, directions, precision, output contract, warmup, repetition policy, synchronization rule, and transfer scope. Report transfers explicitly rather than hiding them behind the word "kernel."

43.5 Optional GPU execution

There are two separate CuPy paths. `nonlinear.execution` evaluates a live device derivative provider together with packet projectors. `nonlinear.gpu` evaluates a finite persisted snapshot. Neither path silently falls back to CPU.

`nonlinear_cupy_available()` calls `importlib.util.find_spec("cupy")`. It answers only whether a module can be discovered. The availability ladder is

$$\begin{gathered}\text{discoverable}\\ \Downarrow ?\\ \text{importable}\\ \Downarrow ?\\ \text{runtime usable}\\ \Downarrow ?\\ N_{\text{device}} > 0\\ \Downarrow ?\\ \text{workload valid}.\end{gathered}$$

Only the later observations establish an executable CUDA path.

43.5.1 Device polynomial provider

`CuPyDeviceDerivativeProvider` is the runtime-checkable protocol consumed by the executor. A conforming object supplies `source_dimension`, `target_dimension`, `max_order`, `exactness`, `name`, and `device_backend`, together with:

```
supports_order(order: int) -> bool
device_derivative(
    order: int,
    point: Any,
    directions: Sequence[Any],
) -> Any
```

The preferred package-level spelling is

```
CuPyPolynomialDerivativeProvider(
    tensors: Mapping[int, Any],
    *,
    source_dimension: int | None = None,
    target_dimension: int | None = None,
    tolerance: float = 1e-10,
    name: str = "CuPy polynomial derivative provider",
)
```

`CupyPolynomialDerivativeProvider` is the original compatibility spelling in `komorebi_math.nonlinear.execution`. It is not imported into the package-level nonlinear namespace. Both names denote the same class in that module.

The same module retains these original spellings:

```
CupyDeviceDerivativeProvider
CupyPacketJetExecutor
```

Their preferred `CuPy*` aliases are the names re-exported from the nonlinear package namespace.

Construction first validates the tensors through the CPU polynomial derivative provider, rejects object-dtype tensors, transfers all dense tensors to the active CuPy device, and fixes `exactness = Exactness.NUMERICAL`. Its public members are:

- `degree` and `supports_order`.
- `device_value` and `value`.
- `device_derivative` and `derivative`.
- `synchronize`.

The `device_*` forms retain CuPy arrays. `value` and `derivative` return NumPy host arrays.

The device derivative implements the same factorial tensor convention as the CPU polynomial provider:

$$D^r F(x)[v_1, \dots, v_r] = \sum_{m=r}^{M} \frac{1}{(m-r)!} T_m[v_1, \dots, v_r, x^{m-r}].$$

43.5.2 Device packet executor

```
CuPyPacketJetExecutor(
    family: PacketJetFamily,
    plan: PacketJetExecutionPlan | None = None,
)
```

The family must use NumPy packet systems for both source and target and its provider must satisfy the runtime-checkable device-provider protocol. Projector matrices and the base point are copied to the active CuPy device at construction. A missing plan is compiled on CPU. A supplied plan uses the same structural `matches` boundary as CPU execution.

```
executor.execute(
    directions,
    *,
    return_host: bool = True,
    input_on_device: bool = False,
    tolerance: float | None = None,
) -> PacketJetBatchResult
```

With `input_on_device=False`, directions are explicitly converted by `cupy.asarray`. With `return_host=True`, active values, reconstructed value, and direct derivative are copied back to NumPy. With `return_host=False`, those values remain device arrays inside the ordinary batch record. The certificate uses theorem `PSC-III-A10G` and residual `device_reconstruction`. It checks device reconstruction against the direct **device** derivative, not against a CPU provider.

`synchronize()` waits on the null stream. `hardware_certificate()` queries the active device and returns its identifier, name, compute capability, and global memory. That certificate proves that the metadata query succeeded. It does not certify speed, thermal state, numerical parity, or suitability for a larger workload.

43.5.3 Optional CuPy snapshot execution

`cupy_runtime_status()` is the non-raising runtime probe. It returns

```
CuPyRuntimeStatus(
    installed: bool,
    runtime_available: bool,
    device_count: int,
    runtime_version: int | None,
    error: str | None = None,
)
```

When CuPy is undiscoverable, `installed` and `runtime_available` are false and the error says that CuPy is not installed. An import or CUDA query failure is captured as an error string. A successful import with zero devices remains `runtime_available=False`.

```
CuPySnapshotExecutor(
    snapshot: PacketJetSnapshot,
    *,
    dtype: Any | None = None,
)
```

`CuPyPacketJetSnapshotExecutor` is an exact alias for this class. Construction transfers an `nnz x order` integer index matrix and an `nnz x target_dimension` value matrix. `evaluate_batch` requires shape

$$(N_{\text{batch}}, r, d_X)$$

and returns a NumPy array of shape (N_{batch}, d_Y). A two-dimensional (r, d_X) input is promoted to a one-item batch. The kernel gathers each direction coordinate, multiplies the r gathered factors, then performs the matrix product with stored target values. `evaluate` and `__call__` handle one ordered direction tuple.

Matched CPU/device parity is requested with

```
validate_cupy_snapshot(
    snapshot: PacketJetSnapshot,
    probes: Sequence[Sequence[Any]],
    *,
    tolerance: float = 1e-9,
) -> CuPyValidationResult
```

The result fields are `probe_count`, `maximum_residual`, `runtime`, and `certificate`. The numerical `PSC-III-N59` certificate checks

$$\rho_{\mathrm{GPU}} = \max_j \left\| J_{\mathrm{GPU}}[V_j] - J_{\mathrm{CPU}}[V_j] \right\|_2 \le \varepsilon.$$

It leaves behavior outside the probes and all performance conclusions unchecked. A CPU-only system emits an unavailable status or raises `BackendUnavailableError` when the executor is constructed. It never emits a false hardware pass.

The recorded build machine reported:

```
CuPy installed: False
CuPy runtime available: False
CUDA devices: 0
```

That is an honest no-runtime observation, not a negative statement about a different machine.

43.5.4 Example ladder, resource model, and claim boundaries

This closing execution section orders the recommended workflow before stating its arithmetic model, failure surface, implementation boundaries, and replayed evidence.

43.5.4.1 Recommended execution ladder

For a new finite workload:

1. Build and test the derivative provider independently.
2. Construct the packet family and discover support under an explicit probe budget.
3. Compile a fresh plan from that exact family and support record.
4. Inspect exact counts before execution.
5. Execute and require the reconstruction certificate on representative directions.
6. Snapshot a fixed block only when d_X^r is within the basis budget.
7. Use the portable envelope for a comfortably in-memory snapshot, or the stream format for chunked persistence.
8. Profile only after the workload, timing scope, warmup, synchronization, and output contract are fixed.
9. Enter the CuPy path only after a runtime probe, then compare matched CPU and device outputs.

This ordering separates mathematical correctness, integrity, resource safety, observational profiling, and optional hardware qualification.

43.5.4.2 Arithmetic and storage model

These are dense reference counts. Provider-specific work may dominate.

- Full packet address enumeration stores and visits BA^r addresses.
- Plan execution forms rA input projections, makes $|G|$ derivative calls, and applies one target projection per active address.
- With dense $d_X \times d_X$ and $d_Y \times d_Y$ projectors, projection work is approximately $O(rAd_X^2 + N_{\mathrm{active}} d_Y^2)$, in addition to provider calls.
- A full basis snapshot makes d_X^r jet evaluations. It stores at most d_X^r coefficient vectors, or $d_Y d_X^r$ scalar values.
- Dense snapshot expansion stores $d_Y d_X^r$ elements.
- A stream has the same total coefficient payload plus JSON, digest, manifest, and per-chunk overhead. Iteration retains one decoded chunk, though a selected range or materialized snapshot additionally stores the selected result.
- A CuPy snapshot stores `nnz * r` integer indices and `nnz * d_Y` device values. Batched contraction additionally forms an approximately `batch * nnz` factor matrix.
- A live CuPy packet executor stores every dense source and target projector on device as well as the provider tensors and base point.
- Profiling multiplies the selected stage work by warmups plus repetitions. Stream profiling also rewrites a fresh temporary stream for every call.

No function in this chapter estimates free disk space, device-memory capacity, thermal throttling, filesystem quota, or provider-internal allocations. The `max_*` parameters are local guards, not global schedulers.

43.5.4.3 Failure surface

Expected package failures include:

- `ValidationError` for a nonpositive address, evaluation, element, coefficient, chunk, repetition, or selection ceiling.
- `ValidationError` for an uncertified or nonpartitioning support record, plan name/order mismatch, wrong direction count, or failed plan certificate.
- `DimensionError` for direction, derivative, point, coefficient, or projector dimension mismatch.
- `KeyError` when requesting a batch value at an inactive address.
- `ValidationError` for duplicate snapshot coefficient indices, out-of-range indices, or dense expansion above its guard.
- `ValidationError` for an existing destination without overwrite, a partial destination without resume, a changed resume fingerprint or chunk size, incomplete-as-complete reading, selection outside the stored range, or materialization above its guard.
- `ValidationError` for malformed JSON, duplicate keys, nonfinite constants, closed-schema field drift, unsupported stream schema/version, noncontiguous ranges, changed chunk bytes, or changed manifest content.
- `BackendUnavailableError` when a promised CuPy execution path cannot be constructed.
- `DimensionError` for a malformed CuPy batch or non-NumPy packet systems in the live CuPy executor.

Portable snapshot migration failures and stream failures are distinct. The former report codec-version or migration-path errors. The latter reject any schema other than the current stream version.

43.5.4.4 Source-observed implementation boundaries

These behaviors were reproduced from the `1.0.0b4` source. They are boundaries to design around, not compatibility promises:

- `PacketJetExecutionPlan.matches` fingerprints only order and packet names. A changed provider, point, projector matrix, backend, tolerance, or same-name support semantics can pass `matches`. Reconstruction often detects stale pruning on the supplied directions, but a zero probe need not. Recompile.
- A supplied plan makes `estimate_packet_jet_complexity` ignore the supplied `support` object except for a diagnostic flag. It does not prove that the plan was compiled from that support record.
- `profile_packet_jet_runtime` checks only that an optional snapshot `jet` has the same order as the family. It does not require the same point, address, provider, or packet systems. Treat the caller as responsible for workload identity.
- Direct stream resume fingerprints provider name and structural metadata, not callable semantics or projector matrices. Changing a same-named provider between calls can mix incompatible chunks while satisfying the recorded fingerprint.
- `PacketJetSnapshot.comparison_certificate` checks address and dimensions but not provider name, exactness, base point, or coefficient provenance. Its one supplied probe can pass accidentally.
- The direct snapshot's `to_dict()` leaves `capture_certificate` as a `Certificate` object. Use the registered portable codec rather than assuming this report mapping is directly JSON serializable.
- `input_on_device=True` in `CuPyPacketJetExecutor.execute` is a caller declaration, not a strict array-origin validator. Passing host objects can undermine a transfer-excluding timing claim.
- The live CuPy provider checks module discovery before importing CuPy. A discoverable but broken installation can fail during import rather than producing the non-raising status record. Call `cupy_runtime_status()` first.
- Exact snapshots sent through `CuPySnapshotExecutor` are converted to the requested numerical device dtype. The GPU result is numerical even when the source coefficient record had `Exactness.EXACT`.

No certificate here proves provider semantics, cryptographic authorship, portable speedup, global sparsity, asymptotic complexity improvement, device stability, or behavior outside the supplied finite probes.

43.5.4.5 Verification evidence

In the recorded verification, the six shipped examples `scalable_nonlinear.py`, `scalable_nonlinear_runtime.py`, `portable_nonlinear_state.py`, `resumable_packet_jet_stream.py`, `filtered_transport.py`, and `kato_feshbach.py` all completed from the recovered source tree. A focused set of execution, persistence, stream, migration, profiling, nonlinear transport, and quantum transport tests reported:

```
66 passed in 3.90s
```

The environment was Python `3.12.13` with NumPy `2.5.2`. CuPy was unavailable, so the guide locally verified the explicit unavailable path but made no CUDA hardware claim.

> **Chapter 43 summary.** Compile active blocks by ordered input packet tuple, prune only certified zeros, and interpret the reconstruction certificate as parity with the same provider on the supplied directions. Exact count records are not timings. Snapshots freeze coefficients rather than callables. Direct stream resume has only a structural provider fingerprint, while snapshot resume binds the complete coefficient record. Stream digests provide integrity, not authorship. Profile scopes must name synchronization and transfers. CuPy discovery, runtime availability, device execution, CPU parity, and speed are five separate claims.

44. Smooth packet transport

An ordinary packet system fixes a finite orthogonal decomposition. Here, the projectors vary with a real parameter t. The implementation fixes their count and ambient dimension after a reference sample, but it does not separately certify constant rank or continuity. It validates each sampled packet family, compares declared derivatives with centered finite differences, constructs the canonical Kato generator, and offers two finite transport discretizations.

The implementation is numerical and finite-dimensional. Every projector is a dense NumPy complex matrix. There is no symbolic, exact, sparse, batched, or CuPy transport backend in version `1.0.0b4`. Smoothness between sampled times and convergence under indefinite mesh refinement remain mathematical hypotheses, not runtime facts.

A first transport experiment. Begin with the two-packet example in Section 44.4.2. Keep packet order fixed at every time, check the declared derivatives and generator, and then compare the endpoint projectors with the transported initial projectors. Use mesh refinement to investigate numerical sensitivity. A direct rotation between two samples and an evolution along a sampled path answer related but different questions.

All transport symbols in this chapter are version-pinned research APIs in `1.0.0b4`. They are absent from both the curated beta manifest and the frozen stable manifest. Namespace visibility does not grant either stability tier.

44.1 Moving packet systems

Let $P_1(t), \dots, P_m(t) \in \mathbb{C}^{n\times n}$ satisfy

$$P_a(t)^* = P_a(t), \qquad P_a(t)^2 = P_a(t),$$

$$P_a(t)P_b(t) = 0 \quad (a \neq b), \qquad \sum_{a=1}^{m} P_a(t) = I_n.$$

`MovingPacketSystem` requires the projector and derivative callables separately:

```
MovingPacketSystem(
    projectors: Callable[[float], Iterable[Any]],
    derivatives: Callable[[float], Iterable[Any]],
    *,
    tolerance: float = 1e-9,
    reference_time: float = 0.0,
)
```

Construction requires callable inputs, a positive finite tolerance, and a finite reference time. It evaluates the packet family at that reference, validates the complete orthogonal decomposition, and freezes `dimension` and `count`. The callables themselves remain live. No projector samples are cached.

`packets(time)` converts every returned matrix to complex NumPy form and checks that it is finite, square, self-adjoint, idempotent, pairwise orthogonal, and part of a complete identity decomposition under an absolute tolerance and zero relative tolerance. Later calls must preserve the reference dimension and packet count.

`packet_derivatives(time)` requires one finite square derivative matrix per packet with the same ambient dimension. It does not by itself establish that these matrices are derivatives of `packets`.

44.1.1 Differentiated packet identities

Differentiating idempotence gives

$$\dot{P}_a = \dot{P}_a P_a + P_a \dot{P}_a.$$

Differentiating the partition of unity gives

$$\sum_a \dot{P}_a = 0.$$

The sampled validation method is

```
system.derivative_certificate(
    time: float,
    *,
    step: float = 1e-6,
) -> PacketDerivativeResult
```

It forms centered finite differences

$$\dot{P}_a^{\mathrm{FD}}(t;h) = \frac{P_a(t+h) - P_a(t-h)}{2h}$$

and records

$$\rho_{\mathrm{FD}} = \max_a \|\dot{P}_a - \dot{P}_a^{\mathrm{FD}}\|_2,$$

$$\rho_{\tan} = \max_a \|\dot{P}_a - \dot{P}_a P_a - P_a \dot{P}_a\|_2, \qquad \rho_\Sigma = \left\| \sum_a \dot{P}_a \right\|_2.$$

`PacketDerivativeResult` fields are:

- `time` and `step`.
- `maximum_derivative_residual`.
- `tangent_residual` and `partition_derivative_residual`.
- `certificate`.

The numerical `PSC-III-D56` certificate requires all three residuals to be at most

$$\tau_{\mathrm{derivative}} = \max(50\varepsilon, 50h^2),$$

where ε is the system tolerance. This is sampled numerical evidence. It does not prove differentiability on an interval or bound a third derivative.

44.1.2 Canonical generator

For a differentiable complete orthogonal family, define

$$K(t) = \sum_a \dot{P}_a(t) P_a(t).$$

The differentiated identities imply

$$K(t)^* = -K(t).$$

The combined transport identity is

$$K(t) = \sum_a \dot{P}_a(t) P_a(t) = \frac{1}{2} \sum_a [\dot{P}_a(t), P_a(t)], \qquad \dot{U}(t) = K(t) U(t).$$

They also give the equivalent commutator form

$$K(t) = \frac{1}{2} \sum_a [\dot{P}_a(t), P_a(t)]$$

and the transport equation

$$\dot{P}_a(t) = [K(t), P_a(t)].$$

`canonical_generator(time)` evaluates the first formula directly. It returns a matrix even when the declared derivatives are wrong. The separate `generator_certificate(time)` should therefore be required. That certificate records

$$\rho_{\text{skew}} = \|K + K^*\|_2, \qquad \rho_{\text{comm}} = \max_a \|\dot{P}_a - (K P_a - P_a K)\|_2$$

and compares their maximum with 20ε. Its theorem identifier is `PSC-III-T57`, with numerical exactness.

44.2 Kato transport

The canonical unitary transport solves

$$\dot{U}(t) = K(t) U(t), \qquad U(t_0) = I.$$

Because $K^* = -K$, the exact solution is unitary. The commutator equation implies

$$P_a(t) U(t) = U(t) P_a(t_0),$$

so each initial packet range is carried to its corresponding moving range.

`KatoTransport(system)` accepts only a `MovingPacketSystem`. It exposes three finite numerical paths.

44.2.1 Midpoint exponential evolution

```
transport.evolve(
    start: float,
    stop: float,
    *,
    steps: int = 256,
) -> ComputationResult[ndarray]
```

For N positive integer steps and $\Delta = (t_1 - t_0)/N$, the code uses

$$U_{j+1} = \exp\big(\Delta K\big(t_0 + \big(j + \tfrac{1}{2}\big)\,\Delta\big)\big)\, U_j, \qquad U_0 = I.$$

At every midpoint it counts a generator failure when $\|K + K^*\|_2 > 20\varepsilon$. At the endpoint it records

$$\rho_U = \|U_N^* U_N - I\|_2, \qquad \rho_{\text{int}} = \max_a \|P_a(t_1) U_N - U_N P_a(t_0)\|_2.$$

The `PSC-III-T58` certificate is valid only when no sampled generator failure occurred and both endpoint residuals are at most

$$\tau_N = \max(50\varepsilon, 20|\Delta|^2).$$

Its diagnostics record step count and signed step size. `start > stop` is a supported backward integration because Δ may be negative. Equal endpoints return a sampled identity evolution.

The matrix exponential uses `dynamics.matrix_exponential` with its default `method="auto"`. It selects SciPy's `scipy.linalg.expm` when SciPy imports and otherwise uses the NumPy scaling-and-Taylor fallback. `KatoTransport.evolve` does not expose a method selector, so the exponential backend can differ across environments. Both routes are finite floating computations.

44.2.2 Product of direct rotations

```
transport.direct_rotation_product(
    times: Iterable[float],
) -> ComputationResult[ndarray]
```

The time sequence must contain at least two finite, strictly increasing values. For $t_0 < \cdots < t_N$, let R_j be the direct polar rotation from $P(t_j)$ to $P(t_{j+1})$. The method returns

$$U_{\mathrm{rot}} = R_{N-1} \cdots R_1 R_0.$$

Every step certificate is required immediately. The final numerical `PSC-III-T59` certificate checks only endpoint intertwining against 50ε. Diagnostics include the minimum singular value encountered and the number of partition steps. The product can fail when even one adjacent overlap sum is singular or unresolved.

44.2.3 Two-mesh refinement

```
transport.refinement_certificate(
    start: float,
    stop: float,
    *,
    coarse_steps: int = 64,
    refinement_factor: int = 2,
    tolerance: float | None = None,
) -> TransportRefinementResult
```

For coarse count N and integer factor $q \geq 2$, the function computes midpoint evolutions at N and qN steps. It records

$$\rho_{\mathrm{mesh}} = \|U_{qN} - U_N\|_2$$

and the fine endpoint intertwining residual. With no explicit tolerance, the threshold is twice the larger of the two evolution certificate tolerances. The result is valid only when both evolution certificates are valid and both new residuals are within the selected threshold.

`TransportRefinementResult` fields are `coarse_steps`, `fine_steps`, `coarse`, `fine`, `difference`, `endpoint_intertwining`, and `certificate`. The `PSC-III-C60` certificate is a two-mesh numerical comparison. It does not prove an asymptotic error order, a Cauchy estimate for all finer meshes, or continuum convergence.

44.3 Direct packet rotation

Two complete orthogonal packet systems $(P_1, \ldots, P_m)$ and $(Q_1, \ldots, Q_m)$ are paired by iterable order. Form the overlap sum

$$S = \sum_{a=1}^{m} Q_a P_a.$$

When S is invertible, its polar unitary is

$$U = S(S^*S)^{-1/2}.$$

The shipped implementation obtains this factor from the singular value decomposition $S = W\Sigma V^*$ as

$$U = WV^*.$$

It then satisfies

$$Q_a U = U P_a, \qquad 1 \le a \le m.$$

The entry point is

```
direct_packet_rotation(
    source: Iterable[Any],
    target: Iterable[Any],
    *,
    tolerance: float = 1e-10,
) -> DirectRotationResult
```

Both families are independently checked as complete orthogonal packet systems. They must have the same packet count and matrix shape. If the minimum singular value of S is not greater than the input tolerance, the overlap is treated as singular or unresolved and the call raises `ValidationError`.

`DirectRotationResult` stores `unitary`, `minimum_singular_value`, and `certificate`. The `PSC-III-T55` certificate checks

$$\rho_U = \|U^*U - I\|_2, \qquad \rho_{\text{int}} = \max_a \|Q_a U - U P_a\|_2$$

against 20 times the input tolerance. The SVD and residuals are numerical, even though the polar-intertwining theorem is exact under its hypotheses.

Direct rotation is local in packet-system space. If the overlap sum becomes singular, the routine refuses to choose a transport across that step. It does not relabel packets, solve a permutation assignment, or track rank changes.

44.4 Shared nonlinear and quantum implementation

Smooth packet transport is implemented once in this module:

```
komorebi_math.nonlinear.transport
```

The compatibility module `komorebi_math.quantum.kato` directly imports and re-exports:

- `DirectRotationResult` and `PacketDerivativeResult`.
- `TransportRefinementResult`.
- `MovingPacketSystem` and `KatoTransport`.
- `direct_packet_rotation`.

The identity is literal, not merely behavioral:

```
from komorebi_math.nonlinear import KatoTransport as NonlinearKato
from komorebi_math.quantum import KatoTransport as QuantumKato

assert QuantumKato is NonlinearKato
```

The nonlinear namespace owns the domain-independent geometry. The quantum namespace retains the earlier import path and uses the same object in quantum leakage, effective-Hamiltonian, and Feshbach examples. A quantum import does not change the algorithm, add a Hamiltonian assumption, or promote its numerical certificate to a physical theorem.

44.4.1 API and certificate ledger

The complete public record constructors are:

```
DirectRotationResult(
    unitary,
    minimum_singular_value,
    certificate,
)

PacketDerivativeResult(
    time,
    step,
    maximum_derivative_residual,
    tangent_residual,
    partition_derivative_residual,
    certificate,
)

TransportRefinementResult(
    coarse_steps,
    fine_steps,
    coarse,
    fine,
    difference,
    endpoint_intertwining,
    certificate,
)
```

All three are frozen slotted dataclasses. Their NumPy array fields are still mutable array objects. Dataclass freezing does not mark those buffers read-only.

Certificate producers and meanings are:

- `direct_packet_rotation`: `PSC-III-T55`. Numerical unitarity and per-packet intertwining of one polar factor.
- `MovingPacketSystem.derivative_certificate`: `PSC-III-D56`. Sampled finite difference, tangent identity, and differentiated partition identity.
- `MovingPacketSystem.generator_certificate`: `PSC-III-T57`. Sampled skew adjointness and projector commutator identity.
- `KatoTransport.evolve`: `PSC-III-T58`. Sampled generator skewness and endpoint unitarity/intertwining for one midpoint mesh.
- `KatoTransport.direct_rotation_product`: `PSC-III-T59`. Every local polar step plus final endpoint intertwining.
- `KatoTransport.refinement_certificate`: `PSC-III-C60`. Validity of two midpoint runs, their finite difference, and fine endpoint intertwining.

Every runtime certificate above has `Exactness.NUMERICAL`. The theorem or provenance status attached to the underlying finite identity does not change the fact that SVD, matrix exponentials, norms, and comparisons use floating arithmetic.

44.4.2 Rotating two-packet example

Let

$$G = 0.4\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}, \qquad P_0 = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix},$$

$$R(t) = e^{tG}, \qquad P_1(t) = R(t)P_0R(t)^*, \qquad P_2(t) = I - P_1(t).$$

Then $\dot{P}_a = [G, P_a]$. The runnable panel below exercises every transport path:

```
import numpy as np

from komorebi_math.dynamics import matrix_exponential
from komorebi_math.nonlinear import (
    KatoTransport,
    MovingPacketSystem,
    direct_packet_rotation,
)

generator = 0.4 * np.array([[0, -1], [1, 0]], dtype=complex)
base = np.diag([1, 0]).astype(complex)

def packets(time):
    rotation = matrix_exponential(time * generator)
    first = rotation @ base @ rotation.conj().T
    return first, np.eye(2) - first

def derivatives(time):
    return tuple(
        generator @ value - value @ generator
        for value in packets(time)
    )

system = MovingPacketSystem(packets, derivatives)
derivative = system.derivative_certificate(0.3, step=1e-5)
generator_check = system.generator_certificate(0.3)
rotation = direct_packet_rotation(
    system.packets(0.0),
    system.packets(0.2),
)

transport = KatoTransport(system)
midpoint = transport.evolve(0.0, 1.0, steps=128)
polar = transport.direct_rotation_product(np.linspace(0.0, 1.0, 129))
refined = transport.refinement_certificate(
    0.0,
    1.0,
    coarse_steps=32,
    tolerance=1e-6,
)

derivative.certificate.require()
generator_check.require()
rotation.certificate.require()
midpoint.certificate.require()

print(derivative.maximum_derivative_residual)
print(rotation.minimum_singular_value)
print(midpoint.certificate.residuals)
```

```
print(np.linalg.norm(midpoint.value - polar.value, ord=2))
print(refined.coarse_steps, refined.fine_steps, refined.difference)
```

Observed on the recorded build environment:

```
6.765885324179971e-12
0.9968017063026193
{'intertwining': 1.4412780446994425e-16,
 'unitarity': 1.0484054863159256e-14,
 'generator_failures': 0.0}
1.639684926003546e-14
32 64 4.537702386448892e-15
```

These residuals are platform-sensitive floating observations. The near-machine precision agreement is expected here because the example is generated by one constant skew matrix. It does not establish the same behavior for a general moving packet family.

The repository also supplies:

- `examples/filtered_transport.py`, which combines a finite spectral sequence with the two-mesh Kato check.
- `examples/kato_feshbach.py`, which imports the identical transport objects from `komorebi_math.quantum` and combines them with a quantum Feshbach reduction.

44.4.3 Failures, cost, and source-observed boundaries

44.4.3.1 Declared failure surface

The transport layer intentionally rejects:

- an empty packet family.
- A nonsquare or nonfinite packet or derivative matrix.
- A nonpositive or nonfinite packet tolerance.
- Non-self-adjoint, non-idempotent, nonorthogonal, or incomplete projectors.
- Packet count or dimension drift after the reference time.
- Derivative count or shape inconsistent with the packet family.
- A nonfinite time or nonpositive/nonfinite derivative step.
- Direct-rotation packet systems with different counts or dimensions.
- A direct overlap sum whose minimum singular value is at or below tolerance.
- A non-`MovingPacketSystem` passed to `KatoTransport`.
- A Boolean, nonintegral, or nonpositive evolution step count.
- A direct-rotation time partition with fewer than two points or without strict increase.
- A refinement factor below two or not exactly integral.
- A nonpositive or nonfinite explicit refinement tolerance.

Most contract failures are `ValidationError`. Matrix or family shape failures are `DimensionError`. The NumPy-only Taylor fallback for a matrix exponential can also raise `ArithmeticError` if it does not converge within its internal term ceiling.

44.4.3.2 Dense cost and storage

Let m be packet count, n ambient dimension, and N time steps. Ignoring user-callable cost and lower-order additions:

- validating self-adjointness and idempotence uses $O(mn^3)$ dense products. Pairwise orthogonality raises complete family validation to $O(m^2n^3)$.
- Storing one packet sample uses $O(mn^2)$ complex scalars.
- A derivative certificate evaluates packets at three times, evaluates the declared derivatives once, and performs $O(mn^3)$ tangent products after the family validations.
- Constructing the canonical generator uses m dense matrix products, $O(mn^3)$ work and $O(n^2)$ result storage.
- One direct rotation forms m products, takes one $n \times n$ SVD, and checks m intertwining residuals, for $O((m+1)n^3)$ work and dense $O(mn^2)$ sampled packet storage.
- Midpoint Kato evolution costs approximately $O(N(m+1)n^3)$, including one dense matrix exponential per step.
- A direct-rotation product has the same order with one SVD per interval.
- Refinement at factor q performs $N + qN$ midpoint steps.

No step stores the entire time history, but user callables may cache their own state. There is no sparse-projector specialization or device-memory route.

44.4.3.3 Recorded implementation boundaries

These source-observed behaviors should remain visible:

- Packet labels are absent from the transport API. Source packet `a` is paired with target packet `a` solely by iterable position. A reordered but otherwise valid family changes the intended correspondence without a label error.
- The validator accepts a zero-by-zero projector as a formal complete family. `MovingPacketSystem` can therefore report dimension zero, while `direct_packet_rotation` later reaches NumPy's empty minimum reduction and raises a raw `ValueError`. Require positive ambient dimension externally.
- The derivative threshold grows as $50h^2$. A very large finite-difference step can make the certificate permissive rather than informative. For the rotating example, `step=100.0` produced derivative residual about `0.405`, tolerance `500000.0`, and `certificate.valid == True`. Use a scale-appropriate small step and inspect the residual itself.
- The evolution tolerance similarly contains $20|\Delta|^2$. A coarse mesh can receive a large threshold. Require an explicit refinement tolerance and examine several meshes when convergence matters.
- `canonical_generator` does not call `generator_certificate`. Callers can use a matrix built from inconsistent declared derivatives. `evolve` checks sampled skewness and endpoint behavior, but not the full commutator residual at every midpoint.
- Projector and derivative callables are assumed deterministic and free of incompatible side effects. The runtime may call them repeatedly at the same time and provides no purity or continuity check.
- `KatoTransport.evolve` uses the environment-dependent automatic matrix exponential backend and provides no direct option to force SciPy or the NumPy Taylor path.
- A two-mesh refinement pass is a posteriori agreement only. Two discretizations can agree for the wrong reason, and no certificate bounds unsampled behavior.

No object in this chapter proves global differentiability, constant rank beyond the evaluated packet families, existence of an infinite-dimensional Kato propagator, adiabaticity, a spectral gap, physical realizability, or continuum convergence.

44.4.4 Verification evidence

The focused 66-test run reported in §43.5.4.5 includes all four tests in

```
test_nonlinear_transport.py
```

and the transport path in

```
test_quantum_transport_effective_spectral.py
```

It checked shared object identity, derivative and generator residuals, direct polar rotation, midpoint evolution, direct-rotation products, refinement, and invalid time-partition arguments. Both transport examples completed.

Those tests cover finite two-dimensional systems and declared failure cases. They do not remove the source-observed coarse-threshold and zero-dimensional boundaries above.

Chapter 44 summary. A moving packet system is a sampled family of complete orthogonal projectors plus declared derivatives. Require both the derivative and generator certificates before transport. Direct polar rotation is canonical only while the ordered overlap sum is invertible. Kato evolution uses midpoint exponentials and must be judged by unitarity, endpoint intertwining, and mesh refinement together. The quantum namespace re-exports the exact nonlinear implementation. It does not add a different algorithm or a stronger physical claim.

45. Matrix dynamics

The finite-dynamics layer turns a square matrix into a semigroup, resolves that semigroup into packets, compares it across resolutions, and specializes the same machinery to finite Markov, Bayesian, fractional, Green, and Feynman-Kac models. It is a dense finite-dimensional layer. It does not silently promote floating residuals to exact equalities, a finite state model to an infinite process, or an approximately clustered partition to a sufficient statistic.

The `komorebi_math.dynamics` package exports 43 names used in Chapters 45 and 46. Three additional public names are submodule-only: `MarkovKind` from `dynamics.markov`, `FeynmanKacKind` from `dynamics.feynman_kac`, and `blocks_from_labels` from `dynamics.martingales`. Seven established entry points are also re-exported from the broad top-level namespace:

```
from komorebi_math import (
    BayesianUpdate,
    FeshbachReduction,
    MarkovLumping,
    MatrixSemigroup,
    MemoryKernel,
    PhaseTypeSurvival,
    fractional_power,
)
```

None of those names is part of `komorebi_math.stable` or `komorebi_math.beta` in version `1.0.0b4`. The strict research manifest does not cover the `komorebi_math.dynamics` namespace itself. It freezes only the seven root bindings shown above. Import other package or submodule names from their documented locations, pin the package version, and do not infer a frozen signature merely from namespace visibility.

The namespace controls are:

```
FEATURE_KEY = "dynamics"
status() -> FeatureSpec
```

`status()` returns the registered implemented feature specification. It does not run verification.

The claims fall into these classes.

- **E** is an exact finite algebraic identity or a finite combinatorial fact.
- **N** is a numerical evaluation or residual certificate at a stated tolerance.
- **C** is conditional on hypotheses which the returned object identifies but does not establish.
- **H** is a heuristic or clustering rule with no exact sufficiency claim.
- **M** is an implementation work or storage model.
- **O** concerns an optional backend.

The source provenance identifiers retain the historical `PSC-VI` prefix even though this guide places matrix dynamics in Part VII. The prefix is a provenance identifier, not a chapter-number assertion.

45.1 Semigroups and resolvents

For a finite square generator $A \in \mathbb{C}^{n\times n}$, the semigroup is

$$T(t) = e^{tA}.$$

For $s, t \geq 0$, matrix-exponential algebra gives

$$T(0) = I, \qquad T(s+t) = T(s)T(t), \qquad \frac{d}{dt}T(t) = AT(t) = T(t)A.$$

These are exact finite matrix identities. `MatrixSemigroup` evaluates them with floating dense linear algebra, so its certificate is **N** rather than an exact symbolic proof.

45.1.1 Matrix exponential execution

```
matrix_exponential(
    matrix: Any,
    *,
    tolerance: float = 1e-15,
    max_terms: int = 256,
    method: Literal["auto", "scipy", "taylor"] = "auto",
) -> ndarray
```

The input must be a finite square array. `method="auto"` uses `scipy.linalg.expm` when SciPy is importable. Otherwise it uses the NumPy-only scaling-and-Taylor path. `method="scipy"` makes SciPy mandatory and raises `BackendUnavailableError` when it is absent. `method="taylor"` forces the base-installation path, which is useful for independent qualification.

For the Taylor path, let $m = \lceil \log_2(\|A\|_1/0.5) \rceil_+$ and $B = A/2^m$. The implementation forms

$$E_B = I + \sum_{k=1}^{K} \frac{B^k}{k!}$$

until the one-norm of the latest term is at most `tolerance` times the larger of one and the accumulated one-norm. It then squares the result m times. Failure to converge within `max_terms` raises `ArithmeticError`. A nonpositive or nonfinite tolerance, a nonpositive or nonintegral term budget, or an unknown method raises `ValidationError`. The fallback is a numerical algorithm, not an interval enclosure. **N/O**

45.1.2 `MatrixSemigroup`

```
MatrixSemigroup(generator: ndarray)
    .dimension -> int
    .at(time: float) -> ndarray
    .operator(time: float) -> ndarray
    .apply(time: float, vector: Any) -> ndarray
    .resolvent(value: complex) -> ndarray
    .semigroup_certificate(
        first: float,
        second: float,
        *, tolerance: float = 1e-10,
    ) -> Certificate
```

`operator` is a compatibility synonym for `at`. Both require finite nonnegative time. `apply` accepts exactly one vector of length n. It does not accept a matrix of right-hand sides. The resolvent convention is

$$R(z; A) = (zI - A)^{-1}.$$

`resolvent` delegates singularity detection to `numpy.linalg.inv`. It does not estimate the distance from z to the spectrum or certify conditioning.

The semigroup-law residual is

$$\rho_{\mathrm{sg}} = \|T(s+t) - T(s)T(t)\|_2 .$$

The certificate accepts when

$$\rho_{\mathrm{sg}} \le \varepsilon \max\{1, \|T(s+t)\|_2\}.$$

It has exactness `NUMERICAL`, theorem identifier `PSC-VI-T01`, and checked assumption `finite matrix generator`. The class definition carries provenance identifier `PSC-VI-D01`.

45.1.3 Packet-resolved semigroups

Let P_a and Q_b denote a complete finite packet family. The transfer blocks are

$$T_{ba}(t) = Q_b T(t) P_a.$$

Completeness inserts the intermediate packet resolution and gives

$$T_{ca}(s+t) = \sum_b T_{cb}(s) T_{ba}(t).$$

`PacketSemigroup` stores a `MatrixSemigroup` and a `PacketSystem` of the same dimension. `blocks(t)` constructs a `Packet Operator` from $T(t)$, while `generator_blocks()` resolves A itself. `transfer_graph()` places an edge where a generator block exceeds its numerical support tolerance.

```
PacketSemigroup(semigroup: MatrixSemigroup, packets: PacketSystem)
    .from_generator(generator: Any, packets: PacketSystem)
        -> PacketSemigroup
    .blocks(time: float) -> PacketOperator
    .generator_blocks() -> PacketOperator
    .transfer_graph(*, tolerance: float = 1e-12) -> TransferGraph
    .convolution_certificate(
        first: float,
        second: float,
        *, tolerance: float = 1e-10,
    ) -> Certificate
    .minimum_transfer_order(
        source: int,
        target: int,
        *, tolerance: float = 1e-12,
    ) -> int | None
```

The convolution residual reconstructs the packet products as dense matrices:

$$\rho_{\mathrm{packet}} = \left\| \mathrm{rec}(T(s) \circ T(t)) - \mathrm{rec}(T(s+t)) \right\|_2 .$$

It uses theorem `PSC-VI-T02` and exactness `NUMERICAL`. `minimum_transfer_order(a,b)` returns zero for $a = b$, the first path length found in the thresholded generator graph, or `None`. It is therefore a finite graph statement about numerically active blocks. It is not a proof that an analytically nonzero transfer first appears at that order. **E/N**

45.1.4 Refinement and Duhamel defects

Let $A_f \in \mathbb{C}^{n_f \times n_f}$, $A_c \in \mathbb{C}^{n_c \times n_c}$, and $C \in \mathbb{C}^{n_c \times n_f}$. The generator defect and finite-time defect are

$$E = C A_f - A_c C, \qquad \Delta(t) = C e^{t A_f} - e^{t A_c} C.$$

The exact Duhamel identity is

$$\Delta(t) = \int_0^t e^{(t-s)A_c} E e^{s A_f} \, ds.$$

The implemented direct norm bound is

$$\|\Delta(t)\|_2 \le t\exp\bigl(t\max\{\|A_f\|_2,\|A_c\|_2\}\bigr)\,\|E\|_2.$$

For z in both resolvent sets,

$$CR_f(z)-R_c(z)C=R_c(z)ER_f(z).$$

`SemigroupRefinement.duhamel` evaluates the integral using a declared Gauss-Legendre order and checks it against `direct_defect`. It rejects quadrature orders below two. Its internally selected tolerance is $10^{-9}\max(1,\|\Delta(t)\|_2)$, independent of a caller-supplied certificate tolerance. `resolvent_defect` evaluates both sides of the resolvent identity and uses $10^{-10}\max(1,\|CR_f-R_cC\|_2)$. A singular inverse propagates a NumPy linear-algebra exception.

```
SemigroupRefinement(
    coarsen: ndarray,
    fine_generator: ndarray,
    coarse_generator: ndarray,
)
    .generator_defect -> ndarray
    .direct_defect(time: float) -> ndarray
    .duhamel(time: float, *, quadrature_order: int = 24)
        -> ComputationResult[ndarray]
    .norm_bound(time: float) -> float
    .resolvent_defect(value: complex)
        -> ComputationResult[ndarray]

semigroup_refinement_defect(
    coarsen: Any,
    fine_generator: Any,
    coarse_generator: Any,
    time: float | None = None,
    *, quadrature_order: int = 24,
) -> SemigroupRefinement | ComputationResult[ndarray]
```

The wrapper returns the comparison object when `time is None` and its Duhamel result otherwise. The class definition has identifier `PSC-VI-D07`. The two certificates use `PSC-VI-T08` and `PSC-VI-T10`. **E/N**

45.1.5 Finite semigroup towers

A tower stores generators $A_0,\dots,A_{L-1}$ from coarse to fine and adjacent maps $C_0,\dots,C_{L-2}$, where C_j maps level $j+1$ to level j. For $i<j$,

$$C_{i\leftarrow j}=C_iC_{i+1}\cdots C_{j-1},\qquad \Delta_{i\leftarrow j}(t)=C_{i\leftarrow j}e^{tA_j}-e^{tA_i}C_{i\leftarrow j}.$$

```
FiniteSemigroupTower(
    generators: Sequence[Any],
    coarsenings: Sequence[Any],
)
    .levels -> int
    .adjacent(level: int) -> SemigroupRefinement
    .accumulated_coarsening(
        coarse_level: int,
        fine_level: int,
    ) -> ndarray
    .total_defect(
        coarse_level: int,
        fine_level: int,
        time: float,
    ) -> ndarray
    .certificate(*, tolerance: float = 1e-10) -> Certificate
```

`ProjectiveSemigroupTower` is the same class object, not a subclass. The tower requires at least one generator and exactly one fewer coarsening map. Its certificate records every adjacent generator-defect norm as `level_0`, `level_1`, and so on, under theorem `PSC-VI-T12`. Acceptance says only that the finite adjacent defects do not exceed the requested tolerance.

45.2 Markov lumping

The Markov layer consistently uses column probability vectors. A continuous generator Q and a discrete transition matrix P satisfy

$$Q_{ij} \geq 0 \quad (i \neq j), \qquad \mathbf{1}^T Q = 0,$$

and

$$P_{ij} \geq 0, \qquad \mathbf{1}^T P = \mathbf{1}^T.$$

Thus

$$p(t) = e^{tQ} p_0, \qquad p_k = P^k p_0.$$

Supplying row-stochastic data without transposing it changes the model and is normally rejected by the column-sum checks.

When importing a transition matrix from another program, identify its state ordering and probability-vector convention first. In this chapter a column describes transitions from one source state, and the state vector is a column. The Feynman-Kac section later acts on observables and therefore uses a transpose. That change is part of the mathematical convention, not a change in state labels.

45.2.1 Partition normalization and aggregation

`normalize_partition(partition, count)` accepts either one label per state or explicit nonempty blocks. Label blocks are ordered by first appearance. Explicit blocks must contain every index from zero through `count - 1` exactly once. Labels themselves need not be consecutive because the routine normalizes them.

For blocks $B_0, \dots, B_{b-1}$, the mass map $C \in \mathbb{R}^{b \times n}$ and uniform section $S \in \mathbb{R}^{n \times b}$ are

$$C_{ai} = \mathbf{1}_{i \in B_a}, \qquad S_{ia} = \frac{\mathbf{1}_{i \in B_a}}{|B_a|}, \qquad CS = I_b.$$

The implemented kernel basis N_C has one column $e_i - e_{i_0}$ for each nonanchor state in a block. It spans `ker(C)`.

```
AggregationMap(
    partition: Sequence[int] | Iterable[Iterable[int]],
    state_count: int | None = None,
)
    .blocks -> tuple[tuple[int, ...], ...]
    .state_count -> int
    .block_count -> int
    .labels -> tuple[int, ...]
    .matrix -> ndarray
    .uniform_section -> ndarray
    .kernel_basis() -> ndarray
    .aggregate(values: Any) -> ndarray
    .lift_uniform(block_values: Any) -> ndarray

aggregation_matrix(
    partition: Sequence[int] | Iterable[Iterable[int]],
    count: int | None = None,
) -> ndarray
```

`aggregate` and `lift_uniform` accept one-dimensional vectors only. They check dimensions but do not themselves validate probability mass.

45.2.2 Finite chains

```
FiniteMarkovChain(
    operator: ndarray,
    kind: Literal["generator", "transition"] = "generator",
    tolerance: float = 1e-12,
)
    .states -> int
    .generator -> ndarray
    .transition_matrix -> ndarray
    .evolution(amount: float | int) -> ndarray
    .evolve(distribution: Any, amount: float | int) -> ndarray
    .stationary_distribution() -> ComputationResult[ndarray]

ContinuousTimeMarkovChain(
    generator: ndarray,
    tolerance: float = 1e-12,
)
    .states -> int
    .transition(time: float) -> ndarray
    .evolve(distribution: Any, time: float) -> ndarray
    .stationary_distribution() -> ComputationResult[ndarray]
```

Continuous evolution accepts finite nonnegative real time. Discrete evolution requires a nonnegative integer and rejects booleans. `evolve` requires a vector that is nonnegative and has unit mass within the chain tolerance. It zeros components whose magnitude is less than ten times that tolerance after propagation.

The stationary distribution is a least-squares solution of

$$Q\pi = 0, \quad \mathbf{1}^T\pi = 1$$

or

$$(P - I)\pi = 0, \quad \mathbf{1}^T\pi = 1.$$

The certificate records stationarity, mass, and negativity residuals and uses `max(chain.tolerance, 1e-10)`. It has exactness `NUMERICAL` and theorem identifier `PSC-VI-C22`. It does not certify uniqueness, irreducibility, or a spectral gap. **N**

45.2.3 Exact and approximate lumping

The kernel obstruction and section-based coarse candidate are

$$\mathcal{O} = CAN_C, \qquad \widetilde{A}_c = CAS.$$

The coordinate residual compares the coarse-rate columns CAe_i inside each source block. Exact lumpability requires those columns to agree, which is equivalent in this finite setting to an operator A_c satisfying

$$CA = A_cC.$$

`MarkovLumping.is_exact` requires both the spectral norm of CAN_C and the maximum coordinate discrepancy to be at most the requested tolerance. `exact_coarse_operator` rejects a failed criterion with `AssumptionError`. `approximate_coarse_operator` always returns CAS.

In `1.0.0b4`, the coordinate-residual path reconstructs a supplied chain with the chain constructor's default tolerance rather than preserving a looser tolerance carried by an existing `FiniteMarkovChain` or `ContinuousTimeMarkovChain`. A

chain which was valid under its own looser tolerance can therefore raise during `is_exact()` before a Boolean decision is returned. Treat this as a source-version boundary, not a theorem condition.

For generator mode, the evolution defect is

$$\Delta(t) = Ce^{tA} - e^{t\widetilde{A}_c}C,$$

with the source bound

$$\|\Delta(t)\|_2 \le te^{t\max(\|A\|_2,\|\widetilde{A}_c\|_2)}\|CA - \widetilde{A}_cC\|_2.$$

```
coordinate_lumpability_residual(
    operator: Any,
    partition: Sequence[int] | Iterable[Iterable[int]],
    *, kind: Literal["generator", "transition"] = "generator",
) -> float

MarkovLumping(
    operator: Any | FiniteMarkovChain | ContinuousTimeMarkovChain,
    partition: Sequence[int] | Iterable[Iterable[int]],
    *, kind: Literal["generator", "transition"] | None = None,
)
    .partition -> tuple[int, ...]
    .blocks -> tuple[tuple[int, ...], ...]
    .aggregation -> ndarray
    .obstruction -> ndarray
    .is_exact(*, tolerance: float = 1e-10) -> bool
    .approximate_coarse_operator() -> ndarray
    .exact_coarse_operator(*, tolerance: float = 1e-10) -> ndarray
    .coarse_operator -> ndarray
    .coarse_generator(*, tolerance: float = 1e-10) -> ndarray
    .coarse_transition(*, tolerance: float = 1e-10) -> ndarray
    .coarse_chain(*, tolerance: float = 1e-10)
        -> FiniteMarkovChain | ContinuousTimeMarkovChain
    .certificate(*, tolerance: float = 1e-10) -> Certificate
    .aggregate(distribution: Any) -> ndarray
    .evolution_defect(
        amount: float | int,
        *, exact_coarse: bool = False,
    ) -> ndarray
    .semigroup_defect(
        time: float,
        *, use_exact_only: bool = False,
    ) -> ndarray
    .error_bound(time: float) -> float
```

The lumping certificate is **N**, uses theorem `PSC-VI-T21`, and records `kernel_obstruction` and `coordinate_residual`. The underlying theorem is exact finite mathematics. A certificate which passes at nonzero tolerance means numerically lumpable at that tolerance, not literally equal entries.

`semigroup_defect` and `error_bound` are generator-only. The default `evolution_defect` uses the approximate coarse operator unless `exact_coarse=True`. Callers should make that choice visible in reports.

45.3 Bayesian partitions and updates

Given a finite prior $p_i \ge 0$ and likelihood $L_i \ge 0$, the evidence and posterior are

$$Z = L^T p, \qquad p'_i = \frac{L_i p_i}{Z}.$$

`BayesianUpdate` normalizes the supplied prior before computing Z. Likelihoods are not normalized. They must be finite, nonnegative, and positive on at least one state. Posterior access raises `AssumptionError` when the evidence under the normalized prior is zero.

For a second likelihood $\widetilde{L}$, the implemented perturbation bound is

$$\left\| p'_L - p'_{\widetilde{L}} \right\|_1 \le \frac{2 \sum_i p_i |L_i - \widetilde{L}_i|}{\max(Z_L, Z_{\widetilde{L}})}.$$

Interpret this as a posterior perturbation bound only when both evidences $Z_L > 0$ and $Z_{\widetilde{L}} > 0$, so both posteriors exist. The current method raises when both evidences are zero, but when exactly one is zero it can return a finite number even though one posterior is undefined. Callers should check both evidences explicitly before using the result as a posterior bound.

```
BayesianUpdate(prior: Any, likelihood: Any)
    .prior -> ndarray
    .likelihood -> ndarray
    .evidence -> float
    .posterior -> ndarray
    .perturbation_bound(other_likelihood: Any) -> float
```

The class definition has provenance identifier `PSC-VI-D33`.

45.3.1 Two-stage coarsening

For a partition block B, define

$$\bar{p}_B = \sum_{i \in B} p_i, \qquad L_B^{\mathrm{eff}} = \begin{cases} \dfrac{\sum_{i \in B} L_i p_i}{\bar{p}_B}, & \bar{p}_B > 0, \\ 0, & \bar{p}_B = 0. \end{cases}$$

Then finite arithmetic gives

$$\mathrm{agg}(p') = \mathrm{Bayes}(\mathrm{agg}(p), L^{\mathrm{eff}}).$$

`BayesianPartition.coarse_posterior` evaluates both sides and records their maximum componentwise difference as `two_stage_update`. Its fixed tolerance is 10^{-12}, its exactness is `NUMERICAL`, and its theorem identifier is `PSC-VI-T36`.

```
BayesianPartition(partition: Sequence[int])
    .labels -> tuple[int, ...]
    .blocks -> tuple[tuple[int, ...], ...]
    .block_count -> int
    .aggregate(probability: Any) -> ndarray
    .effective_likelihood(prior: Any, likelihood: Any) -> ndarray
    .coarse_posterior(prior: Any, likelihood: Any)
        -> ComputationResult[ndarray]
    .is_fixed_sufficient(
        likelihoods: Sequence[Any],
        *, tolerance: float = 1e-12,
    ) -> bool
    .fixed_coarse_likelihood(
        likelihood: Any,
        *, tolerance: float = 1e-12,
    ) -> ndarray
    .information_loss(
        prior: Any,
```

```
        likelihood: Any,
        coarse_likelihood: Any,
    ) -> float
```

Labels are normalized in sorted-label order inside this class. This differs from `normalize_partition`, which preserves first-appearance order. The blocks are mathematically the same, but their numeric labels can be permuted.

45.3.2 Exact sufficiency and approximate profile clustering

A partition is fixed sufficient for supplied likelihoods when

$$i, j \in B \Longrightarrow L_i^{(r)} = L_j^{(r)} \quad \text{for every supplied profile } r.$$

```
coarsest_sufficient_partition(
    likelihoods: Sequence[Any],
    *, tolerance: float = 0.0,
) -> BayesianPartition

approximate_likelihood_partition(
    likelihoods: Sequence[Any],
    *, tolerance: float,
) -> BayesianPartition
```

The exact routine requires `tolerance=0`. It groups identical tuples of floating profile values and rejects a positive tolerance. This is deliberate: pairwise closeness is generally not transitive and therefore does not define an equivalence relation.

The approximate routine builds a graph whose vertices are state profiles and whose edges join pairs within the maximum-norm tolerance. It returns connected components. Because connected components take the transitive closure, two profiles in one component can differ by more than the input tolerance. The result is **H** and is not promoted to Bayesian sufficiency. Call `is_fixed_sufficient` separately when an exact conclusion is required.

45.3.3 Relative entropy and finite information splitting

For normalized probability vectors,

$$D(p\|q) = \sum_{i:p_i>0} p_i \log \frac{p_i}{q_i}.$$

The implementation preserves $+\infty$ if any $p_i > 0$ while $q_i = 0$. For a partition,

$$D(p\|q) = D(\bar{p}\|\bar{q}) + \sum_B \bar{p}_B D(p(\cdot \mid B)\|q(\cdot \mid B)) \,.$$

```
relative_entropy(first: Any, second: Any) -> float

relative_entropy_decomposition(
    first: Any,
    second: Any,
    partition: Sequence[int],
) -> ComputationResult[dict[str, Any]]
```

The result dictionary contains `total`, `coarse`, and `conditional_terms`. If the direct and decomposed values are both infinite, the residual is defined to be zero. Otherwise it is their absolute difference. The certificate uses theorem `PSC-VI-T41` and fixed tolerance 10^{-12}. **E/N**

45.3.4 Bayesian flow and hidden Markov filtering

For a score vector s, the exponential-likelihood flow is

$$p_i(t) = \frac{p_i(0)e^{ts_i}}{\sum_j p_j(0)e^{ts_j}}, \qquad \dot{p}_i = p_i(s_i - \mathbb{E}_{p(t)}s).$$

It obeys

$$\frac{d}{dt}\mathbb{E}_{p(t)}s = \mathrm{Var}_{p(t)}\, s \geq 0.$$

`BayesianFlow.at` subtracts the largest shifted score before exponentiation to avoid overflow. It permits finite positive or negative time. The methods return direct floating values and do not attach a derivative certificate.

For a column-stochastic transition P, one hidden-Markov step is

$$\hat{p} = Pp, \qquad p^+ = \mathrm{Bayes}(\hat{p}, L).$$

Exact coarse filtering requires both exact transition lumpability and a block-constant likelihood. If either hypothesis fails, `HiddenMarkovFilter.coarse_step` returns the directly aggregated fine result with a failed `CONDITIONAL` certificate. It does not fabricate an approximate coarse transition. When both pass, it compares the direct aggregation with the reconstructed coarse filter at the caller's tolerance under theorem `PSC-VI-T46`.

```
BayesianFlow(prior: Any, scores: Any)
    .at(time: float) -> ndarray
    .derivative(time: float) -> ndarray
    .expected_score(time: float) -> float
    .score_variance(time: float) -> float

HiddenMarkovFilter(transition: ndarray)
    .step(prior: Any, likelihood: Any) -> ndarray
    .coarse_step(
        prior: Any,
        likelihood: Any,
        partition: Sequence[int],
        *, tolerance: float = 1e-10,
    ) -> ComputationResult[ndarray]
```

45.4 Fractional powers and Green operators

The fractional layer is a finite Hermitian spectral calculus. For $A = U\,\mathrm{diag}(\lambda_i)U^* \succeq 0$ and $\alpha > 0$,

$$A^\alpha = U\,\mathrm{diag}(\lambda_i^\alpha)U^*, \qquad e^{-tA^\alpha} = U\,\mathrm{diag}(e^{-t\lambda_i^\alpha})U^*.$$

The input must be square, Hermitian to the supplied absolute tolerance, and positive semidefinite to that tolerance. Eigenvalues between $-\varepsilon$ and zero are clipped to zero. The operation uses `numpy.linalg.eigh`. It is **N**, even when the displayed spectral identity is exact.

```
fractional_power(
    matrix: Any,
    exponent: float,
    *, tolerance: float = 1e-12,
) -> ndarray

fractional_semigroup(
    matrix: Any,
    exponent: float,
    time: float,
```

```
    *, tolerance: float = 1e-12,
) -> ndarray
```

Both require a positive finite exponent. The semigroup additionally requires finite nonnegative time.

45.4.1 Naturality and the positive-gap defect bound

Exact intertwining gives the finite spectral identity

$$CA_f = A_c C \Longrightarrow CA_f^{\alpha} = A_c^{\alpha} C.$$

The numerical certificate records both

$$\rho_A = \|CA_f - A_c C\|_2, \qquad \rho_\alpha = \|CA_f^{\alpha} - A_c^{\alpha} C\|_2.$$

For $0 < \alpha < 1$ and a common strictly positive spectral gap γ, the implemented theorem bound is

$$\|CA_f^{\alpha} - A_c^{\alpha} C\|_2 \le \alpha \gamma^{\alpha-1} \|CA_f - A_c C\|_2.$$

```
fractional_naturality_certificate(
    coarsen: Any,
    fine_operator: Any,
    coarse_operator: Any,
    exponent: float,
    *, tolerance: float = 1e-10,
) -> Certificate

fractional_defect(
    coarsen: Any,
    fine_operator: Any,
    coarse_operator: Any,
    exponent: float,
    *, tolerance: float = 1e-12,
) -> FractionalDefectResult
```

`FractionalDefectResult` is a frozen, slotted dataclass with fields `defect`, `bound`, `generator_defect_norm`, `spectral_gap`, and `certificate`. The certificate tests the actual norm against the theorem bound plus a numerical allowance. The naturality and defect identifiers are `PSC-VI-T25` and `PSC-VI-T26`. The computed common gap must exceed the caller's tolerance, not merely be positive. A missing certified gap or an exponent outside $(0, 1)$ raises `ValidationError`. The routine does not emit a vacuous infinite bound. **E/N**

The two helper functions do not forward their caller tolerance to every internal `fractional_power` call. Those nested calls use the default 10^{-12} tolerance. Consequently, an operator which passes an initial Hermitian or positivity check under a looser requested tolerance can still raise during the internal power computation. Validate with the stricter default or catch this source-version boundary explicitly.

45.4.2 Discrete Dirichlet Green operator

For $N \ge 1$ interior points and $h = (N+1)^{-1}$,

$$A_h = h^{-2}\,\mathrm{tridiag}(-1, 2, -1).$$

At grid points $x_i = ih$, the continuum Dirichlet kernel is

$$G(x, y) = \min(x, y)(1 - \max(x, y)),$$

and the source implements the exact finite identity

$$G_h = A_h^{-1} = h\,[G(x_i, x_j)]_{i,j}.$$

```
DirichletGreen1D(interior_points: int)
    .spacing -> float
    .grid -> ndarray
    .operator -> ndarray
    .continuum_kernel_samples -> ndarray
    .inverse -> ndarray
    .solve(source: Sequence[float]) -> ndarray
    .eigenvalues() -> ndarray
    .eigenvalue_error_bound(mode: int) -> float
    .certificate(*, tolerance: float = 1e-10) -> Certificate
```

The discrete eigenvalues are

$$\lambda_{k,h} = \frac{4}{h^2}\sin^2\!\left(\frac{k\pi h}{2}\right), \qquad 1 \le k \le N,$$

and the implemented mode bound is

$$0 \le (k\pi)^2 - \lambda_{k,h} \le \frac{(k\pi)^4 h^2}{12}.$$

The certificate checks only $\|A_h G_h - I\|_2$ under theorem `PSC-VI-T49`. It does not check every mode bound. The source materializes dense $N \times N$ arrays. It does not exploit the tridiagonal solve complexity. **E/N/M**

45.5 Finite Feynman-Kac transfer

`FiniteFeynmanKac` acts on observables, while the Markov objects above act on column probability vectors. For a column generator Q and a nonnegative potential V, the backward killed generator and transfer are

$$L_V = Q^T - \operatorname{diag}(V), \qquad K_V(t) = e^{tL_V}.$$

For a column-stochastic transition P, the declared one-step operator is

$$K_V = \operatorname{diag}(e^{-V})P^T.$$

The order is significant: killing multiplies the observable after the transpose transition in the displayed matrix product. Discrete propagation uses integer powers of this one-step operator.

```
FiniteFeynmanKac(
    markov_operator: Any,
    potential: Any,
    *,
    kind: Literal["generator", "transition"] = "generator",
    tolerance: float = 1e-12,
)
    .states -> int
    .backward_generator -> ndarray
    .one_step_operator -> ndarray
    .operator(amount: float | int) -> ndarray
    .apply(observable: Any, amount: float | int) -> ndarray
    .potential_perturbation_bound(
        other_potential: Any,
        time: float,
    ) -> float
    .coarse_model(
        partition: Sequence[int] | Sequence[Sequence[int]],
```

```
        *, tolerance: float = 1e-10,
    ) -> ComputationResult[FiniteFeynmanKac | None]
```

Continuous propagation requires finite nonnegative time. Discrete propagation requires a nonnegative integer and rejects booleans. The continuous perturbation estimate is

$$\|K_V(t) - K_{\widetilde{V}}(t)\|_2 \le t \exp\Big(t(\|Q^T\|_2 + \max(\|V\|_\infty, \|\widetilde{V}\|_\infty))\Big)\, \|V - \widetilde{V}\|_\infty.$$

Exact coarsening requires both a lumpable Markov operator and a potential constant on every block. When either condition fails, `.value` is `None` and the failed certificate has exactness `CONDITIONAL`, residuals `lumping` and `potential_variation`, and unchecked assumptions naming both requirements. When both hold, `.value` is the coarse model and the certificate is valid and `NUMERICAL`. Both paths use theorem identifier `PSC-VI-C57`. The model definition is documented under `PSC-VI-T55`.

The coarsening path also reconstructs its Markov lumping object without preserving a looser source-model tolerance. After a tolerance-based success, the returned certificate hard-codes its `lumping` residual to `0.0`. That field is not the measured coordinate or obstruction residual and must not be cited as evidence of literal zero.

This finite transfer is a matrix implementation of the Feynman-Kac semigroup. It does not construct sample paths or certify an infinite-state stochastic representation. **E/N/C**

45.6 Finite conditional expectations, martingale towers, and energy diagnostics

Let $w_i > 0$ be finite weights, normalized by the constructor, and let $\mathcal{P}$ be a partition. The weighted conditional expectation is

$$(E_{\mathcal{P}} f)_i = \frac{\sum_{j \in B(i)} w_j f_j}{\sum_{j \in B(i)} w_j}, \qquad \langle f, g \rangle_w = \sum_i w_i \overline{f_i} g_i.$$

The dense matrix is constant by rows inside each block. It obeys

$$E_{\mathcal{P}}^2 = E_{\mathcal{P}}, \qquad \operatorname{diag}(w) E_{\mathcal{P}} = E_{\mathcal{P}}^* \operatorname{diag}(w).$$

`ConditionalExpectation.certificate` checks both spectral-norm residuals at the caller's tolerance under theorem `PSC-VI-T17`.

```
ConditionalExpectation(
    partition: Iterable[Iterable[int]],
    weights: Any,
)
    .blocks -> tuple[tuple[int, ...], ...]
    .weights -> ndarray
    .matrix -> ndarray
    .apply(values: Any) -> ndarray
    .inner(left: Any, right: Any) -> complex
    .certificate(*, tolerance: float = 1e-11) -> Certificate

partition_refines(
    fine: tuple[tuple[int, ...], ...],
    coarse: tuple[tuple[int, ...], ...],
) -> bool
```

For partitions becoming finer with level, let E_j be their conditional expectations. The tower law and martingale differences are

$$E_iE_j = E_{\min(i,j)}, \qquad d_0 = E_0 f, \qquad d_j = E_j f - E_{j-1} f.$$

The finite energy decomposition is

$$\|E_m f\|_w^2 = \sum_{j=0}^{m} \|d_j\|_w^2.$$

```
MartingaleTower(
    partitions: Iterable[Iterable[Iterable[int]]],
    weights: Any,
)
    .weights -> ndarray
    .project(values: Any, level: int) -> ndarray
    .differences(values: Any) -> tuple[ndarray, ...]
    .energy_decomposition(values: Any)
        -> ComputationResult[tuple[float, ...]]
    .tower_certificate(*, tolerance: float = 1e-10)
        -> Certificate

ConditionalExpectationTower(
    weights: Any,
    label_partitions: Iterable[Iterable[int]],
)
    .weights -> ndarray
    .expectations -> tuple[ConditionalExpectation, ...]
    .project(values: Any, level: int) -> ndarray
    .differences(values: Any) -> tuple[ndarray, ...]
    .energy(values: Any) -> ComputationResult[tuple[float, ...]]
    .certificate(*, tolerance: float = 1e-10) -> Certificate
```

`MartingaleTower` rejects an empty tower or a pair of partitions which is not nested coarse-to-fine. `ConditionalExpectationTower` converts each label vector to blocks by first-appearance order. The helper `blocks_from_labels(labels)` is public from `komorebi_math.dynamics.martingales`, but is not re-exported by `komorebi_math.dynamics` in this release.

The tower and energy certificates use theorem `PSC-VI-T18` and exactness `NUMERICAL`. Their success establishes the finite weighted identities for the supplied partitions and vector. It does not establish a stochastic-process martingale outside this finite probability space.

45.6.1 Runnable matrix-dynamics panel

```
import numpy as np

from komorebi_math.dynamics import (
    ConditionalExpectationTower,
    DirichletGreen1D,
    FiniteFeynmanKac,
    MatrixSemigroup,
)

semigroup = MatrixSemigroup(np.diag([-1.0, -2.0]))
law = semigroup.semigroup_certificate(0.2, 0.3)
law.require()

tower = ConditionalExpectationTower(
    [1.0, 1.0, 1.0, 1.0],
    [[0, 0, 0, 0], [0, 0, 1, 1], [0, 1, 2, 3]],
)
energy = tower.energy([1.0, 2.0, 4.0, 8.0])
energy.certificate.require()
```

```
green = DirichletGreen1D(4)
green.certificate().require()

transition = np.kron(
    np.array([[0.8, 0.3], [0.2, 0.7]]),
    np.eye(2),
)
feynman_kac = FiniteFeynmanKac(
    transition,
    [0.1, 0.1, 0.4, 0.4],
    kind="transition",
)
coarse = feynman_kac.coarse_model([0, 0, 1, 1])
coarse.certificate.require()

print("semigroup diagonal", np.diag(semigroup.at(0.5)))
print("semigroup residual", law.residuals["semigroup_law"])
print("martingale energies", energy.value)
print("energy residual", energy.certificate.residuals["energy_decomposition"])
print("green spacing", green.spacing)
print("green inverse residual", green.certificate().residuals["inverse_identity"])
print("Feynman-Kac coarse", coarse.certificate.valid, coarse.value.states)
```

Observed output from the audited source tree:

```
semigroup diagonal [0.60653066 0.36787944]
semigroup residual 0.0
martingale energies (14.0625, 5.0625, 2.125)
energy residual 0.0
green spacing 0.2
green inverse residual 1.0924759764801266e-15
Feynman-Kac coarse True 2
```

45.6.2 Claim strength and completion boundary

The strongest justified statements in this chapter are finite.

- Semigroup, Duhamel, resolvent, lumping, Bayesian, entropy, spectral, Green, Feynman-Kac, and martingale formulas are **E** as finite identities under their displayed hypotheses.
- Source certificates are **N** because they evaluate dense floating arrays and compare residuals with tolerances.
- Failed HMM and Feynman-Kac coarsenings are **C** records. They expose the missing hypotheses instead of returning an exact coarse claim.
- Approximate likelihood partitioning is **H**. Graph connectivity is exact for the constructed graph, but sufficiency is not inferred.
- No API here proves convergence of a refinement tower, an infinite-state Markov limit, continuous-path Feynman-Kac, a continuum fractional operator, or an infinite filtration.

45.6.3 Complexity, storage, and execution tiers

Let n be the fine dimension, b a coarse block count, L a tower depth, m a likelihood-profile count, and N a Green grid size.

- Dense matrix exponentials, eigendecompositions, inverses, and stationary least-squares solves have the usual $O(n^3)$ arithmetic and $O(n^2)$ storage model. **M**
- A forced Taylor exponential uses at most `max_terms` dense multiplications plus the scaling squarings. Its upper work model is $O((K + \log\|A\|)n^3)$. **M**
- Explicit packet blocks and conditional-expectation matrices are dense in this implementation. Even blockwise formulas can materialize $O(n^2)$ data. **M**

- Partition normalization and one Bayesian update are linear in the state count. Exact profile grouping is $O(nm)$ expected dictionary work. Approximate profile clustering performs $O(n^2 m)$ pairwise comparisons and stores an $O(n^2)$ worst-case graph. **M**
- The Green implementation stores dense operator, kernel, and inverse arrays, so construction and application use $O(N^2)$ storage/work despite the tridiagonal structure of A_h. **M**
- Discrete Feynman-Kac propagation uses dense matrix powering, conventionally $O(n^3 \log k)$ for step count k. **M**

Tier 0 is NumPy and the base package. Tier 1 optionally uses SciPy only for the matrix exponential. There is no sparse-matrix, exact-rational, streaming, or CUDA path in `komorebi_math.dynamics 1.0.0b4`. Passing a CuPy array through `numpy.asarray` is not a supported device execution contract.

45.6.4 Source-observed boundaries and defects

- `MarkovKind` and `FeynmanKacKind` are public aliases in their submodules but are not re-exported by `komorebi_math.dynamics.__all__`.
- `blocks_from_labels` has the same submodule-only boundary.
- `BayesianPartition` normalizes labels in sorted order, whereas `AggregationMap` uses first appearance. Do not compare raw label numbers across the two classes without aligning blocks.
- Partition helpers coerce supplied labels and explicit state indices with `int(...)`. Numeric values such as `1.5` can therefore be truncated instead of rejected as nonintegral. Supply genuine integer indices.
- `approximate_likelihood_partition` returns connected components, so endpoint profiles in a tolerance chain can differ by more than the tolerance.
- `FiniteSemigroupTower.total_defect` calls the matrix exponential directly and does not apply `MatrixSemigroup`'s finite nonnegative-time validator. Validate tower times at the calling boundary when that convention matters.
- `FiniteMarkovChain.evolve` checks nonnegativity and total mass but does not explicitly check that every distribution entry is finite. A vector containing `NaN` can evade those comparisons and propagate `NaN`. Validate external distributions before calling it.
- `HiddenMarkovFilter` likewise does not explicitly precheck every transition entry for finiteness. A transition containing `NaN` can therefore reach the filtering arithmetic. Validate the transition matrix as finite before construction.
- The likelihood-profile partition helpers require finite profile entries but do not reject negative finite values at their own boundary. Later Bayesian sufficiency routines do reject negative likelihoods. Validate profiles as nonnegative before asking either profile-partition helper to group them.
- `DirichletGreen1D.certificate` checks the inverse identity only. The mode error bounds are separate returned values and are not included in that certificate.
- `FiniteFeynmanKac.potential_perturbation_bound` is a continuous-generator helper. It is not available in transition mode and is not a pathwise error certificate.
- `FiniteFeynmanKac.potential_perturbation_bound` does not explicitly reject a nonfinite `other_potential`. A `NaN` entry can produce a returned `NaN` bound. Validate comparison potentials as finite at the calling boundary.
- All numerical tolerances are absolute unless the formula above explicitly includes a scale. A passing residual must be interpreted together with conditioning and input scale.

45.6.5 Provenance and certificate ledger

These identifiers must be read together with the symbol that emits them. An identifier alone is not a globally unique evidence key. In this source release, runtime records carrying `PSC-VI-T01`, `PSC-VI-T08`, `PSC-VI-T10`, `PSC-VI-T12`, `PSC-VI-C22`, `PSC-VI-T41`, `PSC-VI-T46`, or `PSC-VI-C57` do not all have a matching attached provenance object on the emitting callable. Treat the fully qualified callable, identifier, package version, and certificate payload as the evidence address.

- `MatrixSemigroup` carries definition record `PSC-VI-D01` for the finite matrix semigroup. `MatrixSemigroup.semigroup_certificate` emits `PSC-VI-T01` for the semigroup-law residual.
- `PacketSemigroup.convolution_certificate` emits `PSC-VI-T02` for packet-semigroup convolution.
- `SemigroupRefinement` carries definition record `PSC-VI-D07`. `SemigroupRefinement.duhamel` emits `PSC-VI-T08`. `SemigroupRefinement.resolvent_defect` emits `PSC-VI-T10`, and `FiniteSemigroupTower.certificate` emits `PSC-VI-T12` for adjacent generator defects.

- `FiniteMarkovChain` carries definition record `PSC-VI-D18` for the finite column-convention Markov operator. `FiniteMarkovChain.stationary_distribution` emits `PSC-VI-C22` for a computed stationary distribution, and `MarkovLumping.certificate` emits `PSC-VI-T21` for exact-lumping residuals.
- `BayesianUpdate` carries definition record `PSC-VI-D33`. `BayesianPartition.coarse_posterior` emits `PSC-VI-T36` for two-stage Bayesian coarsening. `relative_entropy_decomposition` emits `PSC-VI-T41`, and `HiddenMarkovFilter.coarse_step` emits `PSC-VI-T46` for exact or conditionally failed coarse filtering.
- `ConditionalExpectation.certificate` emits `PSC-VI-T17`, while `MartingaleTower.energy_decomposition` and `.tower_certificate` emit `PSC-VI-T18` for energy and tower identities.
- `fractional_power` carries attached record `PSC-VI-T24`. `fractional_naturality_certificate` emits `PSC-VI-T25`, and `fractional_defect` emits `PSC-VI-T26` for the positive-gap bound.
- `DirichletGreen1D.certificate` emits `PSC-VI-T49` for the discrete Green inverse.
- `FiniteFeynmanKac` carries attached record `PSC-VI-T55`, while `FiniteFeynmanKac.coarse_model` emits `PSC-VI-C57` for exact or conditionally failed coarsening.

Every returned `Certificate` states exactness, residuals, checked assumptions, and a theorem identifier. A `ComputationResult` preserves its numerical `.value` even when a conditional certificate is false, except that failed Feynman-Kac coarsening uses `value=None`.

45.6.6 Error model and troubleshooting

- `DimensionError`: nonsquare arrays, incompatible coarsening maps, wrong vector lengths, mismatched likelihood profiles, or a malformed Green source.
- `ValidationError`: invalid method/tolerance/budget, negative semigroup time, malformed partitions, invalid Markov signs or column sums, noninteger discrete steps, invalid probabilities or likelihoods, nonnested towers, non-Hermitian or nonpositive fractional operators, missing positive gap, invalid Green mode, or invalid Feynman-Kac kind/potential.
- `AssumptionError`: a zero-evidence posterior, a nonconstant fixed coarse likelihood, or a requested exact Markov coarse operator for a nonlumpable partition.
- `BackendUnavailableError`: `method="scipy"` without SciPy.
- `ArithmeticError`: Taylor fallback exhaustion.
- `numpy.linalg.LinAlgError`: a requested resolvent or other dense inverse is singular.
- A false certificate is not an exception until the caller invokes `certificate.require()` or `result.require()`.

Evidence: `src/komorebi_math/dynamics/_linalg.py`, `semigroups.py`, `markov.py`, `bayes.py`, `martingales.py`, `fractional.py`, `green.py`, and `feynman_kac.py`.

46. Feshbach reduction, memory, and survival

Chapter 46 eliminates a declared hidden coordinate sector from a finite linear system. In the resolvent domain, elimination produces a Schur or Feshbach effective operator. In the time domain, the same block algebra produces a matrix-valued memory kernel and a hidden-source term. Finite phase-type survival is a separate specialization in which a stable transient Markov subgenerator loses mass to absorption.

The shared algebra does not make every memory kernel a survival law. A survival interpretation additionally requires the column-subgenerator, positivity, mass-loss, and stability conditions in Section 46.5.

Choose the question first. Use the resolvent route for dependence on a spectral parameter, the memory route for the effect of hidden dynamics over time, and the survival route only for an admissible absorbing Markov model. Keep the retained index order and any hidden initial state with the calculation. The sign conventions are written side by side in Section 46.2 so that a formula from another reference can be aligned before comparing values.

46.1 Retained and eliminated blocks

Choose a nonempty set P of retained coordinate indices and let Q be its nonempty complement. Reordering only for display gives

$$A = \begin{bmatrix} A_{PP} & A_{PQ} \\ A_{QP} & A_{QQ} \end{bmatrix}, \qquad u = \begin{bmatrix} x \\ y \end{bmatrix}.$$

The implementation does not physically permute the stored matrix. It uses `numpy.ix_` with the declared retained order and the complementary hidden indices in their original increasing order.

```
FeshbachReduction(matrix: Any, retained: Iterable[int])
    .matrix -> ndarray
    .retained -> tuple[int, ...]
    .hidden -> tuple[int, ...]
    .retained_block -> ndarray
    .hidden_block -> ndarray
    .retained_to_hidden -> ndarray
    .hidden_to_retained -> ndarray
    .a_pq -> ndarray
    .a_qp -> ndarray
```

The historical names require care:

- `retained_to_hidden` returns the top-right block A_{PQ}. As a matrix, it maps a hidden vector into the retained equation.
- `hidden_to_retained` returns the bottom-left block A_{QP}. It maps a retained vector into the hidden equation.
- `a_pq` and `a_qp` are unambiguous aliases for those arrays.

The matrix must be finite and square. Retained indices are coerced by Python `int`, after which they must be nonempty, unique, and in range. At least one hidden coordinate must remain. Construction raises `DimensionError` for a nonsquare matrix and `ValidationError` for invalid values or sectors. The definition carries provenance identifier `PSC-VI-D27`.

46.2 Feshbach/Schur effective operator

The guide records both common sign conventions. For the operator $H - zI$, the Feshbach map is

$$F_P(z) = P(H - z)P - PHQ\,[Q(H - z)Q]^{-1}QHP.$$

This is the $H - z$ convention. For the implementation's $zI - H$ convention,

$$F_P(z) = A_{\text{eff}}(z) - zI_P, \qquad P(zI - H)^{-1}P = -F_P(z)^{-1} = (zI_P - A_{\text{eff}}(z))^{-1}.$$

In source notation,

$$\Sigma(z) = A_{PQ}(zI_Q - A_{QQ})^{-1}A_{QP}, \qquad A_{\text{eff}}(z) = A_{PP} + \Sigma(z).$$

Provided both the hidden and full resolvents exist, block inversion gives

$$P(zI - A)^{-1}P = (zI_P - A_{\text{eff}}(z))^{-1}.$$

```
FeshbachReduction
    .self_energy(spectral_parameter: complex) -> ndarray
    .effective_operator(spectral_parameter: complex) -> ndarray
    .effective_resolvent(spectral_parameter: complex) -> ndarray
    .direct_projected_resolvent(
        spectral_parameter: complex,
    ) -> ndarray
    .resolvent_certificate(
        spectral_parameter: complex,
        *, tolerance: float = 1e-10,
    ) -> ComputationResult[ndarray]
```

The certificate returns the effective resolvent as `.value` and compares it with the retained principal block of the full resolvent:

$$\rho_{\text{Fesh}} = \left\|(zI_P - A_{\text{eff}})^{-1} - P(zI - A)^{-1}P\right\|_2.$$

It accepts when

$$\rho_{\text{Fesh}} \le \varepsilon \max\left\{1, \left\|P(zI - A)^{-1}P\right\|_2\right\}.$$

The exact Schur identity is **E** under the two resolvent hypotheses. The source certificate is **N**, names both hypotheses as checked because both inversions completed, and uses theorem `PSC-VI-T28`. It does not report condition numbers. A singular or numerically singular inverse raises `numpy.linalg.LinAlgError` before a failed certificate can be returned.

The minus sign in the displayed `H-z` relation is not optional. If a caller compares `effective_resolvent(z)` directly with $F_P(z)^{-1}$ under that convention, it will introduce exactly one erroneous sign.

46.3 Rational memory kernels

Consider the finite block system

$$\dot{x} = A_{PP}x + A_{PQ}y, \qquad \dot{y} = A_{QP}x + A_{QQ}y.$$

Variation of constants gives

$$y(t) = e^{tA_{QQ}}y(0) + \int_0^t e^{(t-s)A_{QQ}}A_{QP}x(s)\,ds.$$

Substitution into the retained equation yields

$$\dot{x}(t) = A_{PP}x(t) + f_Q(t) + \int_0^t K(t-s)x(s)\,ds,$$

where

$$K(t) = A_{PQ}e^{tA_{QQ}}A_{QP}, \qquad f_Q(t) = A_{PQ}e^{tA_{QQ}}y(0).$$

The hidden initial state therefore contributes an inhomogeneous source. It cannot be discarded unless $y(0) = 0$ or its retained image is independently known to vanish.

More generally, a finite rational memory kernel is

$$K(t) = Be^{tD}C, \qquad \widehat{K}(z) = B(zI - D)^{-1}C.$$

For finite horizon T, source algebra gives

$$\widehat{K}_T(z) = B(zI - D)^{-1}(I - e^{(D-zI)T})C,$$

and

$$\widehat{K}(z) - \widehat{K}_T(z) = B(zI - D)^{-1}e^{(D-zI)T}C.$$

The last two formulas are algebraic resolvent-exponential identities whenever $zI - D$ is invertible. Interpreting $\widehat{K}(z)$ as the convergent integral from zero to infinity additionally requires a spectral half-plane condition, which `MemoryKernel.laplace` does not check.

```
MemoryKernel(output: Any, hidden: Any, input: Any)
    .output -> ndarray
    .hidden -> ndarray
    .input -> ndarray
    .retained_dimension -> int
    .hidden_dimension -> int
    .at(time: float) -> ndarray
    .evaluate(time: float) -> ndarray
    .laplace(spectral_parameter: complex) -> ndarray
    .finite_laplace(
        spectral_parameter: complex,
        horizon: float,
    ) -> ndarray
    .certificate(
        spectral_parameter: complex,
        *,
        horizon: float = 10.0,
        points: int = 1001,
        tolerance: float = 1e-9,
    ) -> Certificate
```

For $B \in \mathbb{C}^{p\times q}$, $D \in \mathbb{C}^{q\times q}$, and $C \in \mathbb{C}^{q\times p}$, the constructor requires the displayed shapes and finite entries. The retained input and output dimension must be the same. `at` and `finite_laplace` require finite nonnegative time or horizon. `evaluate` is a compatibility synonym for `at`.

`MemoryKernel.certificate` checks the finite-plus-tail algebraic decomposition, not quadrature:

$$\rho_{\mathrm{mem}} = \left\| \widehat{K}_T(z) + B(zI - D)^{-1} e^{(D-zI)T} C - \widehat{K}(z) \right\|_2 .$$

The diagnostics record `horizon`, `requested_quadrature_points`, and `tail_norm`. The `points` value must be at least two, but no quadrature is performed and changing it does not change the computed matrices or validity. The certificate is **N** and uses theorem `PSC-VI-T30`.

`RationalMemoryKernel` is exactly the same class object as `MemoryKernel`. It is not a distinct representation.

46.4 Hidden-state realizations

A rational memory kernel can be executed locally by retaining the hidden state:

$$\frac{d}{dt}\begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix}\begin{bmatrix} x \\ y \end{bmatrix} .$$

Its retained component realizes the Volterra memory equation with the initial hidden-source term included.

```
RationalMemoryRealization(output: Any, hidden: Any, input: Any)
    .output -> ndarray
    .hidden -> ndarray
    .input -> ndarray
    .retained_dimension -> int
    .hidden_dimension -> int
    .kernel() -> MemoryKernel
    .augment(retained_generator: Any) -> ndarray
    .retained_trajectory(
        retained_generator: Any,
        initial_state: Any,
        time: float,
    ) -> ndarray
```

`augment` requires a square retained generator of shape $p \times p$. `retained_trajectory` requires a vector of length $p + q$, exponentiates the full augmented generator, and returns its first p coordinates. It is a dense direct execution, not a Volterra discretization.

46.4.1 Finite local closure

Cayley-Hamilton reduces the closure question to the finite moment list

$$M_j = A_{PQ} A_{QQ}^{j} A_{QP}, \qquad j = 0, \ldots, d_Q - 1.$$

For a hidden dimension d_Q,

$$M_j = 0 \quad \text{for all } j < d_Q \iff K(t) \equiv 0 \iff \text{the retained feedback closes locally.}$$

```
FeshbachReduction
    .memory_kernel() -> MemoryKernel
    .memory_kernel_at(time: float) -> ndarray
    .hidden_source(hidden_initial: Any, time: float) -> ndarray
    .closure_moments() -> tuple[ndarray, ...]
    .local_closure_certificate(
        *, tolerance: float = 1e-10,
    ) -> Certificate
```

`local_closure_certificate` stores one spectral norm per moment as `moment_0`, …, `moment_{d_Q-1}`. It accepts when their maximum is no larger than the tolerance and uses theorem `PSC-VI-T29`. The equivalence at exact zero is **E**. Passing at nonzero tolerance is a numerical near-closure statement, not an exact vanishing proof.

46.4.2 Finite-horizon kernel and trajectory bounds

For two kernels, the implementation samples

$$\delta_K(T) = \int_0^T \|K_1(t) - K_2(t)\|_2 \, dt$$

with trapezoidal quadrature. `kernel_l1_error` returns only that estimate. When both inputs are `MemoryKernel` instances, `memory_kernel_error_bound` augments the estimate by a global derivative allowance and also forms separate exponential-norm bounds. It returns the smaller certified candidate, while retaining the sampled estimate and both allowances in the certificate.

For arbitrary callables, no derivative information is available. The same routine returns only the trapezoidal estimate with exactness `CONDITIONAL` and the unchecked assumption that it upper-bounds the true integral.

```
kernel_l1_error(
    first: MemoryKernel | Callable[[float], Any],
    second: MemoryKernel | Callable[[float], Any],
    horizon: float,
    *, samples: int = 1001,
) -> float

memory_kernel_error_bound(
    first: MemoryKernel | Callable[[float], Any],
    second: MemoryKernel | Callable[[float], Any],
    *, horizon: float,
    samples: int = 1001,
) -> ComputationResult[float]
```

Both require a finite nonnegative horizon and at least two samples. The rational-kernel certificate uses theorem `PSC-VI-T31`, exactness `NUMERICAL`, and residual fields `quadrature_estimate`, `quadrature_allowance`, and `separate_exponential_bound`.

Given declared finite-horizon bounds M for a reference trajectory, a for the retained local generator, and κ for the reference kernel, the source returns

$$\|x_1 - x_2\|_{[0,T]} \le MT\delta_K \exp((a+\kappa)T).$$

```
volterra_trajectory_bound(
    kernel_l1_difference: float,
    horizon: float,
    trajectory_bound: float,
    retained_generator_norm: float | None = None,
    reference_kernel_l1: float | None = None,
    *,
    local_generator_bound: float | None = None,
    kernel_l1_bound: float | None = None,
) -> float
```

The two keyword pairs are compatibility names for the same a and κ. The routine requires one value from each pair and requires every input to be finite and nonnegative. It does not compute or validate the declared trajectory, generator, or reference-kernel bounds. The result is therefore **C** on those caller-supplied hypotheses.

46.5 Phase-type survival models

A phase-type model evolves a column probability vector through a finite transient subgenerator Q. The constructor normalizes its supplied initial vector:

$$p_0 = \frac{p_{\text{supplied}}}{\mathbf{1}^T p_{\text{supplied}}}.$$

For $t \geq 0$,

$$p(t) = e^{tQ} p_0, \qquad S(t) = \mathbf{1}^T p(t), \qquad a = -\mathbf{1}^T Q.$$

The event density and hazard are

$$f(t) = a\, p(t), \qquad h(t) = \frac{f(t)}{S(t)}.$$

The finite admissibility conditions are

$$Q_{ij} \geq 0 \quad (i \neq j), \qquad a_j = -\sum_i Q_{ij} \geq 0, \qquad \max \operatorname{Re} \sigma(Q) < 0.$$

The implementation strengthens the last check to spectral abscissa strictly below `-tolerance`. For cause-specific absorption rows $a^{(c)}$, it requires

$$a_j^{(c)} \geq 0, \qquad \sum_c a_j^{(c)} = a_j$$

within the model tolerance.

The Laplace transform and moments are

$$\mathbb{E}[e^{-sT}] = a(sI - Q)^{-1} p_0,$$

$$\mathbb{E}[T^m] = m!\, \mathbf{1}^T (-Q)^{-m} p_0.$$

Cause densities and the residual initial law are

$$f_c(t) = a^{(c)} p(t), \qquad \sum_c f_c(t) = f(t), \qquad p_t^{\text{res}} = \frac{p(t)}{S(t)}.$$

```
PhaseTypeSurvival(
    subgenerator: Any,
    initial: Any,
    *,
    cause_rates: Any | None = None,
    tolerance: float = 1e-12,
    validate: bool = True,
)
    .subgenerator -> ndarray
    .initial -> ndarray
    .cause_rates -> ndarray | None
    .tolerance -> float
    .states -> int
    .absorption_rates -> ndarray
    .certificate() -> Certificate
    .transient_probability(time: float) -> ndarray
```

```
    .survival(time: float) -> float
    .density(time: float) -> float
    .hazard(time: float) -> float
    .laplace_transform(parameter: float) -> float
    .moment(order: int) -> float
    .cause_density(time: float) -> ndarray
    .residual_initial(time: float) -> ndarray
    .residual_model(time: float) -> PhaseTypeSurvival
    .identities_certificate(
        time: float,
        *, step: float = 1e-6,
    ) -> Certificate
```

By default, construction calls `certificate().require()`. With `validate=False`, it stores even an inadmissible model so that callers can inspect the failed certificate. Subsequent numerical methods are not guarded by an automatic revalidation.

The model certificate has theorem identifier `PSC-VI-T32`, exactness `NUMERICAL`, and residuals:

- `negative_off_diagonal`, the magnitude of the worst forbidden off-diagonal entry.
- `negative_absorption_rate`, the magnitude of the worst negative total absorption rate.
- `cause_rate_sum`, the maximum cause-sum mismatch.
- `spectral_abscissa_failure`, the clipped margin $\max(0, \alpha(Q) + \varepsilon)$, not an exact signed distance to admissibility. At equality $\alpha(Q) = -\varepsilon$, this residual is zero even though the source's strict inequality still makes the certificate invalid.

`hazard` returns positive infinity when survival is no larger than the model tolerance. `laplace_transform` requires a finite nonnegative parameter. `moment` requires a nonnegative integer and returns one at order zero. `cause_density` requires declared causes. A residual restart fails when the survival mass is no larger than tolerance.

`identities_certificate` checks

$$-S'(t) = f(t), \qquad \sum_c f_c(t) = f(t)$$

using a centered difference for the first identity. It requires finite $t \geq h > 0$ and uses a fixed acceptance tolerance 10^{-5}, independent of the model tolerance. The certificate identifier is `PSC-VI-T33`. **E/N**

46.6 Finite completion boundaries

This implementation completes several questions in finite dimension and intentionally leaves stronger questions open.

46.6.1 What is complete

- A declared coordinate split produces all four blocks without ambiguity.
- Whenever the hidden and full resolvents exist, the Schur-Feshbach resolvent identity is exact finite algebra.
- Eliminating a finite hidden linear state yields the displayed source plus Volterra-memory equation.
- Every finite auxiliary realization produces a rational resolvent expression.
- Cayley-Hamilton makes exact local closure decidable from finitely many moments.
- A matrix satisfying the phase-type admissibility conditions defines the finite survival, transform, moment, competing-risk, and restart formulas.

46.6.2 What is not completed by these APIs

- A successful finite resolvent check does not give a uniform spectral region, analytic continuation, or an infinite-dimensional Feshbach theorem.
- The rational expression $B(zI - D)^{-1}C$ is not automatically the Laplace integral on every invertible point. Convergence needs an additional half-plane condition.
- A small closure residual does not prove exact local closure unless the tolerance is zero and arithmetic is exact.
- Finite-horizon kernel estimates do not imply long-time stability.
- The Volterra trajectory formula accepts declared bounds. It does not derive them.
- A generic stable matrix memory kernel is not automatically positive, Markov, or a survival law.
- A phase-type fit does not prove that observed data were generated by that model, identify a unique hidden realization, or establish a continuum lifetime law.
- No minimal-realization, controllability, observability, model-reduction, or statistical-estimation algorithm is supplied in this release.

These boundaries are the correct stopping point for the finite package. A future infinite-dimensional extension would need separate domain, closedness, spectral, convergence, and tightness hypotheses rather than larger finite test sweeps alone.

46.6.3 Runnable Feshbach, memory, and survival panel

The self-contained panel below exercises the finite resolvent, local closure, rational-memory comparison, and phase-type identity paths together.

```
import numpy as np

from komorebi_math.dynamics import (
    FeshbachReduction,
    PhaseTypeSurvival,
    RationalMemoryRealization,
    memory_kernel_error_bound,
)

matrix = np.array([
    [-0.4,  0.2,  0.3,  0.0],
    [ 0.0, -0.6,  0.0, -0.2],
    [ 0.4,  0.0, -1.0,  0.1],
    [ 0.0,  0.5,  0.0, -1.4],
])
reduction = FeshbachReduction(matrix, retained=[0, 1])
resolvent = reduction.resolvent_certificate(2.0 + 0.3j)
resolvent.certificate.require()

first = RationalMemoryRealization([[1.0]], [[-1.0]], [[1.0]])
second = RationalMemoryRealization([[0.9]], [[-1.0]], [[1.0]])
memory_bound = memory_kernel_error_bound(
    first.kernel(),
    second.kernel(),
    horizon=2.0,
    samples=101,
)
memory_bound.certificate.require()

survival = PhaseTypeSurvival(
    [[-0.7, 0.2], [0.3, -0.6]],
    [1.0, 0.0],
)
identity = survival.identities_certificate(0.5)
identity.require()

print("Feshbach residual", resolvent.certificate.residuals["feshbach_resolvent"])
```

```
print("exact local closure", reduction.local_closure_certificate().valid)
print("memory K(1)", first.kernel().at(1.0))
print("memory upper bound", memory_bound.value)
print("survival S(1)", survival.survival(1.0))
print("survival mean", survival.moment(1))
print("identity residuals", identity.residuals)
```

Observed output from the audited source tree:

```
Feshbach residual 1.1259825589158814e-16
exact local closure False
memory K(1) [[0.36787944]]
memory upper bound 0.3672534856322114
survival S(1) 0.6703200460356394
survival mean 2.5
identity residuals {'density_derivative': 9.21618337201835e-12, 'cause_sum': 0.0}
```

The shipped `examples/feshbach_memory.py` additionally prints the complex self-energy, the kernel at zero, and a failed exact-closure result. Its observed output is:

```
self energy at z=2+0.3i:
[[ 0.03960396-0.0039604j   0.00143203-0.00027196j]
 [-0.        +0.j         -0.02918455+0.00257511j]]
memory kernel at zero:
[[ 0.12  0.  ]
 [ 0.   -0.1 ]]
exact local closure: False
```

The failed closure value is expected evidence of retained feedback through the hidden sector, not a failed example.

46.6.4 Complexity and storage

Let p be the retained dimension, q the hidden dimension, $n = p + q$, and S the number of kernel samples.

- One self-energy requires a dense $q \times q$ inverse and the two coupling products, conventionally $O(q^3 + pq^2 + p^2q)$ work and $O(q^2 + pq)$ auxiliary storage. **M**
- The direct projected resolvent in the certificate additionally inverts the full $n \times n$ matrix, so the check is $O(n^3)$. **M**
- One time-domain kernel evaluation requires a hidden matrix exponential and dense products, conventionally $O(q^3)$. **M**
- The closure list contains q retained matrices. The straightforward recurrence stores $O(qp^2)$ output and performs repeated dense products. It is finite but not a Krylov-compressed implementation. **M**
- `kernel_l1_error` performs S evaluations of both kernels. For rational kernels this is $O(Sq^3)$ under a dense-exponential model. **M**
- One phase-type probability or density evaluation uses a dense exponential, while a moment uses a dense inverse and matrix power. No factorization is cached across calls. **M**

All Chapter 46 routines are NumPy CPU routines, except that their shared matrix exponential may use optional SciPy. There is no sparse, GPU, symbolic rational, automatic model-order reduction, or streaming survival tier.

46.6.5 Certificate ledger

As in Chapter 45, pair every theorem identifier with its emitting symbol and package version. An identifier alone is not a complete evidence key.

- `PSC-VI-T28`: Feshbach resolvent. Residual `feshbach_resolvent`. Scaled numerical acceptance.
- `PSC-VI-T29`: local closure. Residuals `moment_j`. Absolute numerical acceptance.
- `PSC-VI-T30`: rational memory transform decomposition. Residual `laplace_decomposition`. Diagnostics include horizon, requested point count, and tail norm.

- PSC-VI-T31: memory_kernel_error_bound emits the rational-kernel upper estimate or callable conditional quadrature, while the attached provenance object carrying this identifier is on volterra_trajectory_bound. Residual fields distinguish the estimate and allowances.
- PSC-VI-T32: phase-type admissibility. Four structural/stability residuals.
- PSC-VI-T33: PhaseTypeSurvival.identities_certificate emits the survival derivative and cause-sum record with fixed 10^{-5} numerical tolerance. The emitting method has no matching attached provenance object in this release.

Every ComputationResult retains both .value and .certificate. .require() returns the value when the certificate is valid and raises the package's certificate failure when it is not. A direct method which needs a matrix inverse can raise before any result record exists.

46.6.6 Error model and troubleshooting

- DimensionError: nonsquare Feshbach matrix, mismatched realization blocks, wrong hidden initial vector, wrong augmented state, wrong retained generator, or wrong survival/cause shape.
- ValidationError: nonfinite matrices, invalid retained indices, no hidden sector, negative/nonfinite memory time or horizon, too few quadrature samples, missing Volterra bounds, invalid survival probability, invalid moment order, unavailable cause rates, or a zero-survival restart. A finite positive constructor tolerance is enforced specifically by PhaseTypeSurvival. Not every certificate method in this chapter validates its tolerance argument.
- numpy.linalg.LinAlgError: a singular hidden, full, transform, or moment inverse.
- Certificate failure: a resolvent residual, local-closure criterion, rational transform decomposition, phase-type admissibility condition, or survival identity exceeds its acceptance rule.
- BackendUnavailableError: only when the shared matrix exponential is forced to method="scipy" without SciPy. Chapter 46 methods call the default auto mode and therefore fall back to Taylor.

46.6.7 Source-observed boundaries and defects

- MemoryKernel.certificate(..., points=...) validates and records points but performs no quadrature. The argument cannot improve this certificate.
- FeshbachReduction.resolvent_certificate, the local-closure certificate, and MemoryKernel.certificate do not consistently reject negative or nonfinite certificate tolerances. Such values can yield invalid records rather than ValidationError. Validate certificate tolerances as finite and positive before these calls.
- FeshbachReduction coerces retained indices with int(...) and does not compare the result with the original value. A numeric value such as 1.5 can be truncated to index one. Supply genuine integers.
- MemoryKernel.certificate forms its horizon expression directly rather than calling finite_laplace. Unlike finite_laplace, it does not explicitly reject a negative or nonfinite horizon. Validate horizon before calling the certificate.
- MemoryKernel.laplace checks invertibility only. It does not check the spectral condition needed to interpret the rational expression as an infinite-horizon Laplace integral.
- RationalMemoryRealization.retained_trajectory and FeshbachReduction.hidden_source do not apply the nonnegative finite-time validation used by MemoryKernel.at. Validate time at the application boundary when forward-time semantics are required.
- PhaseTypeSurvival(validate=False) intentionally bypasses construction-time rejection. Numerical methods remain callable on the invalid object.
- PhaseTypeSurvival does not explicitly prevalidate every subgenerator entry for finiteness. NaN or infinity may reach the eigensolver and raise numpy.linalg.LinAlgError rather than a package validation exception.
- PhaseTypeSurvival.identities_certificate uses a fixed 10^{-5} threshold rather than the model tolerance, and it uses finite differences rather than the available analytic derivative.
- Neither FeshbachReduction nor MemoryKernel estimates resolvent condition numbers. A tiny algebraic residual can coexist with a highly sensitive inverse.
- RationalMemoryKernel and ProjectiveSemigroupTower are aliases. Code should not rely on them to distinguish representations at runtime.

46.6.8 Executed verification evidence

These source-tree checks were executed for the reference baseline with `PYTHONPATH` directed at the delivered repository:

- `test_dynamics_semigroups_markov.py`, `test_dynamics_bayes_martingales.py`, `test_dynamics_fractional_green_feynman_survival.py`, `test_dynamics_feshbach.py`, and `test_block4_hardening.py`: **34 passed**.
- Installed dynamics verification: **11/11 passed**.
- Shipped examples `markov_bayes.py`, `fractional_survival.py`, `feshbach_memory.py`, and `kato_feshbach.py`: **4/4 completed**.

The shipped Markov/Bayesian example reported the coarse generator

$$\begin{bmatrix} -0.1 & 0 \\ 0.1 & 0 \end{bmatrix},$$

coarse posterior `[0.63157895 0.36842105]`, and fixed sufficiency `True`. The fractional/survival example reported square-root spectrum `[1. 2. 3.]`, fractional-transfer diagonal `[0.4965853 0.24659696 0.12245643]`, survival at one `0.6703200460356394`, and mean lifetime `2.5`.

These executions qualify the cited finite source behavior in the audited environment. They do not erase the explicit conditional and infinite-dimensional boundaries above.

Evidence: `src/komorebi_math/dynamics/feshbach.py`, `memory.py`, `survival.py`, `examples/feshbach_memory.py`, `examples/fractional_survival.py`, `examples/markov_bayes.py`, `examples/kato_feshbach.py`, and the focused tests listed above.

Part VIII. Exact finite integration and typed expressions

There are two complementary workflows in this part. Chapters 47 through 49 integrate finite polynomials or sampled callables against explicit measures. Chapters 50 through 52 represent finite rational coordinate calculations as typed expressions that can be checked, evaluated, simplified, planned, and stored. Ordinary integration does not require learning the expression language first.

Your goal	Start here	Keep with the result
Integrate a rational polynomial exactly	Sections 47.1, 47.2, and 48.1	Polynomial, measure, and exact rational inputs
Integrate a callable numerically	Section 48.2	Method, evaluation count, and error-guarantee class
Certify a Simpson error bound	Section 48.3	The matched polynomial, interval, and derivative-bound provenance
Check an integral identity or work in polynomial coordinates	Chapter 49	Both sides of the identity and the basis witness
Build a reusable exact coordinate pipeline	Chapters 50 and 51	Semantic types, exact data, and certificate
Plan or exchange a typed expression	Chapter 52	Budget, canonical expression record, and semantic digest

Use integers and `Fraction` values from the start when rational exactness is intended. A decimal-looking result and an exact rational result may describe similar numbers while carrying different evidence. The worked examples show where that distinction changes the permitted conclusion.

47. Measures and exact polynomials

Integration in Komorebi Math begins with two deliberately small finite objects: a sparse polynomial over $\mathbb{Q}$ and a measure that can return finite monomial moments. This separation is important. A polynomial says what is being integrated. A measure says how monomials are weighted. The dispatcher contracts the two only after their dimensions and certificates agree.

The public objects are exported from `komorebi_math.integration` and from the top-level research API. They are not members of the frozen `komorebi_math.stable` or `komorebi_math.beta` surfaces. All conclusions below are therefore conclusions about the finite integration research API in version `1.0.0b4`.

47.1 `ExactPolynomial`

An `ExactPolynomial` represents

$$p(x_1, \dots, x_d) = \sum_{\alpha \in A} c_\alpha x^\alpha, \qquad x^\alpha = \prod_{j=1}^{d} x_j^{\alpha_j},$$

where $A \subset \mathbb{N}^d$ is finite and every $c_\alpha \in \mathbb{Q}$. The stored representation is immutable, sparse, and canonical: equal exponent tuples are combined, zero coefficients are removed, and the remaining terms are sorted lexicographically.

```
ExactPolynomial(
    dimension: int,
    terms: Mapping[Sequence[int], Rational]
         | Iterable[tuple[Sequence[int], Rational]],
)
```

`Rational` here means `int | fractions.Fraction`. Boolean and floating-point coefficients are rejected. This is not cosmetic type discipline: it prevents an `EXACT` certificate from hiding conversion of a binary float such as `0.1`. The dimension must be positive, each exponent tuple must have that dimension, and every exponent must be a nonnegative integer.

Four constructors cover the common cases:

```
ExactPolynomial.zero(dimension)
ExactPolynomial.constant(value, dimension=1)
ExactPolynomial.monomial(coefficient, exponents)
ExactPolynomial.univariate(coefficients)
```

`univariate((c0, c1, ..., cn))` uses ascending degree order,

$$(c_0, c_1, \dots, c_n) \longmapsto c_0 + c_1 x + \cdots + c_n x^n.$$

An empty coefficient iterable produces the zero polynomial.

For example, an ascending coefficient sequence starts with the constant term, then the linear term, then the quadratic term. Sparse multivariate terms instead pair each coefficient with an exponent tuple whose positions follow the variable order. Confirm that order before comparing a polynomial with a coordinate vector from another basis.

The main query properties are `degree`, `degrees`, and `term_count`. `coefficient(alpha)` returns zero when the canonical term is absent. `to_univariate_coefficients()` returns a dense ascending tuple and rejects a multivariate polynomial.

The finite algebra is exposed by explicit methods rather than Python arithmetic operators:

```
p.add(q)
p.subtract(q)
p.scale(scalar)
p.multiply(q, *, max_terms=100000)
p.power(exponent, *, max_terms=100000)
p.derivative(variable=0, order=1)
p.antiderivative(variable=0, constant=0)
p.evaluate(point)                # p(point) is an alias
```

Addition and multiplication require a common ambient dimension. Powers are nonnegative integers. Differentiation permits order zero. Antidifferentiation adds the supplied constant to the all-zero exponent. The identities are the ordinary finite polynomial identities over $\mathbb{Q}$. In particular,

$$\frac{\partial}{\partial x_j}\left(\sum_{\alpha} c_\alpha x^\alpha\right) = \sum_{\alpha_j > 0} \alpha_j c_\alpha x^{\alpha - e_j}.$$

`multiply`, `power`, and affine pullback enforce `max_terms`. The bound is checked while the sparse expansion is built, so a combinatorial expansion fails explicitly instead of exhausting memory silently. The default budget is 100,000 terms. **E/M**

`integrate_out(variable, lower, upper, *, density=1)` eliminates one variable against a constant-density rational interval. For one monomial it applies

$$\rho \int_a^b x_j^{\alpha_j}\, dx_j = \rho \frac{b^{\alpha_j+1} - a^{\alpha_j+1}}{\alpha_j + 1}.$$

The result is a lower-dimensional `ExactPolynomial`, or a `Fraction` after the final variable is removed. Bounds must satisfy $a \le b$. Oriented bounds are handled separately by `integrate_polynomial_oriented` in Section 48.1.2.

An exact affine pullback is available both as

```
p.pullback_affine(matrix, shift, *, max_terms=100000)
mapping.pullback(p, *, max_terms=100000)
```

For $T(x) = Mx + b$, it constructs $p \circ T$ by substituting one exact linear polynomial for every target coordinate. The matrix shape is `p.dimension x source_dimension`. The output lives in the source dimension.

```
from fractions import Fraction as F

from komorebi_math.integration import ExactPolynomial

p = ExactPolynomial(2, {(2, 0): 1, (0, 1): 3})
q = p.derivative(0)
r = p.antiderivative(1).derivative(1)

print(p((2, 5)))
print(q((2, 5)))
print(r == p)
print(p.multiply(p).degree)
```

Observed output:

```
19
4
True
4
```

The `certificate()` result has theorem identifier `INT.POLY.1` and records dimension, total degree, degree in each variable, and term count. It certifies the canonical finite rational representation, not analytic regularity beyond polynomials. **E**

47.2 Atomic, interval, product, and pushforward measures

47.2.1 The finite `Measure` protocol

The runtime-checkable `Measure` protocol is intentionally minimal:

```
dimension: int
name: str
exactness: Exactness

mass() -> ComputationResult[Any]
moment(exponents: Sequence[int]) -> ComputationResult[Any]
certificate() -> Certificate
```

For a measure μ on a finite-dimensional space, its monomial moment is

$$m_\alpha(\mu) = \int x^\alpha \, d\mu(x).$$

Consequently a sparse polynomial integral is the finite contraction

$$\int p \, d\mu = \sum_{\alpha \in A} c_\alpha m_\alpha(\mu).$$

Implementing the Python protocol is not by itself a proof that a custom object's moments are mathematically correct. `integrate` first requires the structural certificate and propagates its exactness and unchecked assumptions. An exact result requires exact value closure as well as exact, unconditional measure and moment certificates.

47.2.2 Atomic measures

```
AtomicMeasure(
    points: Iterable[Any],
    weights: Iterable[Any],
    *,
    name: str = "atomic measure",
)
```

This object represents the positive finite measure

$$\mu = \sum_{i=1}^{N} w_i \, \delta_{x_i}, \qquad w_i \geq 0.$$

Scalar points define a one-dimensional measure. Tuple-like points define the ambient dimension. The point list must be nonempty, all point dimensions must agree, and the number of weights must equal the number of points. Coordinates and weights may be exact integers/Fractions or finite reals, but negative weights and nonfinite values are rejected.

The basic formulas are finite sums:

$$\mu(X) = \sum_i w_i, \qquad m_\alpha(\mu) = \sum_i w_i x_i^\alpha.$$

When all canonical coordinates and weights are rational, `exactness` is `Exactness.EXACT`. Otherwise it is `NUMERICAL`. `mass()` and `moment()` preserve arbitrary-size exact integers and Fractions. Numerical sums use finite-range checks and accurate scalar summation.

`normalized()` divides every weight by the total mass and rejects a zero-mass measure or numerical underflow. `coalesced()` merges exactly equal canonical point tuples while preserving their first-occurrence order. If zero weights leave no positive atom, it retains one zero-weight atom so the class invariant of nonempty support remains true. Because constructor weights are nonnegative, coalescing never turns this object into a signed functional.

```
from fractions import Fraction as F

from komorebi_math.integration import AtomicMeasure, integrate

mu = AtomicMeasure(
    (-1, 0, 2),
    (F(1, 2), F(1, 3), F(1, 6)),
)
result = integrate(lambda x: (1, x, x * x), mu)

print(result.exact)
print(tuple(result.value))
```

Observed output:

```
True
(Fraction(1, 1), Fraction(-1, 6), Fraction(7, 6))
```

The callable is evaluated once per atom. All outputs must retain one common shape. A scalar at one atom and a vector at another raises `DimensionError`. **E/N**

47.2.3 Interval measures

```
IntervalMeasure(
    lower: Any,
    upper: Any,
    *,
    density: Any = 1,
    name: str = "interval measure",
)
```

This is the positive constant-density measure

$$d\mu(x) = \rho\, dx \quad \text{on } [a, b], \qquad a \le b, \quad \rho \ge 0.$$

Its mass and moments are

$$\mu([a, b]) = \rho(b - a), \qquad m_k(\mu) = \rho \frac{b^{k+1} - a^{k+1}}{k + 1}.$$

Integer or Fraction endpoints and density give exact rational data. Any floating input gives a numerical measure. `structurally_zero` is true when `lower == upper` or `density == 0`. Integration over that measure returns exact zero without evaluating a callable integrand. Reversed endpoints and negative density are rejected because this class models a positive measure, not an oriented integral.

```
from fractions import Fraction as F

from komorebi_math.integration import (
    ExactPolynomial,
    IntervalMeasure,
    integrate,
)

mu = IntervalMeasure(-1, 2, density=F(3, 2))
p = ExactPolynomial.univariate((4, -2, 1))

print(tuple(mu.moment((k,)).require() for k in range(5)))
print(integrate(p, mu).require())
```

Observed output:

```
(Fraction(9, 2), Fraction(9, 4), Fraction(9, 2),
 Fraction(45, 8), Fraction(99, 10))
18
```

`normalized()` replaces the density by $1/(b-a)$, independent of the original nonzero density, and rejects a zero interval. Numerical mass, moment, normalization, and pushforward paths reject detected overflow, underflow, collapsed distinct endpoints, and nonfinite results. **E/N**

47.2.4 Product measures

```
ProductMeasure(
    factors: Iterable[Measure],
    *,
    name: str = "product measure",
)

product_measure(*factors, name="product measure")
```

The factors must form a nonempty finite tuple of `Measure` objects. The dimension is the sum of factor dimensions, and exactness is the weakest factor status. For an exponent tuple split compatibly as $\alpha = (\alpha^{(1)}, \dots, \alpha^{(r)})$,

$$m_\alpha(\mu_1 \otimes \cdots \otimes \mu_r) = \prod_{j=1}^{r} m_{\alpha^{(j)}}(\mu_j).$$

The factor mass, moment, and structural certificates are incorporated into the returned certificate. An invalid or conditional factor cannot be hidden by the product wrapper.

A product of marginals asserts independence. It is not interchangeable with an arbitrary joint atomic law. For the two Bernoulli marginals

$$\mu_X = \mu_Y = \tfrac{1}{2}\delta_0 + \tfrac{1}{2}\delta_1,$$

the product gives $\mathbb{E}[XY] = 1/4$. The joint law $\frac{1}{2}\delta_{(0,0)} + \frac{1}{2}\delta_{(1,1)}$ gives $1/2$. The shipped tests check this distinction directly.

47.2.5 Pushforward measures and exact affine maps

For a map $T : X \to Y$, the pushforward is defined by preimage:

$$(T_{\#}\mu)(B) = \mu(T^{-1}(B)).$$

Its integration law is

$$\int_Y f \, d(T_{\#}\mu) = \int_X f \circ T \, d\mu.$$

The exact map type is

```
ExactAffineMap(
    matrix: Iterable[Iterable[Rational]],
    shift: Iterable[Rational],
    *,
    name: str = "exact affine map",
)
```

and represents $T(x) = Mx + b$ over $\mathbb{Q}$. It exposes `source_dimension`, `target_dimension`, `square`, `apply_point`, callable evaluation, `then`, `pullback`, `determinant`, and `certificate`. Composition `first.then(second)` means `second(first(x))`. `determinant()` requires a square linear part. Rectangular affine maps remain valid typed maps.

```
PushforwardMeasure(
    base: Measure,
    mapping: ExactAffineMap | Callable[[Any], Any],
    *,
    target_dimension: int | None = None,
    name: str = "pushforward measure",
)

pushforward_measure(base, mapping, *, target_dimension=None, name=...)
```

An exact affine map determines its target dimension and preserves the base exactness status. An arbitrary callable requires an explicit positive `target_dimension` and yields at least `CONDITIONAL` status. Its certificate records unchecked global definition, target-dimension, determinism, purity, and finiteness assumptions. Testing the callable on finite atoms does not prove those global properties.

`materialize_atomic()` is available only when the base is atomic. It maps the support once and coalesces equal images. For example, pushing four atoms at $-2, -1, 1, 2$, with source weights $(1/6, 1/3, 1/4, 1/4)$, through $x \mapsto x^2$ produces atoms at 1 and 4 with weights $7/12$ and $5/12$. With a callable map this is explicitly a snapshot. Callable purity and determinism remain unchecked.

For the one-dimensional affine map $y = sx + t$, `IntervalMeasure.pushforward_affine` materializes the image. If $s \neq 0$,

$$[a, b] \longmapsto [\min(sa + t, sb + t), \max(sa + t, sb + t)], \qquad \rho' = \frac{\rho}{|s|}.$$

If $s = 0$, the image is the one-atom measure $\rho(b - a)\delta_t$. Thus mass is preserved in both cases. The absolute Jacobian belongs to the density of the materialized image. It is not an extra factor in the abstract pushforward integration identity.

47.2.6 Two canonical moment ladders

Moment sequences make the finite contract visible before any general polynomial is introduced. For the Bernoulli atomic measure

$$\mu_p = (1-p)\delta_0 + p\delta_1, \qquad 0 \le p \le 1,$$

the exact moments are

$$m_0(\mu_p) = 1, \qquad m_k(\mu_p) = p \quad (k \ge 1).$$

For the constant-density probability measure on $[0, 1]$,

$$m_k = \int_0^1 x^k \, dx = \frac{1}{k+1}.$$

`AtomicMeasure` and `IntervalMeasure` reproduce these ladders as `Fraction` values when p, the endpoints, and the density are rational. A floating parameter produces numerical status instead of being relabelled exact.

47.3 Positive measures versus signed quadrature functionals

An `AtomicMeasure` requires $w_i \ge 0$. A `QuadratureRule`, introduced in Chapter 48, represents the more general linear functional

$$Q[f] = \sum_i w_i f(x_i)$$

and permits negative weights. These notions must not be conflated:

- positivity gives a measure and supports measure semantics.
- Signed weights can still define a valid exact finite functional.
- Exact nodes and weights make evaluation exact but do not prove $Q[f] = \int f \, d\mu$.
- `QuadratureRule.as_atomic_measure()` succeeds only when every weight is nonnegative.

Likewise, reversed bounds are not encoded by a negative interval density. `integrate_polynomial_oriented` records the sign separately while its underlying interval measure stays positive.

47.3.1 Failure contracts, cost, and persistence boundary

Operation	Principal finite cost	Explicit guard or failure
sparse evaluation	proportional to stored term powers	point dimension. Numeric overflow
polynomial product	up to the product of term counts	`max_terms`
affine pullback	expansion-dependent	`max_terms`. Matrix typing
atomic moment	atoms times dimension	point/weight shape. Finite range
interval moment	endpoint exponentiation	ordered endpoints. Finite range
product moment	sum of factor work plus products	factor certificates. Under/overflow
atomic materialization	base atom count	atomic base. Mapped dimension

`ExactPolynomial.to_dict()` emits a plain dictionary, but these integration objects are not among the frozen portable codecs. The integration tests verify that the portable codec contract remains unchanged. Treat ad hoc dictionaries as application data unless a later chapter names a strict codec.

Source anchors: `integration/polynomial.py`, `integration/measures.py`, `integration/quadrature.py`, `tests/test_block19_integration.py`, and `verification/block19_math_verifier.py`.

48. Integration providers and quadrature

The central dispatcher selects a finite algorithm from the integrand and measure types. It does not infer an analytic theorem from successful sampling. Every returned value therefore travels with method, certificate, evaluation count, and an explicitly classified error statement.

Read an integral result in three steps. First inspect or require the certificate. Next inspect `error.guarantee` to distinguish an exact integral, a rigorous bound, an estimate, a conditional statement, and an unknown error. Finally read the value and any bound in the context of the actual integrand and measure. Certificate validity by itself does not mean that a quadrature estimate equals the target integral.

48.1 Exact finite integration

48.1.1 Result and error contracts

```
integrate(
    integrand: ExactPolynomial | Callable[[Any], Any],
    measure: Measure,
    *,
    provider: CompositeSimpson | None = None,
) -> IntegralResult
```

`IntegralResult` contains:

```
value: Any
certificate: Certificate
error: IntegrationError
method: str
evaluations: int
valid -> bool
exact -> bool
require() -> Any
```

`require()` requires certificate validity and then returns `value`. The `exact` property is narrower than certificate validity: it is true only when `error.guarantee` is `ErrorGuarantee.EXACT`.

```
IntegrationError(
    absolute_bound: Fraction | float | None,
    guarantee: ErrorGuarantee,
    sources: tuple[str, ...] = (),
)
```

The guarantee enum is

Value	Meaning
`EXACT`	the library-produced exact path carries zero absolute error
`RIGOROUS`	a proved finite absolute bound, possibly zero, is attached
`CONDITIONAL`	the stated bound depends on unchecked assumptions
`ESTIMATED`	a finite diagnostic estimate, not an enclosure theorem
`UNKNOWN`	no target-integral error bound is supplied

`EXACT` and `RIGOROUS` require a non-`None` nonnegative finite bound. `IntegrationError.exact()` constructs the zero bound used by library-generated exact results. The public dataclass constructor currently does not itself enforce that a caller-labelled `EXACT` record has bound zero, so such a record must not be treated as authoritative merely because it was constructed. The property `error.rigorous` is true for both exact and rigorous guarantees.

48.1.2 Moment contraction, oriented bounds, and coordinate adapters

When the integrand is an `ExactPolynomial` and no provider is supplied, `integrate` contracts its sparse coefficients with measure moments:

$$I = \sum_{\alpha} c_{\alpha} m_{\alpha}(\mu).$$

An exact affine pushforward first constructs the exact pullback and integrates against the base measure. A callable pushforward over an atomic base is materialized as a finite snapshot and retains the callable assumptions. All other supported exact measures provide moments directly.

The result is exact only when every structural and moment certificate is exact and unconditional and all values remain exact. A float-valued moment cannot be upgraded merely because the sparse contraction completes.

```
integrate_polynomial_oriented(
    polynomial: ExactPolynomial,
    lower: int | Fraction,
    upper: int | Fraction,
    *,
    density: int | Fraction = 1,
) -> IntegralResult
```

This helper implements

$$\int_b^a p(x)\rho\,dx = -\int_a^b p(x)\rho\,dx$$

without pretending that a negative density is a positive measure. It accepts only a univariate exact polynomial, rational endpoints, and nonnegative density. Equal endpoints return exact zero.

Two coordinate adapters construct an exact polynomial before using the same moment path:

```
polynomial_from_family_coordinates(family, coefficients)
integrate_polynomial_coordinates(family, coefficients, measure)

polynomial_from_formal_series(series, *, degree=None)
integrate_formal_series(series, measure, *, degree=None)
```

The first expands a finite exact `PolynomialFamily` coordinate vector and rejects coefficients that are not `int` or `Fraction`. The second consumes a finite normalized `FormalSeries`'s already stored `Fraction` coefficients, optionally through the requested degree. It does not re-audit the provenance of values supplied when that series was created: a prior float may already have been converted to its exact binary `Fraction` value. Use explicit `Fraction` inputs when the intended rational value matters.

48.2 Composite quadrature rules

48.2.1 Callable dispatch

For a callable integrand, dispatch is determined by the measure:

Measure	Finite provider
`AtomicMeasure`	one weighted sample per atom
`IntervalMeasure`	composite Simpson, default or supplied
`ProductMeasure`	finite atomic product sum or tensor Simpson construction
`PushforwardMeasure`	atomic image snapshot or composition with the base map

Atomic callable integration can be exact when the nodes, weights, and outputs are exact rational data. Numerical scalar sums use `math.fsum`. Vector or matrix outputs must preserve a common shape.

For product measures, a fully atomic support is enumerated as a finite product sum. Otherwise interval factors generate tensor-product Simpson nodes. The node count grows multiplicatively with factor counts, and `max_evaluations` is checked before evaluation. The tensor fine/coarse difference is `ESTIMATED`. A one-dimensional derivative bound is explicitly rejected as a certificate for a multivariate tensor rule.

For a pushforward, the callable is composed with the mapping and integrated over the base. A derivative bound on f cannot be reused automatically for $f \circ T$. Supplied bounds on pushforward quadrature are rejected because the composed derivative provenance has changed.

```
integrate_derivative_provider(
    provider: Any,
    measure: Measure,
    *,
    quadrature: CompositeSimpson | None = None,
) -> IntegralResult
```

This adapter integrates a provider's `value(point)` map. The provider must expose positive integer `source_dimension` and `target_dimension`. Its source dimension must equal the measure dimension, and each value must have shape `(target_dimension,)`. It does not by itself prove differentiation under an integral sign. That finite fixed-weight contract is addressed in Section 49.6.

48.2.2 Quadrature rules are finite functionals

```
QuadratureRule(points, weights, *, name="quadrature rule")
ExactQuadratureRule(points, weights, *, name="exact quadrature rule")
```

Both classes implement

$$Q[f] = \sum_{i=1}^{N} w_i f(x_i).$$

`ExactQuadratureRule` requires rational nodes and rational signed weights. The base `QuadratureRule` accepts finite numerical data. Important members are:

```
node_count
exact_data
positive
apply(function) -> IntegralResult
moment(exponents) -> Any
integrate_polynomial(polynomial) -> IntegralResult
tensor_product(other) -> QuadratureRule
```

```
as_atomic_measure() -> AtomicMeasure
degree_of_exactness(measure, *, max_degree, tolerance=1e-12)
    -> QuadratureExactness
certify_polynomial_integral(polynomial, measure) -> IntegralResult
certificate() -> Certificate
```

`apply` and `integrate_polynomial` certify only evaluation of the displayed finite functional. Their target-measure error guarantee is `UNKNOWN` until a moment theorem is supplied.

In one dimension, `degree_of_exactness` compares consecutive moments from degree zero through `max_degree`. For exact rule and measure data it uses exact equality. Otherwise it records numerical residuals and the supplied tolerance. Its result stores the last consecutive matching degree, the maximum tested degree, whether the comparison itself was exact, and a certificate.

`certify_polynomial_integral` is stricter: all three objects must be one-dimensional, moment comparison must be exact through the polynomial's degree, and the certified degree must cover that degree. Only then does it return an exact integral result.

Consider Simpson's three-node rule on $[-1, 2]$:

```
from fractions import Fraction as F

from komorebi_math.integration import (
    ExactPolynomial,
    ExactQuadratureRule,
    IntervalMeasure,
    integrate,
)

rule = ExactQuadratureRule(
    (-1, F(1, 2), 2),
    (F(1, 2), 2, F(1, 2)),
    name="exact Simpson",
)
mu = IntervalMeasure(-1, 2)
cubic = ExactPolynomial.univariate((-5, 3, -2, 1))
quartic = ExactPolynomial.univariate((0, 0, 0, 0, 1))

print(rule.degree_of_exactness(mu, max_degree=7).degree)
print(rule.certify_polynomial_integral(cubic, mu).require())
print(rule.integrate_polynomial(quartic).require())
print(integrate(quartic, mu).require())
```

Observed output:

```
3
-51/4
69/8
33/5
```

The exact finite rule evaluates the quartic exactly as a functional, but it does not equal the quartic integral. Calling `certify_polynomial_integral(quartic, mu)` raises `ValidationError`. This is the critical distinction between exact arithmetic and exact quadrature.

An even sharper adversary vanishes at $0, 1/2, 1$ while its exact integral is $1/840$. The shipped verifier confirms that the sampled value is zero, the error guarantee remains `UNKNOWN`, and a false exactness certificate is blocked.

48.2.3 Composite Simpson rules

```
CompositeSimpson(
    subintervals: int = 64,
    derivative_bound: DerivativeBound | None = None,
    max_evaluations: int = 1000000,
)
```

`subintervals` must be at least four and a multiple of four. This ensures that both the fine rule with n panels and the coarse rule with $n/2$ panels are valid Simpson rules. For $h = (b-a)/n$, the fine rule is

$$Q_n[f] = \rho\frac{h}{3}\left(f(a) + f(b) + 4\sum_{j\,\text{odd}} f(a+jh) + 2\sum_{\substack{j\,\text{even}\\0<j<n}} f(a+jh)\right).$$

The implementation evaluates the fine and coarse rules separately. Its recorded evaluation count is

$$(n+1) + (n/2+1) = \frac{3n}{2} + 2.$$

For a general callable with no derivative bound, it returns $Q_n[f]$ and the Richardson diagnostic

$$\widehat{E} = \frac{\|Q_n[f] - Q_{n/2}[f]\|}{15}.$$

This is `ErrorGuarantee.ESTIMATED` and the certificate status is `Exactness.HEURISTIC`. The method does not assert that the diagnostic encloses the true error. Finite samples do not establish smoothness. **H**

In a convergence study, preserve the panel counts and compare successive values on the same integrand and interval. A decreasing fine/coarse difference is useful observed behavior. To report an enclosing error bound, follow the separate provenance-matched construction in Section 48.3 rather than relabelling that observed difference.

For an exact polynomial on an exact rational interval, the same fine and coarse rules are built entirely with `Fraction` nodes and weights. The quadrature value and Richardson difference are therefore exact rational numbers even when the truncation estimate is only heuristic. Again, exact evaluation of Q_n is not automatically an exact integral.

48.3 Rigorous Simpson bounds

For a scalar function with

$$\sup_{x\in[a,b]} |f^{(4)}(x)| \le M_4,$$

the composite Simpson truncation theorem gives

$$\left|\rho\int_a^b f(x)\,dx - Q_n[f]\right| \le \frac{|\rho|(b-a)h^4}{180}M_4.$$

The proof status of M_4 is represented explicitly:

```
DerivativeBound(
    order,
    bound,
    certificate,
    description="derivative supremum bound",
    polynomial=None,
    interval=None,
)
```

```
DerivativeBound.assumed(order, bound, *, description=...)

polynomial_derivative_bound(
    polynomial,
    measure,
    *,
    order=4,
) -> DerivativeBound
```

An internally generated polynomial bound differentiates exactly and uses the coefficient triangle inequality. With $R = \max(|a|, |b|)$ and $p^{(4)}(x) = \sum_k d_k x^k$, it returns

$$M_4 = \sum_k |d_k| R^k.$$

This bound is conservative but exact and replayable. Its provenance includes the exact polynomial and exact rational interval. The Simpson path requires that both match the actual integrand and measure. A bound computed for another polynomial or interval is rejected.

```
from fractions import Fraction as F

from komorebi_math.integration import (
    CompositeSimpson,
    ExactPolynomial,
    IntervalMeasure,
    integrate,
    polynomial_derivative_bound,
)

p = ExactPolynomial.univariate((0, 0, 0, 0, 1))
mu = IntervalMeasure(0, 1)
bound = polynomial_derivative_bound(p, mu)
result = integrate(p, mu, provider=CompositeSimpson(8, bound))

print(result.value)
print(result.error.absolute_bound)
print(result.error.guarantee.value)
print(abs(result.value - F(1, 5)) <= result.error.absolute_bound)
```

Observed output:

```
1229/6144
1/30720
rigorous
True
```

The actual error equals the reported bound in this quartic example. The certificate records 14 evaluations and the exact fine/coarse difference `1/2048`.

`DerivativeBound.assumed` creates a visible conditional boundary. For a callable, the code also records that the bound applies to this callable and interval and that floating node, evaluation, weight, and summation roundoff must lie within the stated bound. It therefore cannot produce an internally `RIGOROUS` result. Passing an internally rigorous polynomial bound with a lambda is rejected: provenance belongs to the exact `ExactPolynomial`, not to observationally similar source code. **C**

48.4 Estimated Richardson error

Without matched theorem provenance, refinement comparison remains useful as a diagnostic:

```
import numpy as np

from komorebi_math.integration import CompositeSimpson, IntervalMeasure, integrate

result = integrate(
    lambda x: np.exp(-x * x),
    IntervalMeasure(0, 1),
    provider=CompositeSimpson(32),
)

print(result.error.guarantee.value)
print(result.certificate.exactness.value)
```

Observed output:

```
estimated
heuristic
```

No amount of agreement between the two finite grids changes this status. A function can vanish on both node sets while differing elsewhere. Use the estimate for diagnostics or convergence studies. Use a provenance-matched bound for a certified enclosure.

48.5 Provenance-matched integrands and bounds

The proof status of a quadrature result follows the complete provenance chain: the concrete integrand, the concrete measure, the derivative bound, and the finite arithmetic path must all match. A bound derived from one polynomial or interval cannot certify another, and an exact functional evaluation cannot by itself certify equality with a target integral.

48.5.1 Provider selection and failure table

Situation	Result or rejection
exact polynomial, no provider	moment contraction
exact polynomial plus Simpson	exact rational Simpson on an exact interval only
callable plus atomic measure	finite weighted sum
callable plus interval	fine/coarse Simpson
callable plus product	atomic product or tensor Simpson
callable plus pushforward	compose with map. Strip unrelated bound
one-dimensional bound on a product	rejected
rigorous polynomial bound on a lambda	rejected
Simpson panels not a multiple of four	rejected
planned evaluations above `max_evaluations`	rejected before evaluation
output shape changes between nodes	rejected
nonfinite output, node, weight, or sum	rejected
structurally zero interval	exact zero. Callable not evaluated

The shipped integration suite also exercises floating underflow and overflow, huge exact integers, complex numerical outputs, invalid custom measure certificates, and adversarial quadrature rules. The point of these guards is not to make finite quadrature universally rigorous. It is to ensure that the result's proof status matches the finite evidence actually available.

48.5.2 Executable exactness and rejection ladder

This compact ladder checks a degree boundary, a tensor moment, an assumed bound, and two rejection paths without turning any of them into a stronger claim:

```
from fractions import Fraction as F

from komorebi_math.exceptions import ValidationError
from komorebi_math.integration import (
    CompositeSimpson,
    DerivativeBound,
    ExactQuadratureRule,
    IntervalMeasure,
    integrate,
)

trapezoid = ExactQuadratureRule((0, 1), (F(1, 2), F(1, 2)))
degree = trapezoid.degree_of_exactness(
    IntervalMeasure(0, 1), max_degree=3
).degree
tensor_moment = trapezoid.tensor_product(trapezoid).moment((1, 1))

assumed = DerivativeBound.assumed(4, 24)
conditional = integrate(
    lambda x: x**4,
    IntervalMeasure(0, 1),
    provider=CompositeSimpson(8, assumed),
)

rejected_panels = []
for count in (2, 6, 5):
    try:
        CompositeSimpson(count)
    except ValidationError:
        rejected_panels.append(count)

signed = ExactQuadratureRule((0, 1), (1, -1))
signed_rejected = False
try:
    signed.as_atomic_measure()
except ValidationError:
    signed_rejected = True

print(degree, tensor_moment)
print(conditional.error.guarantee.value)
print(rejected_panels, signed_rejected)
```

Observed output:

```
1 1/4
conditional
[2, 6, 5] True
```

The same polynomial with a provenance-matched bound from `polynomial_derivative_bound` follows the rigorous path shown in Section 48.3. The assumed callable bound remains conditional by construction.

Source anchors: `integration/quadrature.py`, `integration/rules.py`, `integration/adapters.py`, `tests/test_block19_integration.py`, `verification/block19_math_verifier.py`, and `examples/block19_measure_integration_worked_example.py`.

49. Integral identities and coordinate covectors

Successful finite calculations can be recorded as replayable finite identities. Every identity computes both sides and stores them with a certificate. It does not merely label one side with a theorem name.

Choose an identity constructor by the change being made: antidifferentiation for the finite polynomial FTC, rearranging a product derivative for integration by parts, changing integration order for finite Fubini, and changing variables for pushforward identities. Coordinate covectors express the same integration functional in a chosen basis. The example in Section 49.7.1 brings those coordinate and change-of-variable routes together.

```
IntegralIdentity(
    name: str,
    left: Any,
    right: Any,
    certificate: Certificate,
)

valid -> bool
require() -> IntegralIdentity
```

`require()` requires the certificate and returns the identity record, so callers can inspect both exact sides and diagnostics.

49.1 FTC

The fundamental theorem of calculus identity is

$$p \in \mathbb{Q}[x],\ a, b \in \mathbb{Q} \quad \Longrightarrow \quad \int_a^b p'(x)\,dx = p(b) - p(a).$$

This is the implemented finite rational-polynomial identity, not a claim of a general analytic FTC.

```
fundamental_theorem(
    polynomial: ExactPolynomial,
    measure: IntervalMeasure,
) -> IntegralIdentity
```

The argument named `polynomial` is the integrand. The function constructs its exact zero-constant antiderivative F and checks

$$\int_a^b p(x)\rho\,dx = \rho(F(b) - F(a)).$$

Thus, to express the $\int p' = p(b) - p(a)$ form, pass `primitive.derivative()`.

```
from fractions import Fraction as F

from komorebi_math.integration import (
    ExactPolynomial,
    IntervalMeasure,
    fundamental_theorem,
```

```
)

primitive = ExactPolynomial.univariate((7, -5, F(3, 2), F(-2, 3), F(1, 4)))
identity = fundamental_theorem(
    primitive.derivative(),
    IntervalMeasure(-1, 2),
).require()

print(identity.left)
print(identity.right)
```

Observed output:

```
-51/4
-51/4
```

The function requires a univariate exact polynomial and an unconditionally exact `IntervalMeasure`. Its theorem identifier is `INT.ID.FTC`. **E**

49.2 Integration by parts

```
integration_by_parts(
    left_factor: ExactPolynomial,
    right_factor: ExactPolynomial,
    measure: IntervalMeasure,
) -> IntegralIdentity
```

For exact univariate u, v, the checked identity is

$$\rho \int_a^b u(x)v'(x)\,dx = \rho[u(x)v(x)]_a^b - \rho \int_a^b u'(x)v(x)\,dx.$$

The code builds the polynomial products and derivatives, evaluates both integrals by exact moments, and retains the boundary term in certificate diagnostics. With $u = 1 + x^2$, $v = -2x + x^3$, and $[-1, 2]$, both sides are $84/5$. Omitting the boundary term would fail this exact check.

49.3 Finite Fubini

```
fubini_identity(
    polynomial: ExactPolynomial,
    measure: ProductMeasure,
    *,
    order: tuple[int, ...] | None = None,
) -> IntegralIdentity

all_fubini_orders(
    polynomial: ExactPolynomial,
    measure: ProductMeasure,
    *,
    max_dimensions: int = 7,
) -> tuple[IntegralIdentity, ...]
```

The supported theorem is finite and exact. The polynomial dimension must equal the product dimension, and the factors must be either:

- all exact one-dimensional interval measures, or
- all exact one-dimensional atomic measures.

A mixed interval/atomic product is not accepted by this identity constructor, even though other integration paths may evaluate it. Every factor and the product must have valid, unconditionally exact certificates.

For interval factors, `fubini_identity` repeatedly uses `integrate_out`, tracking how original variable labels move as dimensions disappear. For atomic factors, it evaluates the finite nested weighted sums. The requested `order` must be a permutation of every variable.

For

$$p(x, y) = x^2y + 3xy^2, \qquad (x, y) \in [0, 1] \times [1, 2],$$

both possible iterated orders and the direct moment contraction equal 4. `all_fubini_orders` enumerates all $d!$ permutations and refuses dimensions above `max_dimensions`, which defaults to seven. This is a finite factorial resource guard, not a statement about infinite product spaces. **E/M**

49.4 Affine pushforward and Jacobians

Two related identities keep abstract pushforward semantics separate from a materialized density formula.

```
pushforward_identity(
    polynomial: ExactPolynomial,
    base: Measure,
    mapping: ExactAffineMap,
) -> IntegralIdentity
```

This certifies

$$\int_Y p(y)\, d(T_{\#}\mu)(y) = \int_X p(Tx)\, d\mu(x)$$

by exact affine pullback and exact base moments. There is no extra Jacobian factor: the left side already integrates against the pushforward measure.

```
affine_interval_change_of_variables(
    polynomial: ExactPolynomial,
    base: IntervalMeasure,
    mapping: ExactAffineMap,
) -> IntegralIdentity
```

For $y = sx + t$ with $s \neq 0$, this separately materializes the image interval and its density $\rho/|s|$, then checks equality with the pullback integral. The transformed interval is ordered, so the absolute Jacobian handles a negative scale. A zero scale is valid as a pushforward to an atom but is rejected by the interval Jacobian identity.

The complete worked example uses

$$x \in [0, 1], \qquad y = 2x + 1, \qquad f(y) = y^4 - 2y + 1.$$

The image measure is $\frac{1}{2}dy$ on $[1, 3]$, and

$$f(2x + 1) = 16x^4 + 32x^3 + 24x^2 + 4x.$$

All three exact computations agree:

$$\int f\,d(T_{\#}\mu) = \frac{1}{2}\int_1^3 f(y)\,dy = \int_0^1 f(2x+1)\,dx = \frac{106}{5}.$$

49.5 Coordinate integration covectors

Let $q_0, \dots, q_n$ be an exact graded polynomial basis and write

$$p(x) = \sum_{k=0}^{n} c_k q_k(x).$$

Integration is a covector

$$\ell_\mu = (\ell_0, \dots, \ell_n), \qquad \ell_k = \int q_k\,d\mu, \qquad \int p\,d\mu = \ell_\mu c.$$

```
PolynomialIntegrationCovector(
    family: str,
    degree: int,
    measure: IntervalMeasure,
    weights: tuple[Fraction, ...],
    basis_witness: tuple[tuple[Fraction, ...], ...] | None = None,
)

polynomial_integration_covector(
    family: PolynomialFamily,
    degree: int,
    measure: IntervalMeasure,
) -> PolynomialIntegrationCovector
```

The finite covector has length `degree + 1`. `apply(coefficients)` requires the same length and rational coordinates, then returns the exact pairing.

A subtle but essential provenance rule applies. Direct construction with a family name and weights creates a usable rational functional, but without a `basis_witness` the claim that those weights are moments of the named family is `CONDITIONAL`. The factory `polynomial_integration_covector` obtains every basis polynomial from the actual `PolynomialFamily`, recomputes all interval moments, stores the witness, and returns an unconditionally exact covector. The property `basis_verified` reports this distinction. Directly supplied stored weights must be actual `Fraction` objects. Use the factory for ordinary construction and replayable provenance.

For a family derivative matrix D, endpoint evaluation row vectors `ev_a`, `ev_b`, and constant density ρ,

```
coordinate_fundamental_theorem(family, degree, measure)
```

checks the coordinate FTC

$$\ell_\mu D = \rho(\mathrm{ev}_b - \mathrm{ev}_a).$$

If $C_{s\to t}$ maps source coordinates to target coordinates, the same physical functional transforms contragrediently:

$$c_t = C_{s\to t} c_s, \qquad \ell_t C_{s\to t} = \ell_s.$$

```
coordinate_transport_identity(
    source: PolynomialFamily,
    target: PolynomialFamily,
    degree: int,
    measure: IntervalMeasure,
) -> IntegralIdentity
```

The shipped verifier checks coordinate FTC through degree seven in the monomial, Euler, Fibonacci, and Legendre families, and checks Euler to Fibonacci covector transport exactly.

```
from komorebi_math.coordinates import (
    connection_transform,
    euler_polynomial_family,
    monomial_polynomial_family,
)
from komorebi_math.integration import (
    ExactPolynomial,
    IntervalMeasure,
    polynomial_integration_covector,
)

p = ExactPolynomial.univariate((1, -2, 0, 0, 1))
mu = IntervalMeasure(1, 3, density=1 / 2)  # see exact version below
```

Use `Fraction(1, 2)`, not `1 / 2`, when exactness is required:

```
from fractions import Fraction as F

mu = IntervalMeasure(1, 3, density=F(1, 2))
monomial = monomial_polynomial_family()
euler = euler_polynomial_family()
coordinates = connection_transform(monomial, euler, 4).apply(
    p.to_univariate_coefficients()
)
ell = polynomial_integration_covector(euler, 4, mu)

print(ell.basis_verified)
print(ell.apply(coordinates))
```

Observed output:

```
True
106/5
```

The first short snippet intentionally exposes the Python boundary: `1 / 2` is a float and therefore makes a numerical interval. The factory then rejects it because exact covectors require exact `Fraction` interval data.

49.6 Differentiation through fixed finite measures

For fixed atoms and fixed weights,

$$F(x) = \sum_{i=1}^{N} w_i f_i(x) \quad \Longrightarrow \quad D^k F(x)[h_1, \dots, h_k] = \sum_{i=1}^{N} w_i D^k f_i(x)[h_1, \dots, h_k].$$

```
AtomicIntegratedDerivativeProvider(
    providers: Sequence[Any],
    weights: Sequence[int | Fraction | float],
    name: str = "atomic integrated derivative provider",
)
```

Every provider must expose a common positive `source_dimension` and `target_dimension`, an `Exactness` value, `supports_order(order)`, `value(point)`, and `derivative(order, point, directions)`. The provider and weight lists must be nonempty and have equal length. Weights are finite and nonnegative because the class models positive atomic integration.

`value` and `derivative` compute the fixed weighted sum. Every output must have shape `(target_dimension,)`. Nonfinite numerical data and overflow are rejected. The combined exactness is the weakest provider/weight status. The certificate checks only the finite structure and records the unchecked assumption that the component providers represent globally correct derivatives.

This class intentionally excludes parameter-dependent measures. If $w_i = w_i(x)$, then

$$D\sum_i w_i(x)f_i(x) = \sum_i Dw_i(x)f_i(x) + \sum_i w_i(x)Df_i(x),$$

and the first term is absent from the fixed-weight API. Do not use the class to silently drop it. **E/C**

The independent verifier constructs quadratic providers with scales one and three, weights $1/4$ and $3/4$, point $x = 2$, and direction $h = 5$. The returned first directional derivative is exactly `50`.

49.7 Analysis-synthesis commutation

For a fixed linear analysis map A, synthesis map S, atomic weights w_i, and physical samples v_i, finite linearity predicts

$$A\left(\sum_i w_i v_i\right) = \sum_i w_i A v_i.$$

When the system reconstructs the relevant coefficient vector, it also predicts

$$S\left(\sum_i w_i A v_i\right) = \sum_i w_i v_i.$$

```
analysis_synthesis_integration_certificate(
    system: AnalysisSynthesisSystem,
    measure: AtomicMeasure,
    physical_values: Sequence[Any],
    *,
    tolerance: float = 1e-10,
) -> Certificate
```

The number of physical values must equal the atom count, and every value must be a vector of `system.source_dimension`. The function incorporates both the system and measure certificates and computes three numerical residuals:

1. analysis of the weighted physical sum versus the weighted analyzed sum.
2. Synthesis of the weighted coefficient sum versus the physical sum.
3. The coefficient-gauge residual $(AS)c - c$.

All three must be at most the finite nonnegative tolerance. The returned exactness is at most `NUMERICAL`, even when the atomic weights are Fractions, because the system calculation uses NumPy floating arrays and norms. An invalid analysis-synthesis system certificate or invalid measure certificate cannot be hidden by small commutation residuals. **N**

This certificate is a finite commutation check for the supplied samples and fixed maps. It is not a theorem about Bochner integration, infinite frames, measurability, or parameter-dependent systems.

49.7.1 End-to-end exact example

The shipped `examples/block19_measure_integration_worked_example.py` joins the three chapters:

1. construct $[0, 1]$ and the exact chart $y = 2x + 1$.
2. Integrate $y^4 - 2y + 1$ by pushforward, materialized image density, and pullback.
3. Represent the polynomial in monomial, Euler, and Fibonacci coordinates.
4. Pair every coordinate vector with its verified integration covector.
5. Certify a provenance-matched Simpson enclosure.
6. Reject a polynomial that fools the three Simpson nodes.

Observed summary:

```
chart: y = 2x + 1, x in [0,1]
pushed measure: (1/2) dy on [1,3]
integrand: f(y) = y^4 - 2y + 1
pullback: f(2x+1) = 16x^4 + 32x^3 + 24x^2 + 4x
exact integral: 106/5
monomials pairing: 106/5
Euler polynomials pairing: 106/5
Fibonacci polynomials pairing: 106/5
Simpson: 21.200032552083332, error 3.255e-05,
         rigorous bound 3.255e-05
node adversary: sampled 0, true 1/840,
                false certificate blocked=True
```

The displayed decimal Simpson value is presentation only. The internal certified path keeps the Simpson value and bound as exact Fractions.

49.7.2 Identity boundaries and verification evidence

Claim	Implemented boundary
FTC	exact univariate rational polynomial. Exact constant-density interval
integration by parts	two exact univariate polynomials. Exact interval
Fubini	finite polynomial. All-exact interval factors or all-exact 1-D atomic factors
all Fubini orders	factorial enumeration capped by `max_dimensions`
pushforward identity	exact affine map and exact base moments
interval Jacobian	one-dimensional nonzero exact affine scale
coordinate covector	exact family witness and exact interval for unconditional status
differentiation	fixed finite nonnegative weights. Compatible providers
frame commutation	supplied finite atomic samples. Numerical tolerance

The pytest module `tests/test_block19_integration.py` exercises the complete API, resource guards, invalid-certificate propagation, finite-range failures, and adversarial cases. The independent pytest-free verifier `verification/block19_math_verifier.py` reports **16/16 passed** in the audited source tree. Its named checks include exact interval moments, pushforward and change of variables, Fubini in every finite order, FTC, integration by parts, coordinate covariance, the Simpson degree boundary, the sampled-zero adversary, rigorous Simpson enclosure, fixed-weight derivative commutation, and analysis-synthesis commutation.

These executions qualify the finite source behavior described above. They do not extend the contracts to general analytic measures, arbitrary measurable maps, infinite products, infinite-dimensional integration, or unverified symbolic identities.

Source anchors: `integration/identities.py`, `integration/coordinates.py`, `integration/adapters.py`, `integration/measures.py`, `integration/quadrature.py`, `examples/block19_measure_integration_worked_example.py`, `tests/test_block19_integration.py`, and `verification/block19_math_verifier.py`.

50. Typed finite expression model

The expression package is a typed language for finite, exact rational linear algebra. It turns coordinate vectors, rational matrices, and a small family of replayable polynomial maps into immutable expression trees. The result is not a general computer-algebra system. It does not parse arbitrary formulas, quantify over variables, simplify analytic functions, or prove identities in an infinite-dimensional space. Its deliberately narrow promise is useful: every accepted closed term has a finite rational denotation that can be recomputed, compared entry by entry, planned, and transported without loading user code.

First workflow. Choose the coordinate space, create exact literal data, construct maps with matching source and target types, then evaluate the closed expression. Inspect the certificate before using the returned value. Add symbol binding, simplification, planning, and persistence when the application needs them. The Fibonacci-Euler pipeline in Section 51.2 is the main worked example of this sequence.

The complete public surface lives in `komorebi_math.expression`. It is a research-tier namespace, additive to the package and outside the frozen stable and beta API manifests. Exactness in this chapter therefore describes the implemented arithmetic and evidence path. It does not elevate these names into the stable compatibility contract.

The semantic universe is

$$\mathbb{Q}, \qquad \mathsf{P}_n^B, \qquad \mathsf{Lin}(X, Y),$$

where P_n^B is the $(n+1)$-dimensional coordinate space of univariate polynomials through degree n in one explicit graded basis $B = (b_0, \dots, b_n)$. Vectors inhabit coordinate spaces. Matrices inhabit linear-map types. Arbitrary CAS terms, nonlinear maps, higher-order functions, general measures, analytic identities, and infinite-dimensional operators are outside this model. **E**

50.1 Scalar, vector, matrix, polynomial, operator, and measure types

The model has two coordinate-space classes and one linear-map type.

```
RationalSpace()

PolynomialCoordinateSpace(
    variable: str,
    degree: int,
    basis: tuple[tuple[Fraction, ...], ...],
    label: str = "",
)

LinearMapType(
    source: CoordinateSpace,
    target: CoordinateSpace,
)
```

`RATIONAL_SPACE` is the shared instance of `RationalSpace`. Every `RationalSpace()` has the same semantic identity, dimension one, and key `("Q",)`. An exact scalar is consequently represented internally by a one-entry coordinate vector rather than by a separate untyped node.

`PolynomialCoordinateSpace` snapshots one complete graded basis. Each basis member is stored in ascending monomial coefficients:

$$b_j(x) = \sum_{k=0}^{j} B_{kj} x^k, \qquad B_{jj} \neq 0.$$

The constructor enforces all these conditions:

- `variable` is a nonempty NFC-normalized string.
- `degree` is a nonnegative integer and cannot be a boolean.
- `basis` contains exactly `degree + 1` members.
- Member j has exactly $j + 1$ rational coefficients.
- Each leading coefficient is nonzero.
- Coefficients are integers or `Fraction` values, never binary floats.

The nonzero diagonal makes the triangular basis matrix invertible. It is this checked witness, not a family name, that lets the runtime convert between bases exactly.

```
PolynomialCoordinateSpace.from_family(
    family: Any,
    degree: int,
    *,
    variable: str = "x",
    label: str | None = None,
) -> PolynomialCoordinateSpace

space.dimension -> int
space.semantic_key -> tuple[...]
space.truncate(degree: int) -> PolynomialCoordinateSpace
```

`from_family` calls `family.polynomial(index)` for every index from zero through the requested degree and freezes the resulting rational witnesses. `truncate(r)` returns the compatible prefix through degree r, and rejects an attempt to increase degree. No future mutation of the source family is consulted by the coordinate space.

For a space X, a literal vector is constructed by

```
exact_value(
    space: CoordinateSpace,
    entries: Iterable[Any],
) -> ExactValueLiteral
```

and must have exactly `space.dimension` rational entries. For a map $A : X \to Y$, the constructor

```
exact_map(
    map_type: LinearMapType,
    matrix: Iterable[Iterable[Any]],
    *,
    label: str = "",
) -> ExactMapLiteral
```

requires matrix shape

$$(\dim Y) \times (\dim X).$$

Rows must have a common length and every entry must be an integer or `Fraction`. The optional map label is display metadata, not authority to invoke a polynomial rewrite.

There is no expression-level measure type. Exact interval integration enters the language as a typed linear functional $\mathsf{P}_n^B \to \mathbb{Q}$, documented in Chapter 51. General measure objects and quadrature rules remain in `komorebi_math.integration`. Passing one of them where an expression coordinate space is required is a type error.

Minimal type construction

```
from fractions import Fraction

from komorebi_math.expression import (
    RATIONAL_SPACE,
    LinearMapType,
    PolynomialCoordinateSpace,
    exact_map,
    exact_value,
)

Q = Fraction
monomials_2 = PolynomialCoordinateSpace(
    "x",
    2,
    (
        (Q(1),),
        (Q(0), Q(1)),
        (Q(0), Q(0), Q(1)),
    ),
    "monomials",
)

coordinates = exact_value(monomials_2, (1, -2, 3))
endomorphism = exact_map(
    LinearMapType(monomials_2, monomials_2),
    ((1, 0, 0), (0, 2, 0), (0, 0, 3)),
    label="display-only diagonal map",
)

print(RATIONAL_SPACE.dimension)
print(monomials_2.dimension)
print(coordinates.entries)
print(endomorphism.matrix)
```

Observed output, with `Fraction` values rendered by Python, is

```
1
3
(Fraction(1, 1), Fraction(-2, 1), Fraction(3, 1))
((Fraction(1, 1), Fraction(0, 1), Fraction(0, 1)),
 (Fraction(0, 1), Fraction(2, 1), Fraction(0, 1)),
 (Fraction(0, 1), Fraction(0, 1), Fraction(3, 1)))
```

50.2 Basis witnesses and semantic identity

For a polynomial-coordinate space the semantic key is

$$\mathrm{key}(\mathsf{P}_n^B) = (\texttt{"polynomial"}, x, n, B).$$

The complete rational basis witness B, the physical variable, and the degree participate in equality and hashing. The mutable human idea of a "Fibonacci basis" does not. The `label` field is excluded from dataclass comparison, so two differently labelled snapshots of the same witness are the same type. Conversely, two spaces with the same label and dimension but different basis coefficients are different types.

```
from fractions import Fraction
from komorebi_math.expression import PolynomialCoordinateSpace
```

```
Q = Fraction
left = PolynomialCoordinateSpace(
    "x", 2,
    ((Q(1),), (Q(0), Q(1)), (Q(0), Q(0), Q(1))),
    "custom basis",
)
renamed = PolynomialCoordinateSpace(
    "x", 2,
    left.basis,
    "a new display label",
)
spoof = PolynomialCoordinateSpace(
    "x", 2,
    ((Q(1),), (Q(0), Q(1)), (Q(0), Q(1), Q(1))),
    "custom basis",
)

print(left == renamed, left.semantic_key == renamed.semantic_key)
print(left.label == spoof.label, left.dimension == spoof.dimension)
print(left == spoof, left.semantic_key == spoof.semantic_key)
```

Observed output:

```
True True
True True
False False
```

This distinction closes a common spoofing path. Neither `apply` nor `compose` accepts two endpoints merely because their dimensions or display labels agree. The whole semantic witness must agree:

$$A : X \to Y, \quad v : Z, \quad Z \neq X \quad \Longrightarrow \quad A(v) \text{ is rejected.}$$

The same rule governs basis-aware polynomial primitives. A coordinate-change matrix is recomputed from the source and target witnesses. A caller cannot activate that rule by labelling an ordinary exact matrix "coordinate change." This is why the expression system distinguishes `PolynomialPrimitive` from `ExactMapLiteral` even when their replayed matrices happen to be equal.

A type mismatch between equally sized vectors is therefore worth investigating before changing any labels. Confirm the physical variable, degree, and basis coefficients. If the vectors use different valid bases, insert the explicit coordinate-change map; renaming a space does not perform that conversion.

50.3 Expression nodes and typed constructors

The immutable node grammar is small enough to display completely.

Node	Public constructor	Formation rule
`ExactValueLiteral`	`exact_value(X, entries)`	$v : X$
`ExactMapLiteral`	`exact_map(LinearMapType(X,Y), rows)`	$A : X \to Y$
`Symbol`	`symbol(name, T)`	$s : T$
`Let`	`let(s, value, body)`	`value` must have the declared type of s
`IdentityMap`	`identity(X)`	$I_X : X \to X$
`ZeroMap`	`zero_map(LinearMapType(X,Y))`	$0_{X,Y} : X \to Y$
`Compose`	`compose(B, A)`	$A : X \to Y,\ B : Y \to Z \Rightarrow B \circ A : X \to Z$
`Sum`	`add(a, b, ...)`	every term has one identical expression type
`Scale`	`scale(q, value)`	$q \in \mathbb{Q}$, type is preserved
`Apply`	`apply(A, v)`	$A : X \to Y,\ v : X \Rightarrow A(v) : Y$
`PolynomialPrimitive`	functions in Section 51.2	a branded replayable map

Node	Public constructor	Formation rule

The helper signatures are

```
symbol(name: str, declared_type: ExpressionType) -> Symbol
let(binding: Symbol, value: Expression, body: Expression) -> Let
identity(space: CoordinateSpace) -> IdentityMap
zero_map(map_type: LinearMapType) -> ZeroMap
compose(*maps: Expression) -> Expression
then(*maps: Expression) -> Expression
add(*terms: Expression) -> Expression
scale(scalar: int | Fraction, value: Expression) -> Scale
apply(operator: Expression, argument: Expression) -> Apply
```

`compose` receives factors in mathematical outermost-to-innermost order:

$$\mathrm{compose}(B, A) = B \circ A.$$

`then` receives them in the order in which they act:

$$\mathrm{then}(A, B) = B \circ A.$$

This difference is intentional. For a pipeline that first changes basis and then differentiates, these two expressions are identical:

```
compose(derivative_in_target, source_to_target)
then(source_to_target, derivative_in_target)
```

`compose()` and `add()` reject an empty argument list. With exactly one well-typed argument each returns that argument unchanged. A raw `Compose` or `Sum` dataclass node, by contrast, requires at least two children. These helpers are therefore the convenient way to assemble a variable-length pipeline.

The core formation rules are

$$\frac{v \in X}{\mathrm{Value}(v) : X}, \qquad \frac{A \in \mathsf{Lin}(X, Y)}{\mathrm{Map}(A) : X \to Y},$$

$$\frac{A : X \to Y \quad B : Y \to Z}{B \circ A : X \to Z}, \qquad \frac{A, B : T}{A + B : T},$$

$$\frac{q : \mathbb{Q} \quad e : T}{qe : T}, \qquad \frac{A : X \to Y \quad x : X}{A(x) : Y}.$$

Construction validates these local rules immediately. The later `check_expression` pass replays them from exact built-in classes, which also detects hostile in-memory mutation or subclasses that forge an `expression_type` property.

50.4 Lexical binding and alpha equivalence

`Symbol` uses object identity instead of value equality. Two symbols can have the same name and type and still be different variables. This gives `Let` ordinary lexical scope:

$$\text{let } x = e_1 \text{ in } e_2.$$

Construction requires

$$\text{type}(e_1) = \text{declared}(x).$$

The free variables of the whole term are those of the value plus the free variables of the body after removing occurrences that are the exact binder object. A same-name symbol created separately remains free.

```
check_expression(
    expression: Expression,
    bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    *,
    budget: ExpressionBudget | None = None,
) -> CheckedExpression
```

`CheckedExpression` records `expression_type`, structural `stats`, sorted `free_symbols`, and a certificate. Missing values for free symbols do not make the expression ill typed. The checker lists them in diagnostics. Exact normalization does require a compatible binding.

Bindings may be keyed by the particular `Symbol` object or by its name. Object-keyed matches take precedence. Multiple matching entries are accepted only when their `ExpressionBinding` values agree. A binding's declared type and runtime shape are both replayed.

```
exact_binding(
    value: Any,
    declared_type: CoordinateSpace | LinearMapType,
    *,
    theorem_id: str = "EXPR.BINDING.EXACT",
) -> ExpressionBinding
```

The portable semantic digest represents a bound occurrence by lexical distance, not by display name. Consequently alpha-renamed terms have the same digest:

$$\text{let } x = 7 \text{ in } x \equiv_\alpha \text{let } y = 7 \text{ in } y.$$

Shadowing and free-versus-bound identity remain distinct.

```
from komorebi_math.expression import (
    RATIONAL_SPACE,
    exact_binding,
    exact_value,
    expression_digest,
    let,
    normalize_expression,
    symbol,
)

x = symbol("x", RATIONAL_SPACE)
y = symbol("renamed", RATIONAL_SPACE)
seven = exact_value(RATIONAL_SPACE, (7,))

print(expression_digest(let(x, seven, x)) ==
      expression_digest(let(y, seven, y)))
```

```
outer = symbol("same", RATIONAL_SPACE)
inner = symbol("same", RATIONAL_SPACE)
shadow_inner = let(
    outer, exact_value(RATIONAL_SPACE, (1,)),
    let(inner, exact_value(RATIONAL_SPACE, (2,)), inner),
)
shadow_outer = let(
    outer, exact_value(RATIONAL_SPACE, (1,)),
    let(inner, exact_value(RATIONAL_SPACE, (2,)), outer),
)
print(normalize_expression(shadow_inner).data)
print(normalize_expression(shadow_outer).data)

binder = symbol("collision", RATIONAL_SPACE)
same_name_free = symbol("collision", RATIONAL_SPACE)
free_body = let(binder, exact_value(RATIONAL_SPACE, (3,)), same_name_free)
print(normalize_expression(
    free_body,
    {"collision": exact_binding((9,), RATIONAL_SPACE)},
).data)
```

Observed output:

```
True
(Fraction(2, 1),)
(Fraction(1, 1),)
(Fraction(9, 1),)
```

50.5 Resource limits and cycle rejection

Expression validation happens before potentially expensive normalization, planning, or serialization. `ExpressionBudget` supplies one explicit finite envelope:

```
ExpressionBudget(
    max_nodes: int = 10000,
    max_depth: int = 1000,
    max_steps: int = 50000,
    max_degree: int = 512,
    max_entries: int = 1000000,
    max_coefficient_bits: int = 1000000,
    max_serialized_bytes: int = 64000000,
    max_symbol_length: int = 1024,
)

budget.preflight(root: Expression) -> ExpressionStats
budget.require(root: Expression) -> ExpressionStats
```

All limits are positive integers. The returned `ExpressionStats` contains

```
ExpressionStats(
    nodes: int,
    depth: int,
    steps: int,
    exact_entries: int,
    maximum_degree: int,
    maximum_coefficient_bits: int,
    serialized_bytes: int,
)
```

`nodes` counts unique object identities in the in-memory DAG. `steps` is the unique-node count plus traversed edges. `exact_entries` includes literal entries, matrix entries, primitive parameters, and the coefficients of unique semantic basis witnesses. `serialized_bytes` is a deterministic structural accounting used for preflight. It is not a pickle size or a promise that JSON will have exactly that length.

The traversal is iterative and uses a three-color object graph check. A gray node encountered again is a cycle and raises `ValidationError`. This matters even though the public dataclasses are frozen: hostile code can bypass normal construction with `object.__setattr__`, and a decoder must not trust that an object arrived through an honest path.

Data growth is checked again during normalization and execution. A small input DAG can produce a rational numerator with many more bits, so passing the structural preflight does not waive `max_coefficient_bits` for intermediate or final normal forms.

The portable form expands DAG sharing into a JSON tree. Its encoder therefore replays the generated record through the decoder under the same budget. A shared leaf used eleven times may be only one in-memory node, yet it counts as eleven serialized occurrences. `expression_to_dict` refuses to emit a record that its paired decoder would reject.

Failure matrix

Invalid construction or payload	Failure boundary
literal vector length differs from `space.dimension`	`DimensionError`
exact matrix shape differs from target-by-source shape	`DimensionError`
adjacent composition endpoints disagree	`ValidationError`
sum terms have different semantic types	`ValidationError`
application argument differs from operator source	`ValidationError`
`Let` value differs from binder declaration	`ValidationError`
float or boolean used as an exact coefficient	`ValidationError`
singular or incomplete graded basis witness	`ValidationError` or `DimensionError`
object-level expression cycle	`ValidationError`
node, depth, degree, entry, bit, text, or byte limit exceeded	`ResourceLimitError`
unsupported node subclass	`TypeError` during exact-class replay
mutated supported node	`ValidationError`, `DimensionError`, or `TypeError` according to the replayed invariant

These failures are part of the type model. They occur before any claim that a closed expression has an exact normal form.

51. Expression evaluation and certification

Evaluation is finite matrix algebra with evidence propagation. Every closed, well-typed value term normalizes to an exact coordinate vector. Every closed, well-typed map term normalizes to an exact rational matrix. Basis-aware polynomial operations are not accepted as opaque user callbacks. They are branded primitives whose matrices are regenerated from the frozen basis witnesses and rational parameters.

51.1 Exact normal forms

For a closed term $e : T$, the normal form is

$$\mathrm{NF}(e) \in \begin{cases} \mathbb{Q}^{\dim X}, & T = X, \\ \mathbb{Q}^{\dim Y \times \dim X}, & T = \mathsf{Lin}(X, Y). \end{cases}$$

The public operation is

```
normalize_expression(
    expression: Expression,
    bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    *,
    budget: ExpressionBudget | None = None,
) -> NormalForm
```

`NormalForm` stores `expression_type`, exact `data`, a semantic `digest`, and the composed `certificate`. The digest is computed from canonical type and rational data, so equality is never delegated to floating tolerance.

Normalization assigns these denotations:

$$\begin{aligned} [\![I_X]\!] &= I_{\dim X}, \\ [\![0_{X,Y}]\!] &= 0_{\dim Y \times \dim X}, \\ [\![B \circ A]\!] &= [\![B]\!][\![A]\!], \\ [\![e_1 + e_2]\!] &= [\![e_1]\!] + [\![e_2]\!], \\ [\![qe]\!] &= q[\![e]\!], \\ [\![A(v)]\!] &= [\![A]\!][\![v]\!]. \end{aligned}$$

Literal data remain exact. `PolynomialPrimitive` nodes call `replay`, and a lexical symbol resolves first to the nearest binder object, then to an external `ExpressionBinding`. Normalizing an unbound free symbol raises `ValidationError`, even though `check_expression` can still report that open term's type.

`normal_form_digest(data, expression_type) -> str` is also public for callers that already possess exact data and the complete type witness. It validates both before hashing. The digest is an integrity identifier, not a signature, authorization token, or proof that data came from a trusted author.

51.2 Typed evaluation

The basis-aware primitive ledger consists of nine exact constructors.

PrimitiveKind	Constructor	Type and meaning
`COORDINATE_CHANGE`	`coordinate_change(source, target)`	$C_{S \to T} : \mathsf{P}_n^S \to \mathsf{P}_n^T$
`DERIVATIVE`	`derivative(source)`	$D_B : \mathsf{P}_n^B \to \mathsf{P}_{n-1}^B$, or a zero endomorphism at degree zero

PrimitiveKind	Constructor	Type and meaning
ANTIDERIVATIVE	antiderivative(source, target, basepoint=0)	$J_{a,B} : \mathsf{P}^B_{n-1} \to \mathsf{P}^B_n$
EVALUATION	evaluation(source, point)	$e_{a,B} : \mathsf{P}^B_n \to \mathbb{Q}$
INTERVAL_INTEGRATION	interval_integration(source, lower, upper, density=1)	$\ell_{B,[a,b],\rho} : \mathsf{P}^B_n \to \mathbb{Q}$
AFFINE_SUBSTITUTION	affine_substitution(source, scale=1, shift=0)	$S_{s,t}p(x) = p(sx+t)$ in the same coordinate space
FINITE_DIFFERENCE	finite_difference(source, step=1)	$\Delta_h p(x) = p(x+h) - p(x)$, re-encoded in P^B_n
BOUNDARY_FUNCTIONAL	boundary_functional(source, lower, upper, density=1)	$\rho(p(b) - p(a))$
CONSTANT_INJECTION	constant_injection(target)	$\iota : \mathbb{Q} \to \mathsf{P}^B_n$

Every constructor accepts only integers or `Fraction` parameters. Coordinate changes require the same physical variable and equal degree. An antiderivative target must have degree exactly one higher and must extend the source basis witness exactly. Interval endpoints obey $a \le b$, density is nonnegative, and finite-difference step is nonzero.

The derivative uses a tight target:

$$D_B : \mathsf{P}^B_n \longrightarrow \mathsf{P}^B_{n-1} \quad (n > 0).$$

At degree zero, it is the zero endomorphism $\mathsf{P}^B_0 \to \mathsf{P}^B_0$. `finite_difference`, by contrast, returns an endomorphism of the original P^B_n, even though its image has degree at most $n-1$. This fixed codomain lets it compose with other endomorphisms without silently changing the declared type.

```
replay(primitive: PolynomialPrimitive) -> Matrix
replay_matrix(primitive: PolynomialPrimitive) -> Matrix

primitive_matrix_equal(
    primitive: PolynomialPrimitive,
    matrix: Iterable[Iterable[Any]],
) -> bool

primitive_certificate(
    primitive: PolynomialPrimitive,
    *,
    claimed_matrix: Iterable[Iterable[Any]] | None = None,
) -> Certificate
```

`replay_matrix` is an alias of `replay`. For coordinate change, replay forms

$$C_{S \to T} = B_T^{-1} B_S.$$

Each `PolynomialPrimitive` also exposes `expression_type`/`map_type`, its enum-valued `kind`, exact `parameters`, a theorem-ID property, and two convenience accessors:

```
primitive.theorem_id -> str
primitive.matrix -> Matrix
primitive.certificate(
    *,
    claimed_matrix: Iterable[Iterable[Any]] | None = None,
) -> Certificate
```

The last two delegate to `replay` and `primitive_certificate`. They do not cache or trust a previously supplied matrix.

Every other matrix is produced by applying its monomial operation to each basis polynomial and converting back through the target basis matrix. The certificate has exactness `EXACT`, tolerance zero, and a theorem identifier specific to the primitive. If `claimed_matrix` is supplied, validity also requires exact entrywise equality with the replayed matrix.

The replayed maps satisfy the finite identities

$$C_{T\to U}C_{S\to T} = C_{S\to U}, \qquad C_{T\to S}C_{S\to T} = I,$$

$$D_T C^{(n)}_{S\to T} = C^{(n-1)}_{S\to T} D_S,$$

$$J_{a,T}C^{(n-1)}_{S\to T} = C^{(n)}_{S\to T}J_{a,S}, \qquad D_B J_{a,B} = I,$$

but

$$J_{a,B}D_B = I - u_B e_{a,B},$$

where $u_B = \iota(1)$ is the coordinate vector of the constant polynomial one. Thus differentiating after basepoint integration is an identity, while integrating after differentiation loses the value at the basepoint. The runtime contains a distinct certified rewrite for this defect and does not replace JD by an identity.

Evaluation and integration covectors transport with basis changes:

$$e_{a,T}C_{S\to T} = e_{a,S}, \qquad \ell_T C_{S\to T} = \ell_S,$$

and the density-weighted finite polynomial FTC is

$$\ell_{n-1}D_n = \rho(e_b - e_a).$$

These are finite rational polynomial identities, not a general analytic fundamental theorem of calculus.

Exact Fibonacci-Euler pipeline

The shipped worked example begins with the Fibonacci-coordinate polynomial

$$G_3(x) = F_4(x) = x^3 + 2x, \qquad c_F = (0,0,0,1)^T.$$

Let `F3`, `F4`, `E3`, and `E4` be the snapshotted Fibonacci and Euler spaces through degrees three and four. Define

$$P = C_{E_3\to F_3}\, D_{E_4}\, C_{F_4\to E_4}\, J_{0,F_3}.$$

The four successive coordinate vectors are

$$\begin{aligned}
J_{0,F_3}c_F &= \left(-\frac{1}{2}, 0, \frac{1}{4}, 0, \frac{1}{4}\right)^T,\\
C_{F_4\to E_4}J_{0,F_3}c_F &= \left(\frac{5}{8}, \frac{3}{2}, \frac{7}{4}, \frac{1}{2}, \frac{1}{4}\right)^T,\\
D_{E_4}C_{F_4\to E_4}J_{0,F_3}c_F &= \left(\frac{3}{2}, \frac{7}{2}, \frac{3}{2}, 1\right)^T,\\
Pc_F &= (0,0,0,1)^T.
\end{aligned}$$

Exact matrix replay gives

$$P = I_4.$$

The Fibonacci integration covector on $[0,1]$ is

$$\ell_F = \left(1, \frac{1}{2}, \frac{4}{3}, \frac{5}{4}\right),$$

so

$$\ell_F P c_F = \frac{5}{4}.$$

This example is executed independently by the installed expression verifier, the focused test suite, and `examples/block20_typed_expression_worked_example.py`.

51.3 Decidable equality

For two closed, well-typed terms, equality in this finite language is

$$e_1 \equiv e_2 \iff \mathrm{type}(e_1) = \mathrm{type}(e_2) \wedge \mathrm{NF}(e_1) = \mathrm{NF}(e_2).$$

The public decision procedure is

```
equivalent(
    left: Expression,
    right: Expression,
    *,
    left_bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    right_bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    budget: ExpressionBudget | None = None,
) -> EquivalenceResult
```

`EquivalenceResult` stores `equivalent`, optional left and right normal forms, and a certificate. If the semantic types differ, the result is immediately false and both normal-form fields are `None`. If the types agree, the comparison is exact and entrywise. `require_equivalent()` first requires the certificate and then raises `ValidationError` unless the result is true.

A valid comparison certificate can accompany `equivalent=False`: the comparison itself was performed correctly and found a mismatch. Use `require_equivalent()` when equality is required for the next step. Requiring only the comparison certificate does not assert the equality outcome.

```
from komorebi_math.expression import (
    PolynomialCoordinateSpace,
    add,
    equivalent,
    identity,
    scale,
)

M1 = PolynomialCoordinateSpace(
    "x", 1,
    ((1,), (0, 1)),
    "monomials",
)
constructed = add(scale(2, identity(M1)), scale(-1, identity(M1)))
decision = equivalent(constructed, identity(M1))

print(decision.equivalent)
print(decision.left.data)
print(decision.certificate.theorem_id)
```

Observed output:

```
True
((Fraction(1, 1), Fraction(0, 1)),
 (Fraction(0, 1), Fraction(1, 1)))
EXPR.EQUALITY.DECIDABLE
```

This decision rule does not prove a universally quantified identity between open terms. When the semantic types agree, `equivalent()` normalizes both sides and therefore requires compatible bindings for every free symbol. When the semantic types differ, it returns false with no normal forms before normalization. Equality after supplying bindings is equality for those bindings, not for every assignment. Direct node comparison is merely structural and is not quantified equality.

51.4 Certified rewrites and simplification

```
simplify_expression(
    expression: Expression,
    bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    *,
    budget: ExpressionBudget | None = None,
) -> SimplificationResult
```

The simplifier is conservative. Before accepting any candidate rewrite it normalizes both sides and requires identical semantic type and exact data. Each accepted step records

```
RewriteStep(
    rule: str,
    theorem_id: str | None,
    before_digest: str,
    after_digest: str,
    side_conditions: tuple[str, ...],
    certificate: Certificate,
)
```

The local algebraic rules include

$$I \circ A \to A, \quad A \circ I \to A, \quad 0 \circ A \to 0, \quad A \circ 0 \to 0,$$

$$A + 0 \to A, \quad 1A \to A, \quad 0A \to 0, \quad q(re) \to (qr)e,$$

plus flattening of nested sums and compositions and literal matrix-vector application. Polynomial-specific proposals include coordinate cocycles, derivative naturality, $DJ = I$, the JD basepoint defect, the density-weighted FTC row, and transport of evaluation, integration, and boundary functionals.

These specialized rules trigger only for `PolynomialPrimitive` instances with matching kinds and exact source/target witnesses. An `ExactMapLiteral` whose label contains `EXPR.REWRITE.DJ` is still an ordinary matrix and cannot trigger the derivative/antiderivative rule.

`SimplificationResult` stores the simplified `expression`, `before` and `after` normal forms, the tuple of `steps`, and a composed certificate. It requires

$$\mathrm{NF}(e_{before}) = \mathrm{NF}(e_{after})$$

for every step and for the whole transformation. A 256-step local convergence guard and the shared `max_steps` budget bound rewrite work.

For the Fibonacci-Euler pipeline above, the observed rule sequence is

```
derivative coordinate naturality
flatten composition and remove identities
coordinate cocycle
flatten composition and remove identities
derivative-antiderivative cancellation
```

and the final node is `IdentityMap`. Both the pre-simplification and post-simplification normal forms are I_4.

51.5 Binding-certificate propagation

External values enter through `ExpressionBinding(value, declared_type, certificate)`. Their evidence cannot be laundered by exact internal arithmetic. Certificate composition uses the public strongest-to-weakest order

$$\text{EXACT} \prec \text{NUMERICAL} \prec \text{CONDITIONAL} \prec \text{HEURISTIC} \prec \text{PLANNED},$$

where the maximum is the weakest guarantee. The empty meet is exact. If any child is invalid, the parent is invalid. Unchecked assumptions are unioned. Their presence imposes at least `CONDITIONAL`, even when all child statuses were `EXACT`.

Formally, for child certificates $C_1, \dots, C_m$,

$$H_?^{out} = \bigcup_{j=1}^{m} H_?(C_j),$$

$$\tau_{out} = \max_{\prec} \left(\{\tau(C_j) : 1 \le j \le m\} \cup \{\text{CONDITIONAL} : H_?^{out} \neq \emptyset\} \right).$$

Residual keys receive deterministic `childN:` prefixes, the output tolerance is the largest child tolerance, and child diagnostics remain in separate namespaces. A key collision therefore cannot make evidence disappear.

The public helpers are

```
exactness_strength(value: Exactness) -> int
weakest_exactness(*values: Exactness) -> Exactness

compose_certificates(
    certificates: Iterable[Certificate],
    *,
    operation: str | None = None,
    theorem_id: str | None = None,
    assumptions_checked: Iterable[str] = (),
    assumptions_unchecked: Iterable[str] = (),
    diagnostics: Mapping[str, Any] | None = None,
) -> Certificate

exact_internal_certificate(
    operation: str,
    *,
    theorem_id: str | None = None,
    assumptions_checked: Iterable[str] = (),
    diagnostics: Mapping[str, Any] | None = None,
) -> Certificate
```

Three boundaries follow immediately:

1. exact parent plus an invalid child gives an invalid result.
2. Exact parent plus a numerical binding remains at most numerical.
3. Exact matrices plus an unchecked premise become conditional.

`evaluate_expression(...).require()` calls the final certificate's `require` method before returning data. Reading `.value` or `.scalar` alone does not perform that explicit validity assertion. `.scalar` is defined only for `RationalSpace`. Applying it to a vector or map result raises `DimensionError`.

52. Expression planning and persistence

The direct normalizer evaluates compositions in their written order. The planning layer adds a second, independently replayed route: it compiles the same expression into a small instruction sequence, optimizes dense matrix chains by dynamic programming, validates a content digest, executes the plan, and compares its final exact data with direct normalization. Persistence then encodes the original typed expression as strict canonical JSON with a semantic SHA-256 digest.

These are separate integrity boundaries. The execution-plan digest content-addresses the canonical execution record rather than every field of the in-memory Python objects. The portable expression digest binds canonical semantic JSON. Neither is a keyed MAC, cryptographic signature, proof of authorship, or sandbox for arbitrary code. **E**

Keep three records distinct when exchanging a calculation. The expression describes the typed computation, its normal form describes the resulting exact vector or matrix, and its execution plan describes one checked route to that result. A content digest identifies the record it was computed from; it does not replace the record or the mathematical type witness needed to interpret it.

52.1 Matrix-chain recurrence

For dimensions

$$(p_0, p_1, \dots, p_n), \qquad A_i \in \mathbb{Q}^{p_i \times p_{i+1}} \quad (0 \le i < n),$$

the planner minimizes classical dense scalar multiplication count over all order-preserving binary parenthesizations. Let $m[i, j]$ be the cost of the half-open matrix interval containing $A_i, \dots, A_{j-1}$. Then

$$m[i, i+1] = 0,$$

and, for $j > i + 1$,

$$m[i, j] = \min_{i<k<j} \left\{ m[i, k] + m[k, j] + p_i p_k p_j \right\}.$$

In the one-based closed-interval notation often used in textbooks, write $\widetilde{A}_i \in \mathbb{Q}^{d_{i-1} \times d_i}$, with $d_r = p_r$. The same recurrence is

$$m[i, j] = \min_{i \le k < j} \{ m[i, k] + m[k + 1, j] + d_{i-1} d_k d_j \}.$$

The implementation records the smallest split index when costs tie. Its theorem is narrow:

> `matrix_chain_plan` is exact and optimal among binary parenthesizations of the supplied order-preserving chain under classical dense scalar multiplication count.

It does not optimize addition count, sparsity, rank structure, memory traffic, parallelism, device transfers, kernel launches, Strassen-like algorithms, rounding stability, or wall-clock time.

```
matrix_chain_plan(
    dimensions: Sequence[int],
) -> MatrixChainPlan

matrix_chain_parenthesization(
    plan: MatrixChainPlan,
```

```
    labels: Sequence[str] | None = None,
) -> str

matrix_chain_multiply(
    matrices: Sequence[Iterable[Iterable[Any]]],
    plan: MatrixChainPlan,
) -> Matrix
```

`dimensions` must contain at least two positive integers. Booleans are rejected. A chain with n matrices explores

$$\frac{n(n-1)(n+1)}{6}$$

candidate splits. A fixed one-million-step planning guard rejects a dimension sequence that would exceed this count before constructing the tables.

`MatrixChainPlan` stores:

- the normalized dimension tuple.
- A `MatrixChainTree` root record.
- Optimal `scalar_operation_cost`.
- `left_associative_cost` and `right_associative_cost`.
- An unconditional exact certificate with theorem ID `EXPR.PLAN.MATRIX_CHAIN_DP`.

Construction of a `MatrixChainPlan` re-runs the dynamic program and rejects a tree or cost that does not match. `matrix_chain_multiply` repeats that replay, validates the number and exact shape of all rational matrices, and evaluates the recorded tree iteratively.

Classical six-matrix example

```
from komorebi_math.expression import (
    matrix_chain_parenthesization,
    matrix_chain_plan,
)

plan = matrix_chain_plan((30, 35, 15, 5, 10, 20, 25))
print(plan.scalar_operation_cost)
print(plan.left_associative_cost)
print(plan.right_associative_cost)
print(matrix_chain_parenthesization(plan))
print(plan.certificate.theorem_id)
```

Observed output:

```
15125
40500
47500
((A0 @ (A1 @ A2)) @ ((A3 @ A4) @ A5))
EXPR.PLAN.MATRIX_CHAIN_DP
```

For a tie such as dimensions `(2, 2, 2, 2)`, the deterministic smallest-split rule produces `(A0 @ (A1 @ A2))`.

52.2 Planned versus direct evaluation

The expression compiler emits only five opcodes:

Opcode	Inputs	Payload	Cost model
`constant`	0	exact vector or matrix	0
`add`	2	none	number of result entries
`scale`	1	exact rational scalar	number of result entries
`matrix_chain`	at least 2 maps	replayable `MatrixChainPlan`	optimal dense multiplication cost
`apply`	map and vector	none	target dimension times source dimension

One instruction is

```
PlanInstruction(
    opcode: str,
    inputs: tuple[int, ...],
    expression_type: CoordinateSpace | LinearMapType,
    payload: Any,
    scalar_operation_cost: int,
    certificate: Certificate,
)
```

and the complete plan is

```
ExpressionPlan(
    expression_digest: str,
    expression_type: CoordinateSpace | LinearMapType,
    instructions: tuple[PlanInstruction, ...],
    output_index: int,
    scalar_operation_cost: int,
    plan_digest: str,
    certificate: Certificate,
)
```

Every input index must name an earlier output. Instruction types, payloads, and costs are re-derived in `ExpressionPlan.__post_init__`. The aggregate cost must equal the sum of instruction costs. The plan digest is

$$d_P = \mathrm{SHA256}(\mathrm{CanonicalJSON}(d_e, T, (I_k), k_{out})),$$

where d_e is the semantic digest of the source expression, T its complete type, (I_k) the instruction records, and k_{out} the output index. The canonical instruction payload includes each opcode, dependency, typed payload, cost, and selected certificate fields. It does not serialize certificate diagnostics or messages, the plan-level certificate, or every other Python object field. Constructor replay separately requires the aggregate cost to equal the sum of instruction costs.

The public pipeline is

```
compile_expression(
    expression: Expression,
    bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    *,
    budget: ExpressionBudget | None = None,
) -> ExpressionPlan

execute_plan(
    plan: ExpressionPlan,
```

```
    *,
    budget: ExpressionBudget | None = None,
) -> NormalForm

evaluate_expression(
    expression: Expression,
    bindings: Mapping[str | Symbol, ExpressionBinding] | None = None,
    *,
    budget: ExpressionBudget | None = None,
) -> ExpressionResult
```

`compile_expression` first type-checks and directly normalizes the source. It then emits a self-contained plan, reconstructs the digest, executes the plan, and refuses to return it unless the executed result equals the independent direct normal form.

`execute_plan` calls the plan constructor checks again, recomputes the content digest, verifies topological order, checks every result against the instruction type and budget, and composes the instruction certificates.

`evaluate_expression` performs both routes again and requires

$$\mathrm{NF}_{direct}(e) = \mathrm{NF}_{plan}(e)$$

entry by entry. `ExpressionResult` exposes `normal_form` for the planned result, `direct_normal_form`, the `plan`, and the combined `certificate`. Its `.value` property returns exact data. `.scalar` projects the unique entry only for a rational-space result. `.require()` requires the certificate first.

For the Fibonacci-Euler expression from Chapter 51, the four-map chain has dimensions

$$(4, 4, 5, 5, 4).$$

The selected parenthesization is

$$C_{E_3 \to F_3}\left(D_{E_4}\left(C_{F_4 \to E_4} J_{0,F_3}\right)\right),$$

with dense multiplication cost 244 instead of 260 for a left-associated chain. The full expression plan contains nine instructions and has aggregate cost 264 after the final map-vector application and integration functional. Both routes produce $5/4$.

These isolated mutations fail closed: changing an opcode to an unknown value, introducing a forward dependency, altering an instruction or aggregate cost, or changing either digest without updating its dependent content makes `execute_plan` raise `ValidationError`. These are replay and consistency checks, not authentication. A plan received across a trust boundary still needs an authenticated channel or an external signature.

52.3 Strict expression JSON

Portable expressions use a dedicated research schema:

```
EXPRESSION_SCHEMA = "komorebi_math.expression.v1"
EXPRESSION_SCHEMA_VERSION = 1
EXPRESSION_NODE_VERSION = 1
EXPRESSION_TYPE_VERSION = 1
```

This schema is intentionally isolated from the frozen general portable-codec registry. The expression API can evolve as a research surface without silently changing the stable persistence contract.

```
type_to_dict(
    expression_type: ExpressionType,
    *,
    budget: ExpressionBudget | None = None,
```

```
) -> dict[str, Any]

type_from_dict(
    value: Mapping[str, Any],
    *,
    budget: ExpressionBudget | None = None,
) -> ExpressionType

expression_to_dict(
    expression: Expression,
    *,
    budget: ExpressionBudget | None = None,
) -> dict[str, Any]

expression_from_dict(
    value: Mapping[str, Any],
    *,
    budget: ExpressionBudget | None = None,
) -> Expression

expression_to_json(
    expression: Expression,
    *,
    budget: ExpressionBudget | None = None,
) -> str

expression_from_json(
    value: str | bytes,
    *,
    budget: ExpressionBudget | None = None,
) -> Expression
```

An envelope contains exactly four fields:

```
expression
schema
schema_version
semantic_sha256
```

Every node and type record has an explicit `kind` and `version`. Unknown or missing fields are rejected. Extras are not ignored. Polynomial type records carry the complete variable, degree, basis witness, and transport label. Linear-map records recursively carry source and target types.

Rationals are reduced integer pairs

```
{"denominator":2,"numerator":1}
```

with a positive denominator. Floats, booleans, nulls, nonfinite constants, and unreduced pairs such as `2/4` are invalid exact primitives. Strings must be valid UTF-8 and NFC. JSON output uses sorted keys, no insignificant whitespace, no ASCII escaping requirement for ordinary Unicode text, and no NaN values.

A complete scalar example is

```
from fractions import Fraction
from komorebi_math.expression import (
    RATIONAL_SPACE,
    exact_value,
    expression_to_json,
)
```

```
text = expression_to_json(exact_value(RATIONAL_SPACE, (Fraction(1, 2),)))
print(text)
```

Observed output:

```
{"expression":{"entries":[{"denominator":2,"numerator":1}],"kind":"exact_value","space":{"kind":"rational_space",
    ↪  "version":1},"version":1},"schema":"komorebi_math.expression.v1","schema_version":1,"semantic_sha256":
    ↪  "5111acf0ceae03747c2a8d9a27734664d0de8ecc7ab607fef5658947ad515a4f"}
```

The decoder requires the input text itself to equal that canonical encoding. Pretty-printed JSON can describe the same generic JSON value but is rejected as a noncanonical expression transport. Call `expression_from_dict` when an already parsed mapping is the intended boundary. It validates structure and digest without imposing a previous text representation.

52.4 Digest and canonical text

The semantic digest is

$$d(e) = \mathrm{SHA256}\left(\mathrm{CanonicalUTF8NFCJSON}(\mathrm{semantic_record}(e))\right).$$

```
expression_digest(
    expression: Expression,
    *,
    budget: ExpressionBudget | None = None,
) -> str
```

The semantic record includes every type witness, exact entry, free-symbol name, node kind, and primitive parameter. It intentionally omits display labels. Bound symbol names are replaced by lexical distance. Therefore:

- changing a basis coefficient changes the digest.
- Changing a free symbol's name changes the digest.
- Changing an exact literal or primitive parameter changes the digest.
- Changing only a space or map display label does not change the digest.
- Consistently alpha-renaming a `Let` binder does not change the digest.
- Changing which same-name binder an occurrence refers to does change it.

The transport JSON retains display labels for human reconstruction even though they are absent from the semantic hash. Two differently labelled exact maps may thus have different `expression_to_json` text but identical `expression_digest` values.

On decode, the implementation reconstructs the exact built-in expression, reruns structural and budget preflight, computes a fresh semantic digest, and compares it with `hmac.compare_digest`. This checks internal consistency against the envelope's unkeyed checksum. It detects accidental corruption or a changed semantic tree when the recorded digest is held fixed. Anyone able to alter both can recompute it. It does not authenticate the producer. Use an external signature, MAC, or authenticated channel when provenance matters.

End-to-end roundtrip

```
from fractions import Fraction
from komorebi_math.expression import (
    RATIONAL_SPACE,
    exact_value,
    expression_digest,
    expression_from_json,
    expression_to_json,
    normalize_expression,
)
```

```
source = exact_value(RATIONAL_SPACE, (Fraction(1, 2),))
text = expression_to_json(source)
restored = expression_from_json(text)

print(expression_digest(source))
print(expression_digest(restored))
print(normalize_expression(restored).data)
```

Observed output:

```
5111acf0ceae03747c2a8d9a27734664d0de8ecc7ab607fef5658947ad515a4f
5111acf0ceae03747c2a8d9a27734664d0de8ecc7ab607fef5658947ad515a4f
(Fraction(1, 2),)
```

The worked $5/4$ expression has semantic digest

```
161d64ab695774a8293b9450f88654eabe28a1265a623575a84c73d64c7d9138
```

in the shipped `1.0.0b4` worked-example record.

52.5 Tamper, spoof, cycle, and resource adversaries

The decoder's threat model is restrictive by design. It reconstructs only the known finite node and type grammar. It never imports a class named by the payload, evaluates source text, invokes a callback, resolves an arbitrary module path, or executes a pickle reducer.

It explicitly rejects:

- duplicate object keys.
- Floating-point and nonfinite JSON tokens.
- Booleans and null values at exact-data positions.
- Noncanonical or unreduced rational pairs.
- Non-NFC strings and invalid UTF-8.
- Unknown schema, schema-version, node-version, or type-version values.
- Missing fields and unrecognized extra fields.
- Unknown node, type, or primitive tags.
- A malformed, uppercase, or mismatched semantic digest.
- Dangling bound-symbol indices.
- Incompatible expression endpoints or malformed basis witnesses.
- Circular in-memory containers and expression object cycles.
- Depth, node, step, degree, entry, coefficient-bit, text-length, or byte limits beyond the supplied `ExpressionBudget`.

The graph and transport models have different sharing semantics. An in-memory expression can be a DAG, and normalization caches a shared node. JSON is a tree, so each occurrence is written separately. The encoder preflights the expanded envelope through the strict decoder. This symmetry prevents the encoder from producing a record that is legal only on its side of the API.

Minimal digest-tamper demonstration

```
from copy import deepcopy
from fractions import Fraction

from komorebi_math.exceptions import ValidationError
from komorebi_math.expression import (
    RATIONAL_SPACE,
    exact_value,
```

```
    expression_from_dict,
    expression_to_dict,
)

record = expression_to_dict(
    exact_value(RATIONAL_SPACE, (Fraction(1, 2),))
)
hostile = deepcopy(record)
hostile["semantic_sha256"] = "0" * 64

try:
    expression_from_dict(hostile)
except ValidationError as exc:
    print(type(exc).__name__)
    print(str(exc))
```

Observed output:

```
ValidationError
expression semantic SHA-256 mismatch
```

Changing semantic content and recomputing the unkeyed digest creates a self-consistent record. Treat `semantic_sha256` as a deterministic content identifier and consistency check, not as adversarial tamper protection or authentication.

Operational verification

The installed finite-expression verifier is

```
python -m komorebi_math verify expression
```

For `1.0.0b4` it exercises 22 named checks covering semantic space typing, strict rationals and NFC, primitive replay, coordinate identities, the Fibonacci-Euler and affine examples, exact equality, certified rewrites, matrix-chain optimality and execution, direct/planned agreement, portable roundtrips, lexical alpha equivalence, canonical-text and digest rejection, evidence propagation, budgets, cycles, same-label spoofing, and forged or singular primitives. The expected final line is

```
verification passed 22/22 checks
```

For an end-to-end readable record, run

```
python .\examples\block20_typed_expression_worked_example.py --json
```

from the repository root. The example asserts every intermediate vector, $P = I_4$, the $5/4$ integral, optimal plan cost $244 < 260$, portable roundtrip equality, and the affine/pushforward value $106/5$ before printing the record.

Chapter boundary

The expression layer proves exact facts about the finite typed terms it accepts. It does not convert a finite replay into a general theorem about all polynomials, all bases, all measures, or all programs. The type witness, resource budget, certificate status, and transport digest should travel with the computation whenever the result crosses a process or publication boundary.

Part IX. Quantum, deformation, and finite Langlands models

This part develops three related finite execution layers. The quantum layer turns finite Hilbert spaces, symmetry sectors, circuit paths, channels, moving projectors, and effective operators into packet calculations with residual certificates. The deformation layer replaces a single finite space by explicit lift levels, exact reduction maps, cohomology groups, support loci, and Frobenius trace data. The finite Langlands layer then assembles finite fields, tame packets, Heisenberg models, induced representations, Clifford towers, ramification records, and explicit completion gates.

The word *finite* is essential throughout. A successful computation proves or checks a statement about the supplied matrices, residue levels, groups, characters, or gate record. It does not silently construct an infinite-volume quantum field theory, an infinite prime-power lift, a local or global Langlands correspondence, or an automorphic realization. The certificate class makes the boundary visible:

- exact certificates are finite algebraic or arithmetic identities.
- Numerical certificates record a residual and tolerance for floating matrix calculations.
- Conditional certificates preserve external hypotheses that the runtime does not prove.

The recommended imports are organized by domain:

```
from komorebi_math import quantum
from komorebi_math import deformation
from komorebi_math.langlands import (
    completion,
    finite_image,
    global_,
    local,
    ramification,
)
```

Many promoted names are also available from `komorebi_math`, but the domain imports make the mathematical provenance of each object easier to see.

Reading routes and prerequisites. The quantum route assumes complex linear algebra and begins with Chapter 53. The deformation route begins with Chapter 56 and uses finite sets, reduction maps, and exact linear algebra over prime fields. The local representation route begins with Chapter 57 and uses finite-field arithmetic and finite group representations. Chapter 58 brings those finite records into conditional completion arguments.

Your question	Start here	Meaning of the finite result
Which sectors or transitions occur in a finite quantum model?	Chapters 53 and 54	Matrix, projector, path, or channel diagnostics
Does a declared error family satisfy a code criterion?	Sections 55.1 and 55.2	A check tied to that finite code and error set
How does an eliminated sector affect a retained one?	Section 55.3, with Chapter 46	Effective resolvent and memory feedback
Which lift candidates survive the supplied levels?	Section 56.1	Stable cores and branches through the represented depth
What do finite fields, characters, or group packets compute?	Chapters 57 and 58	Explicit finite arithmetic and representation data
Which external premises are still needed?	Sections 58.5 through 58.7	Conditional support and completion records

The three domains share computational tools, but their objects have different meanings. Keep the domain, scalar field, basis or state ordering, and certificate with a result when moving it into another calculation.

53. Finite quantum foundations

The quantum foundation is a finite-dimensional operator calculus. It starts with a family of observables and seed vectors, resolves the resulting Hilbert space into symmetry packets, and supplies diagnostics for Euclidean transfer, spectral scaling, leakage, and constraint closure. Every matrix is validated for shape and, where appropriate, Hermiticity, unitarity, or projector identities before the calculation begins.

For a first example, choose a small Hilbert space and write down its basis ordering before constructing observables, states, or projectors. The same ordering must be used by every matrix and vector. Tensor products also need a consistent factor order. A shape check can detect incompatible dimensions, but it cannot recover a different physical interpretation of the same-sized array.

53.1 Observable and seed systems

Let $\mathcal{H} \cong \mathbb{C}^d$, let $\mathcal{A} = \langle A_1, \dots, A_r \rangle$ be the finite algebra generated by supplied observables, and let $S = (s_1, \dots, s_k)$ be a finite seed family. The generated orbit space is

$$\mathcal{O}(\mathcal{A}, S) = \operatorname{span}\{as_j : a \in \mathcal{A},\ 1 \le j \le k\}.$$

`QuantumSeedSystem` delegates the closure calculation to the common finite seed engine. `orbit_basis()` returns a maximal independent numerical basis, `orbit_dimension()` returns its rank, and `is_generating()` asks whether that rank is d. The certificate is numerical because independence is decided with a floating tolerance.

```
from komorebi_math.quantum import QuantumSeedSystem

system = QuantumSeedSystem(
    {
        "x": [[0, 1], [1, 0]],
        "z": [[1, 0], [0, -1]],
    },
    ([1, 0],),
)

assert system.dimension == 2
assert system.orbit_dimension() == 2
assert system.is_generating()
system.certificate().require()
```

For n qubits, `computational_basis_generation(n)` constructs the all-zero seed and the 2^n tensor products of Pauli X addresses. It returns the seed, the address operators, and a numerical orthogonality certificate. The construction is explicit and therefore grows exponentially with the qubit count.

The bipartite helpers separate two related ranks. If a pure state is reshaped as a $d_L \times d_R$ matrix M_ψ, then

$$r = \operatorname{rank}(M_\psi)$$

is its numerical Schmidt rank, while the orbit dimension under the full left matrix algebra is

$$\dim(M_{d_L}(\mathbb{C})\psi) = d_L r.$$

`schmidt_rank()` returns r, and `local_orbit_dimension()` returns $d_L r$. Neither routine infers an asymptotic entanglement law. It reports a finite singular-value rank at the requested tolerance.

53.2 Symmetry projectors

For a finite unitary representation U_g and an irreducible character χ of degree d_χ, the central isotypic projector is

$$P_\chi = \frac{d_\chi}{|G|} \sum_{g \in G} \overline{\chi(g)} U_g.$$

`finite_group_projector()` evaluates this expression from aligned mappings of group keys to representation matrices and character values. It checks the unitarity and common dimension of every supplied matrix, but it does not independently prove that the keys and multiplication law form a group or that the supplied values are an irreducible character. Those are declared inputs.

For a unitary V with declared order n, the cyclic packet projectors are

$$P_q = \frac{1}{n} \sum_{m=0}^{n-1} \omega^{-qm} V^m, \qquad \omega = e^{2\pi i/n}, \qquad q = 0, \dots, n-1.$$

`cyclic_symmetry_projectors(V, n)` first verifies $V^n = I$, then returns a `PacketSystem` whose names are the charge labels. The packet certificate checks idempotence, pairwise orthogonality, and completeness numerically.

If an operator A has charge q, then

$$VAV^* = \omega^q A, \qquad P_b A P_a = 0 \quad \text{unless} \quad b \equiv a + q \pmod{n}.$$

`charge_certificate()` checks the first identity, and `charge_selection_certificate()` checks every forbidden packet block in the second. `total_charge_packets(left, right)` groups tensor products according to the addition rule $a+b \equiv q \pmod{n}$. These are useful diagnostics for selection rules because a failure returns the largest forbidden residual instead of only a Boolean.

53.3 Euclidean transfer and spectral diagnostics

`EuclideanTransfer` begins with a finite Hermitian Hamiltonian H, a lattice spacing $a > 0$, and either the computed ground energy or a supplied lower shift E_0. It forms

$$\widetilde{H} = H - E_0 I \succeq 0, \qquad T_m = \exp(-ma\widetilde{H}).$$

For vectors v_i placed at nonnegative integer times t_i, the finite reflection matrix is

$$R_{ij} = \langle v_i, T_{t_i + t_j} v_j \rangle.$$

`reflection_certificate()` symmetrizes this matrix and checks that its smallest eigenvalue is no less than the negative tolerance. This is a finite reflection positivity test for the supplied transfer system. It is not a continuum reconstruction theorem. `EuclideanTransfer.from_transfer()` performs the inverse finite calculation for a positive definite contraction by applying $-a^{-1}$ log to its eigenvalues.

The spectral helpers use a nonnegative finite Hermitian operator L:

$$Z(t) = \operatorname{Tr}(e^{-tL}), \qquad d_s(t) = 2t \, \frac{\operatorname{Tr}(Le^{-tL})}{\operatorname{Tr}(e^{-tL})}.$$

`heat_trace()` evaluates $Z(t)$, and `spectral_dimension()` evaluates the scale-dependent diagnostic $d_s(t)$. In finite dimension, $d_s(t)$ tends to zero as time decreases to zero. Its large-time limit is zero when the operator has a zero eigenvalue. For a positive-definite operator, it instead grows asymptotically linearly with time. A plateau across an intermediate time window can be informative, but the function does not promote that plateau to a continuum dimension theorem.

`periodic_laplacian(shape)` constructs the nearest-neighbor periodic lattice matrix. `periodic_lattice_eigenvalues(shape)` independently returns

$$\lambda_k = \frac{4}{h^2} \sum_{j=1}^{D} \sin^2\left(\frac{\pi k_j}{N_j}\right).$$

`low_mode_dispersion_bound()` returns the discrete eigenvalue, its continuum quadratic approximation, and the quartic upper error expression used by the finite diagnostic.

The shipped replay is:

```
python .\examples\euclidean_spectral.py
```

Expected output:

```
Euclidean and spectral example passed
```

53.4 Leakage and constraint checks

For a fixed orthogonal projector P, $Q = I - P$, and Hermitian H, the finite leakage routine checks

$$\left\| Q e^{-itH} P \right\|_2 \leq |t| \, \|QHP\|_2.$$

`fixed_packet_leakage()` returns the observed norm, the bound, the coupling norm, and a numerical certificate. The bound is most useful when the off-diagonal coupling QHP is small. It can be valid but uninformative when $|t|\|QHP\|_2$ is large.

For a differentiable moving packet family $P_j(t)$, the shared `MovingPacketSystem` computes the Kato generator

$$K(t) = \sum_j \dot{P}_j(t) P_j(t).$$

The geometric coupling for packet P is implemented as

$$Q(t)(H(t) - iK(t))P(t).$$

`moving_packet_leakage_bound()` integrates its norm with sampled trapezoidal quadrature. Its certificate explicitly leaves the between-sample quadrature error unchecked.

Constraint closure is a separate finite diagnostic. Given Hermitian constraints $C_1, \ldots, C_r$, `constraint_closure()` projects each commutator onto their declared complex span:

$$[C_i, C_j] \approx \sum_k f_{ij}^k C_k.$$

The report contains the least-squares coefficients, the residual matrix, and the maximum obstruction. `transported_constraint_defect()` compares fine and coarse constraints through a coarsening map R by returning

$$R C_i^{\text{fine}} - C_i^{\text{coarse}} R.$$

Neither routine infers missing constraints. Closure is only with respect to the declared span, and a small floating residual is a numerical statement at the chosen scale.

54. Circuits, channels, and open dynamics

The next layer moves from static packets to processes. Circuit paths resolve a unitary product into addressed blocks. Quantum channels act on operator space. Lindblad generators evolve density matrices. Kato transport follows moving packet sectors. Finite Hamiltonian towers measure adjacent compatibility.

Choose the state representation before the evolution method. Circuit gates act on state vectors, channels act on matrices, and a Lindblad generator acts on density matrices through its generator equation. The superoperator acts on vectorized operator entries rather than state-vector entries. Preserve the documented column-vectorization convention when comparing direct actions with superoperator calculations.

54.1 Circuit packet expansions

Let $U = U_m \cdots U_1$, and let $\{P_a^{(j)}\}_a$ be a complete packet family before the first gate, between each pair of gates, and after the last gate. Repeated insertion of the identity gives

$$P_{a_m}^{(m)} U P_{a_0}^{(0)} = \sum_{a_1,\ldots,a_{m-1}} P_{a_m}^{(m)} U_m P_{a_{m-1}}^{(m-1)} \cdots U_1 P_{a_0}^{(0)}.$$

`CircuitPacketExpansion` stores the gates and $m+1$ packet systems. `path_blocks(source, target)` returns every internal address path and its operator block. `block()` sums those paths, and `reconstruction_certificate()` sums every source and target block to recover the full unitary.

The number of internal paths is the product of the internal packet counts. The constructor enforces `max_paths`, which defaults to one million. This is a safety limit, not an approximation rule. If the exact enumeration is too large, construction fails before allocating the path family.

For a source vector, `interference()` computes

$$p_{b\leftarrow a} = \left\| \sum_\gamma \psi_\gamma \right\|^2 = \sum_\gamma \|\psi_\gamma\|^2 + 2 \sum_{\gamma<\eta} \mathrm{Re}\langle \psi_\gamma, \psi_\eta \rangle.$$

The report separates the incoherent sum from the interference term and checks their reconstruction of the direct target probability. A negative interference value is allowed. It represents destructive interference, not a negative probability.

```
import numpy as np

from komorebi_math.quantum import (
    CircuitPacketExpansion,
    cyclic_symmetry_projectors,
)

symmetry = np.diag([1, -1]).astype(complex)
packets = cyclic_symmetry_projectors(symmetry, 2)
hadamard = np.array([[1, 1], [1, -1]], dtype=complex) / np.sqrt(2)

circuit = CircuitPacketExpansion(
    (hadamard, hadamard, hadamard),
    (packets, packets, packets, packets),
)
circuit.reconstruction_certificate().certificate.require()
circuit.block_unitarity_certificate().require()
```

```
report = circuit.interference(
    np.array([1, 0], dtype=complex),
    0,
    0,
)
report.certificate.require()
print(report.target_probability)
```

Observed output:

```
0.4999999999999998
```

54.2 Quantum channels

`QuantumChannel` represents a finite completely positive map through a nonempty Kraus family:

$$\Phi(X) = \sum_i K_i X K_i^*, \qquad \sum_i K_i^* K_i = I \quad \text{for trace preservation.}$$

Rectangular Kraus matrices are accepted, so input and output dimensions may differ. The certificate checks the trace-preservation residual and the smallest eigenvalue of the Choi matrix. Because these are floating matrix calculations, the certificate uses `Exactness.NUMERICAL` even though a Kraus representation is an exact mathematical guarantee of complete positivity.

The main methods are:

- `apply(X)` and `apply_density(rho)` for the Schrödinger action.
- `adjoint(Y)` for the Hilbert-Schmidt adjoint.
- `superoperator()` for column-vectorized operator space.
- `choi_matrix()` for the output-tensor-input Choi ordering.
- `compose(previous)` and `tensor(other)` for process composition.
- `covariance_certificate()` for declared input and output symmetries.

Operator packets use both a left and a right address. For projectors P_a,

$$X = \sum_{a,b} P_a X P_b.$$

`operator_packets()` constructs these blocks, `reconstruct_operator_packets()` sums them, and `dephase()` keeps only the diagonal blocks. Channel packet blocks use the induced operator-space projectors and therefore carry four addresses: output left, output right, input left, and input right.

The built-in amplitude-damping constructor uses

$$K_0 = \begin{pmatrix} 1 & 0 \\ 0 & \sqrt{1-\gamma} \end{pmatrix}, \qquad K_1 = \begin{pmatrix} 0 & \sqrt{\gamma} \\ 0 & 0 \end{pmatrix}, \qquad 0 \le \gamma \le 1.$$

```
import numpy as np

from komorebi_math.quantum import amplitude_damping

channel = amplitude_damping(0.2)
channel.certificate().require()

excited = np.diag([0, 1]).astype(complex)
output = channel.apply_density(excited)
assert np.allclose(np.diag(output), [0.2, 0.8])
```

54.3 Lindblad generators

For a Hermitian Hamiltonian H and finite jump family L_j, `LindbladGenerator` implements

$$\mathcal{L}(X) = -i[H, X] + \sum_j \left(L_j X L_j^* - \frac{1}{2} L_j^* L_j X - \frac{1}{2} X L_j^* L_j \right).$$

`apply()` evaluates the generator directly. `superoperator()` returns its column-vectorized matrix, and `evolve(rho, time)` applies the finite matrix exponential before validating and normalizing the resulting density matrix. This is dense finite evolution. It is not a large sparse solver and it does not control model error in a Markovian approximation.

`trace_preservation_certificate()` checks that the trace derivative vanishes on every matrix unit. `coherence_preservation_certificate(V, n)` checks that the superoperator commutes with conjugation by the declared cyclic symmetry. The latter is a direct finite covariance test. It does not assume charges for the jump operators without checking the resulting superoperator relation.

54.4 Kato transport through moving sectors

`MovingPacketSystem` accepts two callables, one for the projector family $P_j(t)$ and one for $\dot{P}_j(t)$. It checks the packet identities at a reference time and can compare the supplied derivative with a finite difference. Its canonical generator is assembled from the moving projectors.

`KatoTransport(system).evolve(start, stop, steps=n)` numerically integrates the transport equation on a uniform mesh. `direct_rotation_product(times)` instead multiplies the canonical direct rotations between successive packet families. `refinement_certificate()` compares a coarse and refined integration. These certificates test internal numerical agreement. They do not bound every higher derivative of an arbitrary moving family.

This shipped example combines moving transport with the effective operator of Chapter 55:

```
python .\examples\kato_feshbach.py
```

Expected output:

```
Kato and Feshbach example passed
```

54.5 Quantum tower diagnostics and finite compatibility

`BoundedHamiltonianTower` stores a finite sequence of Hermitian matrices on one common Hilbert space. Its adjacent differences are

$$\delta_j = \|H_{j+1} - H_j\|_2,$$

and the finite total variation is $\sum_j \delta_j$. For each adjacent pair, the report also checks the Duhamel perturbation bound

$$\|e^{-itH_{j+1}} - e^{-itH_j}\|_2 \le |t|\, \delta_j.$$

The report leaves infinite tail summability unchecked. A small finite total variation is evidence about the supplied levels only. It is not a certificate that an unrepresented infinite tower converges.

Operationally, the entire quantum domain is checked with:

```
python -m komorebi_math verify quantum
```

For `1.0.0b4`, the expected final line is:

```
verification passed 9/9 checks
```

The nine checks cover seeds and Schmidt orbits, cyclic packets, circuit paths, fixed and moving leakage, channels, Lindblad evolution, finite error correction, Feshbach reduction, Euclidean transfer, spectral diagnostics, constraint closure, and bounded towers.

55. Error correction and effective dynamics

A chosen sector can remain meaningful in two ways. A quantum code demands that a declared error family act indistinguishably on the code space. A Feshbach reduction instead permits coupling to a hidden sector and records its exact energy-dependent feedback.

55.1 Quantum codes and error sets

`QuantumCode(projector, errors)` validates an orthogonal projector P of positive rank and a nonempty finite error family $E_1, \dots, E_r$ on the same Hilbert space. The code dimension is the numerical rank of P.

The constructor does not require the raw error family to be a trace-preserving channel. That condition is checked later when the equal-weight error channel is used. This distinction matters. A family can satisfy the compression criterion but fail to define a physical equal-weight noise model.

`encode_density(logical_state)` chooses an orthonormal eigenbasis for the code projector and embeds a logical density matrix into the ambient space. The choice of basis is deterministic for the numerical eigensolver but is not a canonical symbolic encoding.

55.2 Knill-Laflamme finite checks

The finite Knill-Laflamme criterion is

$$PE_i^* E_j P = \alpha_{ij} P \qquad \text{for every } i, j.$$

`knill_laflamme_report()` computes

$$\alpha_{ij} = \frac{\operatorname{Tr}(PE_i^* E_j P)}{\operatorname{rank} P}$$

and records the spectral norm of every compression obstruction. Its `coefficient_matrix`, `residual_matrix`, `maximum_residual`, and certificate make a failed pair directly inspectable.

When the criterion passes, `recovery_channel()` diagonalizes the Hermitian coefficient matrix, constructs active syndrome isometries, and completes the recovery on the unused syndrome complement. `recovered_channel_certificate()` then forms the equal-weight noise channel and checks recovery on every code matrix unit. If the equal-weight errors do not preserve trace, the returned certificate is invalid and names that missing assumption.

The shipped example uses the two-dimensional repetition subspace

$$\mathcal{C} = \operatorname{span}\{|000\rangle, |111\rangle\}$$

and the identity plus one Pauli X error on each qubit:

```
python .\examples\quantum_channel_qec.py
```

Expected output:

```
quantum channel and error correction example passed
```

This example certifies the declared finite error set. It does not claim correction of arbitrary two-qubit errors, a threshold theorem, or fault tolerance under repeated noisy gates.

55.3 Effective operators and Feshbach reduction

Let a Hermitian Hamiltonian be split into retained and hidden coordinates:

$$H = \begin{pmatrix} H_{PP} & H_{PQ} \\ H_{QP} & H_{QQ} \end{pmatrix}.$$

For a spectral parameter z outside the hidden spectrum, `QuantumFeshbachReduction` implements the self-energy

$$\Sigma(z) = H_{PQ}(zI - H_{QQ})^{-1}H_{QP}$$

and the effective Hamiltonian

$$H_{\text{eff}}(z) = H_{PP} + \Sigma(z).$$

The projected resolvent identity is

$$P(zI - H)^{-1}P = \left(zI - H_{\text{eff}}(z)\right)^{-1}.$$

`resolvent_certificate(z)` checks this identity numerically. For $\operatorname{Im} z > 0$, `upper_half_plane_sign_certificate(z)` checks that the Hermitian imaginary part of $\Sigma(z)$ is nonpositive. A spectral parameter on the hidden spectrum is rejected rather than regularized silently.

Eliminating the hidden sector also produces a finite memory kernel. The `memory_kernel()` method returns the shared dynamics object whose Laplace transform reproduces the self-energy with the package's Schrödinger sign convention. `bare_closure_certificate()` checks whether $H_{PQ} = 0$. If that coupling vanishes, retained dynamics closes without memory. Otherwise, the energy-dependent operator is not interchangeable with the bare block H_{PP}.

55.4 Finite-dimensional scope boundaries

These distinctions should remain explicit in downstream work:

1. A numerical projector certificate is not exact symbolic idempotence.
2. A Knill-Laflamme pass covers the declared finite error span, not an unspecified physical noise environment.
3. A constructed recovery channel is tied to the supplied code basis and finite matrix tolerance.
4. A Feshbach map is exact as a finite block identity away from hidden poles, while this implementation verifies it numerically.
5. A finite Hamiltonian tower does not supply an infinite-volume limit.
6. Euclidean reflection matrices do not by themselves establish continuum reconstruction or locality.

These boundaries are not omissions from the certificate. They are part of its meaning. The quantum APIs provide a controlled finite laboratory in which the packet decomposition, coupling, interference, recovery, and hidden feedback can be inspected without claiming a stronger physical theory.

56. Finite deformation systems

The deformation package represents finite inverse systems directly. A node is an explicit lift candidate, a reduction map specifies compatibility between adjacent depths, a stable core records which nodes survive every represented level, and a branch records one compatible choice through the finite forest. Support and cohomology are computed by their own algebraic models. They are not relabelled as spectral projectors.

The chapter answers several different finite questions. A lift forest asks which candidates remain compatible with later supplied levels. A cochain complex computes cohomology of explicit differentials. A module presentation describes relations and fibers. A trace separator distinguishes candidates using a supplied table. Select the object that represents the question; agreement of counts alone does not identify these constructions with one another.

56.1 Residual forests

`FiniteLiftForest(levels, reductions)` expects levels indexed consecutively from one. The reduction at depth m maps level m to level $m-1$. Every image is validated during construction.

For n at depth d, `reduce()` composes reductions to a shallower level, `children()` returns immediate lifts, and `image(source, target)` returns the finite image set. The stable core at depth d is

$$C_d = \bigcap_{m=d}^{M} \operatorname{im}(X_m \longrightarrow X_d),$$

where M is the deepest supplied level. `branches()` enumerates compatible tuples through level M and enforces a branch-count safety limit. The report checks that full finite branches and nonempty stable cores agree.

`residue_forest(values_by_depth, prime=p)` supplies the common reduction

$$x \bmod p^m \longmapsto x \bmod p^{m-1}.$$

Duplicate residues are normalized within each level. The report is exact for the represented finite levels. It does not assert that a branch continues beyond M.

56.2 Visibility and counting charts

`rational_valuation(x, p)` computes the exact prime valuation of a rational number, with $v_p(0) = \infty$. `VisibilityTree(values, prime=p)` uses the separation depth

$$s(i,j) = v_p(x_i - x_j) + 1$$

to form nested finite partitions. `partition(m)` groups coordinates that are indistinguishable at depth m, and `ultrametric_certificate()` exhaustively checks the nonarchimedean separation inequality on every triple.

The counting helpers implement exact formulas for basic local charts. Above one residual root in a smooth d-dimensional chart,

$$N_m^{\mathrm{smooth}} = q^{d(m-1)}.$$

For $x^e = 0$ at depth m,

$$N_m^{\mathrm{nil}} = q^{m-\lceil m/e \rceil}.$$

For the normal crossing $xy = 0$,

$$N_m^{\mathrm{nc}} = q^m + m(q-1)q^{m-1}.$$

`weighted_chart_count()` delays visibility coordinate by coordinate, and `diagonal_nilpotent_count()` multiplies independent nilpotent counts. The corresponding `RationalCountingSeries` objects generate exact `Fraction` coefficients through their denominator recurrences. These formulas describe the implemented basic charts. They are not a general singularity classifier.

56.3 Finite cohomology complexes

`FiniteCochainComplex` stores a bounded cochain complex over $\mathbb{F}_p$:

$$\cdots \longrightarrow C^{i-1} \xrightarrow{d^{i-1}} C^i \xrightarrow{d^i} C^{i+1} \longrightarrow \cdots, \qquad d^i d^{i-1} = 0.$$

All entries are integral and reduced modulo the prime. Matrix shapes and the successive-zero identities are checked exactly at construction. `row_rank_mod` uses modular row reduction, and `cohomology(i)` returns

$$\dim H^i = \dim C^i - \operatorname{rank} d^i - \operatorname{rank} d^{i-1}.$$

`packet_cohomology(projectors)` accepts a complete orthogonal idempotent family in every degree. It requires the same packet order at every degree and checks that the projectors commute with the differentials. The result is the exact dimension data for each packet and degree.

This is genuine finite cohomology over a prime field. It does not infer a deformation ring, obstruction theory, or inverse-limit cohomology that was not supplied.

56.4 Support and Fitting-fiber diagnostics

`PresentedModule` uses a matrix with one row per module generator and one column per relation. Its cokernel is the represented finite module. Symbolic presentation and Fitting operations require the optional SymPy backend.

For a module with g generators, `fitting_generators(k)` returns the distinct $(g-k)$-minors. `fiber(point, prime=None)` evaluates the presentation and computes the exact characteristic-zero rank. With `prime=p`, rational entries are reduced into $\mathbb{F}_p$ when every denominator is a unit. The fiber dimension is

$$\dim M_x = g - \operatorname{rank} A(x).$$

The certificate checks that positive fiber dimension agrees with vanishing of the zeroth Fitting generators at the point. `finite_support()` repeats this calculation over an explicit finite point set.

`nested_subspace_occupancy()` addresses a different question. Given numerical column-space bases, it computes successive intersections using principal angles and returns the dimension sequence, final intersection dimension, and first observed stabilization index. This certificate is numerical. An equal dimension at one step does not prove stabilization for an unrepresented infinite family.

56.5 Frobenius companion systems

`FrobeniusSpine` stores monic polynomials of one common degree at finitely many places. `agrees(other)` compares two spines on their common or selected places. `CompanionForest` couples such a spine to a prime and a finite lift forest.

The trace separator solves a finite identifiability problem. Suppose the row at place v contains traces $t_{v1}, \dots, t_{vr}$ of candidate constituents. `finite_frobenius_separator()` greedily retains rows that increase the exact column rank. If the selected trace matrix T has rank r, then `recover(observed_traces)` solves

$$T\,m = b$$

for the unique multiplicity vector m. Rational data use exact `Fraction` elimination. Nonrational exact data use the optional SymPy backend. The certificate leaves Chebotarev density beyond the supplied table unchecked.

`CompatibleCarrier` adds named capacity bounds. `select(multiplicities)` returns a constituent dictionary only when every recovered multiplicity is nonnegative and no larger than its declared capacity.

56.6 Worked deformation replay and CLI contract

The shipped support example is:

```
import numpy as np

from komorebi_math.deformation import (
    nested_subspace_occupancy,
    normal_crossing_count,
    residue_forest,
)

forest = residue_forest(
    {
        1: (0, 1),
        2: (0, 1, 2, 3),
        3: (0, 1, 4, 5),
    },
    prime=2,
)
report = forest.report()
report.certificate.require()

occupancy = nested_subspace_occupancy(
    (
        np.eye(3),
        np.array([[1, 0], [0, 1], [0, 0]], dtype=float),
        np.array([[1], [0], [0]], dtype=float),
    )
)
occupancy.certificate.require()

print(tuple(len(level) for level in report.levels))
print(tuple(len(core) for core in report.stable_cores))
print(len(report.branches))
print(occupancy.intersection_dimension)
print(normal_crossing_count(3, 2))
```

Observed output:

```
(2, 4, 4)
(2, 2, 4)
4
1
21
```

The finite Frobenius example prints separating places `(2, 3)`, recovered multiplicities `(3, 2)`, and the selected carrier `{'rho1': 3, 'rho2': 2}`.

Run the installed domain verifier with:

```
python -m komorebi_math verify deformation
```

Expected final line:

```
verification passed 4/4 checks
```

The CLI counting entry point is `komorebi deformation count`. It reports only the implemented finite chart formulas and should not be described as a general deformation-ring point counter.

57. Local finite Langlands packets

The local package provides small exact and numerical models for finite field arithmetic, tame Frobenius orbits, Weil relation matrices, Gauss phases, Heisenberg representations, symplectic commutator envelopes, and finite packet bridges. These objects are computational components and diagnostics. They do not implement the local Langlands correspondence.

For the arithmetic examples, keep the field modulus and polynomial-basis convention with every encoded element. An integer code is a representation of an element in that chosen field, not a field-independent value. For the representation examples, also retain the ordered group labels and character data. Those declarations determine which finite matrix relation a certificate is checking.

57.1 Finite fields and Frobenius orbits

`FiniteField(p, degree=n, modulus=f)` represents

$$\mathbb{F}_{p^n} \cong \mathbb{F}_p[x]/(f(x))$$

in the supplied polynomial basis. Coefficients of `modulus` are listed from constant to leading term. The modulus must be monic, have degree n, and pass the package's exact irreducibility test. Extension fields require an explicit modulus.

Elements have canonical integer codes whose base-p digits are the polynomial coefficients. Addition, multiplication, powers, inversion, field trace, norm, primitive-element search, and discrete logarithms are exact finite operations. They enumerate small fields and are not optimized for cryptographic sizes. Zero has no inverse or discrete logarithm and is rejected where appropriate.

`FrobeniusOrbit(q, degree=n, exponent=a)` acts on tame character exponents modulo $q^n - 1$:

$$a \longmapsto qa \pmod{q^n - 1}.$$

The packet is regular when its orbit length equals n. The object also reports the dual exponent and whether the dual lies in the same orbit. `regular_orbit_count(q, n)` uses a Mobius inversion count for full orbits.

57.2 Tame packets and Gauss data

For a regular orbit $(a_0, \dots, a_{n-1})$, `TameWeilPacket` forms a diagonal inertia matrix and a cyclic Frobenius matrix. The certificate checks the tame relation

$$FIF^{-1} = I^q.$$

The orbit is exact integer data, while the relation certificate is numerical because the inertia eigenvalues are complex roots of unity. The Frobenius determinant orientation is

$$\det F = (-1)^{n-1}c,$$

where c is the supplied closing scalar.

`tame_tensor_refinement(m, n)` reports the finite decomposition governed by $\gcd(m, n)$ and $\operatorname{lcm}(m, n)$. `SpecialMonodromyBlock` supplies the finite nilpotent Jordan chain and its compatible Frobenius scaling diagnostic.

For an explicit `FiniteField`, `additive_character()`, `multiplicative_character()`, and `gauss_sum()` compute finite character sums. The returned `GaussSumResult` contains the complex value, magnitude, normalized phase, and a numerical certificate. A magnitude check is a finite character sum identity at the chosen floating tolerance, not an analytic continuation statement.

57.3 Finite Heisenberg models

`HeisenbergModel(prime=p, rank=r)` uses the finite phase space $\mathbb{F}_p^r \times \mathbb{F}_p^r \times \mathbb{F}_p$ and a Schrödinger representation on a space of dimension p^r. The constructor enforces a maximum representation dimension, which defaults to 4096.

In the package convention, coordinates multiply by

$$(x, \xi, z)(y, \eta, w) = (x + y, \xi + \eta, z + w - \eta \cdot x).$$

Translation and modulation matrices satisfy this law up to the declared root of unity phase. `group_law_certificate()` verifies the matrix identity for a chosen pair. `trace_support_certificate()` exhaustively checks that the representation trace vanishes away from the center.

The standard translation selector is the subgroup average

$$P = \frac{1}{p^r} \sum_{x \in \mathbb{F}_p^r} T_x.$$

`selector_certificate()` checks self-adjointness, idempotence, and rank one. This is a concrete finite isotropic selector. It is not a general classification of all Heisenberg representations.

57.4 Symplectic packets and finite diagnostics

`AlternatingForm(matrix, prime=p)` validates an exact alternating matrix over $\mathbb{F}_p$. It reports rank, radical dimension, nondegeneracy, a radical basis, and exact evaluations. In characteristic two, `QuadraticRefinement` stores a finite quadratic function q whose polar form is the declared alternating form:

$$q(x + y) - q(x) - q(y) = B(x, y).$$

The polar certificate exhausts all binary vectors up to the configured dimension limit. For a nondegenerate even-dimensional form, the object returns the integral Gauss sum, Arf invariant, and normalized Gauss sign.

`ProjectiveIntertwinerEnvelope` starts from labelled invertible complex operators. It evaluates their commutators, tests whether each commutator is a scalar p-th root of unity, and recovers the associated alternating form. Because scalar phase recognition is numerical, `EnvelopeRecovery` carries residuals for every basis pair.

`SymplecticBridge.construct()` checks an exact prime-field isometry between two forms. `LocalPacketBridge` wraps a finite transport graph and exposes its fundamental-cycle holonomy certificate. Neither object supplies missing local representation data. They validate a declared comparison.

57.5 Worked local packet replay

The shipped local example is:

```
import numpy as np

from komorebi_math.langlands.local import (
    FrobeniusOrbit,
    HeisenbergModel,
    TameWeilPacket,
)

orbit = FrobeniusOrbit(q=2, degree=3, exponent=1)
orbit.certificate().require()

tame = TameWeilPacket(orbit)
tame.relation_certificate().require()

heisenberg = HeisenbergModel(prime=3, rank=1)
left = heisenberg.element((1,), (2,), 1)
```

```
right = heisenberg.element((2,), (1,), 2)
heisenberg.group_law_certificate(left, right).require()
heisenberg.selector_certificate().require()

print(orbit.elements)
print(tame.dimension)
print(complex(np.linalg.det(tame.frobenius_matrix())))
print(heisenberg.dimension)
print(int(np.linalg.matrix_rank(heisenberg.translation_selector())))
```

Observed output:

```
(1, 2, 4)
3
(1+0j)
3
1
```

The corresponding CLI commands are `komorebi langlands tame-orbit` and `komorebi langlands heisenberg`. They expose these finite diagnostics. They do not claim to attach automorphic representations.

58. Finite-image, ramification, and completion models

The final chapter of Part IX assembles the finite local pieces into explicit group models and conditional global records. The finite-image calculations can be exact or numerically certified. Ramification and automorphic completion remain conditional whenever required phase choices, descent theorems, support comparisons, or realization results are external.

58.1 Finite groups, characters, and orbits

`FiniteGroup` validates an explicit element set, multiplication law, identity, closure, inverses, and, below the configured size limit, associativity. The constructors `cyclic_group(n)` and `symmetric_group(n)` provide common examples. `FiniteSubgroup` validates closure inside one specific parent group object and supports normality, intersection, and conjugation.

`LinearCharacter` requires one complex value on every subgroup element and checks multiplicativity. `InducedRepresentation(G, chi)` chooses deterministic left-coset representatives and constructs the monomial matrices of $\mathrm{Ind}_H^G \chi$. The representation certificate exhaustively checks the matrix law. The group and coset logic is exact, while the complex matrix residual is numerical.

`MonomialAction` decomposes symmetric, exterior, and tensor bases into finite orbits. Every `OrbitPacket` stores a representative, its orbit, its stabilizer, and stabilizer character values. `packet_certificate()` checks dimension conservation. The routines enumerate basis states, so degree and representation dimension should remain modest.

58.2 Mackey and Clifford towers

`mackey_tensor_packets()` uses deterministic double-coset representatives to construct the finite packets for a tensor product of two induced characters. For each representative g, it records

$$H \cap gKg^{-1}$$

and the pulled-back product character. Its exact certificate checks that the sum of induced packet dimensions equals $[G : H][G : K]$.

A `CliffordStep` represents a prime-cyclic quotient. An induction step `I` requires the parent representation degree to be the prime index times the child degree. An extension step `E` keeps the degree unchanged. A higher-rank extension step is a nonabelian descent gate.

`CliffordTower` checks that group orders and degrees form a chain. Its word is the sequence of `I` and `E` letters, and its depth is the number of higher-rank extension gates. The finite report is exact for the declared order and degree data. `automorphic_plan()` is conditional. It records unresolved attached descent assumptions instead of converting an `E` step into an automorphic conclusion.

```
from komorebi_math.langlands.finite_image import (
    CliffordStep,
    CliffordTower,
)

tower = CliffordTower(
    (
        CliffordStep(24, 12, 3, 3, "E"),
        CliffordStep(12, 4, 3, 1, "I"),
        CliffordStep(4, 2, 1, 1, "E"),
```

```
    )
)

report = tower.report()
report.certificate.require()
assert report.word == "EIE"
assert report.depth == 1
assert report.unresolved_extension_steps == (0,)
```

`AutomorphicInductionPlan` and `VirtualCharacterResolution` are symbolic planning objects. The former lists class-field and automorphic-induction steps with external hypotheses. The latter can expose negative virtual terms and render a formal product of labelled L-functions. A formal expression is not a positivity or holomorphy proof.

58.3 Ramification towers

`ProjectiveMultiplicityPacket` stores a prime, quotient rank, alternating commutator form, and optional phase information. Its radical dimension and symplectic rank are exact. The irreducible Heisenberg dimension of the nondegenerate quotient is

$$p^{\operatorname{rank}(B)/2}.$$

At $p = 2$, a matching `QuadraticRefinement` can supply the Arf invariant and Gauss sign. If neither a phase label nor an appropriate dyadic refinement is present, the phase remains unresolved.

A `RamificationStage` records a nonnegative break number, parent and child orders, orbit size, and multiplicity dimension. It enforces

$$\text{orbit size} = \frac{\text{parent order}}{\text{child order}}, \qquad \text{reconstructed dimension} = \text{orbit size} \times \text{multiplicity dimension}.$$

`RamificationCliffordTower` requires strictly increasing breaks and a chained order sequence. Its report is conditional and names unresolved phase stages. `tensor_packet()` combines two aligned towers stage by stage. The direct-sum commutator form is finite data, while multiplicativity of phase normalization remains an explicit condition.

58.4 Dyadic and Hecke packets

`FiniteHeckePackets` validates a complete orthogonal family of finite projectors. When commuting operators are supplied, every projector must commute with them. `packets()` reports numerical ranks, and `occupied()` tests whether a packet meets either the full carrier or a supplied subcarrier.

The term *Hecke packet* here means a finite central-idempotent model on the declared carrier. It is not an automatic construction of a global Hecke eigensystem.

At coefficient prime two, rational sign projectors do not remain distinct integral idempotents. `dyadic_sign_diagnostic()` records the finite replacement in $\mathbb{F}_2[C_2]$: if $X = g - 1$, then

$$X^2 = 0.$$

The returned certificate is exact for this residual group algebra. It does not assert that every dyadic global sign problem is resolved by the same local coordinate.

58.5 Patching plans

`SupportComparison.construct()` compares finite component labels and reports which required source components are missing from a declared image. `PatchingSupportReport` then exposes five support conditions:

1. A patched object exists.
2. It has full support.
3. Support descends to finite level.
4. The comparison preserves required support.
5. A characteristic-zero fiber is nonzero.

The report is complete only when all five Boolean inputs are true. Its certificate remains conditional because these values are supplied results, not the output of a general patching theorem implemented by the package.

58.6 Five formal completion gates

`AutomorphicCompletionReport` uses the canonical gate order

$$\text{residual} \longrightarrow \text{patching} \longrightarrow \text{comparison} \longrightarrow \text{fiber} \longrightarrow \text{realization}.$$

Every gate requires a `GateStatus(satisfied, detail, external=True)`. Missing gate keys are rejected. `complete` is true only if all five statuses are true, `unmet_gates` preserves canonical order, and `external_gates` records which claims depend on imported arithmetic results.

`result()` returns a `ConditionalResult[bool]`. A false value is not a proof that automorphy fails. It means the supplied record does not close every gate. A true value means every declared gate has been supplied, while the certificate still identifies the argument as conditional.

When preparing a completion record, use each gate's detail to identify the specific supporting result and the hypotheses under which it applies. Keep unmet gates explicit. This makes the record useful for review: it distinguishes a missing premise from a failed finite computation and avoids treating five true flags as a substitute for the external arguments they summarize.

`CompatiblePropagationReport` similarly requires a common Frobenius spine, semisimplicity, one automorphic member, and local-global compatibility. It records a one-member propagation argument only after all four assumptions are present.

58.7 Conditional global scope

The package draws a hard line between finite computation and global arithmetic conclusion:

- Finite group laws, residue ranks, orbit counts, and prime-field alternating forms use exact finite arithmetic.
- Complex representation, projector, and phase relations are numerically certified.
- Automorphic induction, attached descent, patching support, compatible propagation, and realization remain conditional when they use external theorems.
- No finite gate record is described as a proof of the local or global Langlands correspondence.

This separation allows a long argument to be represented without erasing its open hypotheses. Downstream code should carry the certificate, especially its `assumptions_unchecked`, with any claimed conclusion.

58.8 End-to-end finite replay

The finite-image example constructs an induced representation of C_4, decomposes its third symmetric power, and inspects an `EIE` Clifford word. Observed output is:

```
{'induced_dimension': 2,
 'symmetric_packet_dimensions': (2, 2),
 'clifford_word': 'EIE',
 'clifford_depth': 1,
 'unresolved_extension_steps': (0,)}
```

The ramification example constructs a dyadic projective packet and leaves the realization gate unmet. Observed output is:

```
{'ramification_breaks': (0, 1),
 'ramification_dimensions': (4, 2),
 'arf_invariant': 0,
 'completion_ready': False,
 'unmet_gates': ('realization',)}
```

Run them with:

```
python .\examples\finite_image_clifford.py
python .\examples\ramification_completion.py
```

The installed domain verifier is:

```
python -m komorebi_math verify langlands
```

For `1.0.0b4`, the expected final line is:

```
verification passed 12/12 checks
```

The twelve checks cover finite fields and Gauss phases, tame packets, Heisenberg selectors, dyadic refinements, projective envelopes, induced and Mackey packets, Clifford depth, finite Hecke packets, support diagnostics, ramification packets, and the five-gate completion record.

58.9 Chapter boundary

Part IX supplies an executable finite bridge from operator packets to residual support and arithmetic representation data. It does not collapse those objects into one type. A quantum symmetry projector, a deformation support component, and a finite Hecke idempotent can interact through explicit maps, but they retain different semantics and different certificate requirements.

The practical rule is simple: exact finite data may be transported exactly, floating matrix relations must retain their tolerances, and imported global theorems must remain visible as conditional gates. The next part turns these typed results into documents, portable records, extensions, and command-line workflows.

Part X. Export, persistence, extension, and command-line use

Part X moves verified mathematical objects across three boundaries. The document layer turns typed values into renderer-neutral reports. The export layer writes those reports and ordinary data to controlled filesystem targets. The persistence layer reconstructs registered objects from a strict, versioned, digest-checked envelope. Provenance records and extensions add discoverability without silently changing the stable core, while the command line exposes the same finite operations to scripts.

These layers are related but not interchangeable. Presentation serialization is intended for readable JSON, tables, and reports. Portable persistence is a reconstruction contract. A rendered equation is not automatically a portable object, and a portable payload is not automatically a polished document. Keeping those roles separate is the main design rule for this part.

Choose the output by what the recipient needs to do with it.

Intended use	Read	Preserve with the output
Read a mathematical report	Chapters 59 and 60	values, equations, certificate explanation, and any figure files
Load supported typed objects again	Chapter 61	the portable envelope and the package or extension codec identity
Inspect the origin of a claim	Chapter 62	the provenance record and its assumptions
Automate a command	Chapter 63 and Appendix F	the exact invocation, exit status, and documented output fields
Share several rendered formats	Sections 60.5 and 70.3	the archive and its manifest

For a first export, start from a small result you already understand. Render it, open the resulting document, and check that the values and certificate are readable. If you also need to resume computation, save a supported portable object separately and test loading it. The report and the reusable state serve different readers and can use different formats.

59. Mathematical document model

The document model is a small typed intermediate representation. A document is an immutable metadata record paired with an ordered, mutable construction buffer of validated blocks:

$$\mathcal{D} = \mathcal{M} \times \mathcal{B}^*.$$

Renderers consume this structure without mutating it. That gives one report a common semantic source even when its Markdown, HTML, text, and LaTeX bytes are different.

59.1 Metadata and block grammar

`DocumentMetadata` stores `title`, `author`, `date`, `abstract`, and a tuple of `keywords`. The title defaults to `Komorebi Math Export` and must contain at least one non-whitespace character. The other fields are optional presentation strings. Metadata is frozen, so a report that needs a different title receives a new metadata value rather than an in-place mutation.

The public block sum type is:

$$\begin{aligned}\mathcal{B} = \mathsf{Heading} \sqcup \mathsf{Paragraph} \sqcup \mathsf{Equation} \sqcup \mathsf{Table} \\ \sqcup \mathsf{CodeBlock} \sqcup \mathsf{ListBlock} \sqcup \mathsf{Figure} \sqcup \mathsf{RawLatex}.\end{aligned}$$

Each constructor owns its local invariant. A `Heading` has nonempty text and a level from 1 through 6. An `Equation` has nonempty LaTeX source and may carry a label, numbering flag, and prose description. A `Table` has at least one column, every row matches the header width, and an optional alignment tuple contains one of `l`, `c`, or `r` for each column. A `ListBlock` is nonempty. A `Figure` normalizes its path and rejects an empty LaTeX width. Paragraph and code contents may be empty because the renderer can represent deliberate spacing or an empty literal block.

`RawLatex` is the deliberate exception to renderer neutrality. It is trusted source for the LaTeX renderer, not a portable mathematical meaning. Use it only when a report truly needs a LaTeX construct that the typed blocks cannot express.

59.2 Fluent `MathDocument` construction

`MathDocument` contains metadata and an ordered `blocks` list. Its `add`, `section`, `paragraph`, `equation`, `table`, `code`, `bullet_list`, and `figure` methods append blocks and return the same document. The blocks themselves are frozen records even though the list is a construction buffer.

```
from fractions import Fraction

from komorebi_math.export import (
    DocumentMetadata,
    MathDocument,
    render_markdown,
)

document = MathDocument(
    DocumentMetadata(
        title="Exact coordinate report",
        author="Komorebi Math",
        keywords=("exact arithmetic", "coordinates"),
    )
)
document.paragraph("The table records exact rational values.")
document.section("Values")
document.equation(r"a_n=\frac{1}{n+1}", numbered=True, label="eq:values")
document.table(
```

```
    ("n", "a_n"),
    tuple((n, Fraction(1, n + 1)) for n in range(4)),
    caption="Four exact values",
)
document.code("assert a_0 == 1", language="python")
document.bullet_list(("typed blocks", "ordered construction"))

markdown = render_markdown(document)
assert len(document.blocks) == 6
assert markdown.startswith("# Exact coordinate report")
print(len(document.blocks), markdown.splitlines()[0])
```

Observed output:

```
6 # Exact coordinate report
```

The same `document` can be sent to every renderer. Rendering must not reorder or replace its blocks. Equality here is semantic: the HTML and LaTeX outputs present the same block sequence, but escaping, markup, styling, and whitespace make byte equality neither expected nor desirable.

59.3 Tables, figures, and renderer boundaries

`Table.from_rows()` converts ordinary header and row sequences into tuples and then applies the same rectangularity checks as the direct constructor. Values inside table cells remain typed until a renderer chooses their presentation. This is why an exact `Fraction(1, 2)` can remain recognizable to JSON export while a text renderer prints a human-readable value.

Figures are path references at construction time. Markdown, HTML, LaTeX, and PDF export localize each figure beside the target document under a deterministic name such as `report_asset_001.png`. The document model does not read the image or prove that the path exists. That filesystem check belongs to the writer.

59.4 Report builders

Three builders cover common conversions:

- `document_from_data(value, ...)` creates a general report from a supported scalar, mapping, table-like object, dataclass, result, or existing document.
- `sequence_document(values, ...)` presents an indexed finite sequence.
- `certificate_document(certificate, ...)` expands certificate fields into a report that keeps validity, exactness, diagnostics, assumptions, and limitations visible.

If `document_from_data` receives an existing `MathDocument`, the writer uses that document rather than wrapping it in a second report. For ordinary data it passes through the presentation serializer and table-shape logic. This route is intentionally more permissive than portable persistence: it produces a report, not authority to reconstruct an arbitrary Python class.

```
from komorebi_math import Certificate, Exactness
from komorebi_math.export import certificate_document, render_text

certificate = Certificate(
    True,
    Exactness.NUMERICAL,
    tolerance=1e-10,
    residuals={"reconstruction": 2e-13},
    assumptions_checked=("finite matrix dimensions",),
)
report = certificate_document(certificate, title="Numerical certificate")
text = render_text(report)
assert "reconstruction" in text
assert "1e-10" in text
print(report.metadata.title, len(report.blocks))
```

The model rejects structural errors early, but it does not certify the mathematical truth of prose or raw equations. Evidence remains the responsibility of the object and certificate used to build the report.

60. Renderers and writers

The export package separates pure renderers from filesystem writers. A renderer maps a document and renderer options to text. A writer resolves a format, enforces destination policy, localizes assets, writes bytes, and returns an `ExportResult` or `ExportBundleResult` with a certificate.

60.1 Text, Markdown, HTML, and LaTeX

`render_text`, `render_markdown`, `render_html`, and `render_latex` cover every typed document block. Text is a low-markup human view. Markdown uses headings, tables, fenced code, lists, display math, and ordinary image references. HTML escapes prose and can include a MathJax loader. LaTeX escapes presentation text, preserves equation source, chooses `tabular` or `longtable`, and emits a complete compilable document.

`HtmlRenderOptions` contains `include_mathjax` and an optional standalone `title`. `LatexRenderOptions` contains the document class, class options, package tuple, table-of-contents flag, section-numbering flag, and geometry. The class and option strings are validated before they can enter the preamble. `latex_escape()` protects ordinary text characters such as `_`, `&`, and `%`, while `latex_label()` normalizes label material. Equation source and `RawLatex` remain trusted LaTeX and are not escaped as prose.

60.2 Eleven on-disk formats

`ExportFormat` defines the supported universe:

Format	Typical suffix	Writer behavior
JSON	`.json`	sorted-key presentation data with finite JSON values
YAML	`.yaml`, `.yml`	safe PyYAML dump. Optional dependency
CSV	`.csv`	rectangular table with comma delimiter
TSV	`.tsv`	rectangular table with tab delimiter
text	`.txt`	renderer-neutral document converted to plain text
Markdown	`.md`, `.markdown`	Markdown report with localized figures
HTML	`.html`, `.htm`	standalone HTML report with localized figures
LaTeX	`.tex`	complete LaTeX source with localized figures
PDF	`.pdf`	generated LaTeX compiled by a local engine
NPY	`.npy`	one NumPy array with `allow_pickle=False`
NPZ	`.npz`	compressed named arrays with pickle disabled

`infer_export_format()` uses the target suffix. Explicit names accept the aliases `md`, `tex`, `txt`, and `yml`. An unknown or absent suffix raises `ValidationError` unless the caller supplies a format.

`ExportOptions` centralizes title, author, date, abstract, overwrite policy, parent creation, type preservation, JSON indentation, certificate inclusion, generated-TeX retention, and HTML, LaTeX, and compiler options. The default is conservative about replacement: an existing output is rejected unless `overwrite=True`.

60.3 Results and path safety

`export_data()` writes one value. `export_document()` is the explicit document route. `export_many()` writes one value under several suffixes, and `export_bundle()` creates a ZIP containing a selected multi-format family. Each single-file result records the absolute path, resolved format, byte count, companion files, and certificate. `result.require()` first requires the certificate and then returns the primary path.

Text and binary writers stage bytes in the destination directory and replace the target after the staged write completes. Parent directories are created by default. `create_parents=False` converts a missing parent into a validation failure. These helpers provide controlled local replacement, not a distributed transaction or a guarantee against every operating-system failure.

Figure localization checks that the source is a regular file. A conflicting localized asset is rejected unless overwrite is enabled. If the existing asset already has exactly the same bytes, it can be reused safely.

```
from pathlib import Path
from tempfile import TemporaryDirectory
from zipfile import ZipFile

from komorebi_math.export import ExportOptions, export_bundle, export_many

value = tuple({"n": n, "square": n * n} for n in range(5))
with TemporaryDirectory() as temporary:
    root = Path(temporary)
    options = ExportOptions(overwrite=True, title="Square table")
    results = export_many(
        value,
        root / "many",
        base_name="squares",
        formats=("json", "csv", "markdown", "latex"),
        options=options,
    )
    assert all(result.valid for result in results)

    bundle = export_bundle(
        value,
        root / "squares.zip",
        base_name="squares",
        formats=("json", "markdown", "latex"),
        options=options,
    )
    bundle.certificate.require()
    with ZipFile(bundle.path) as archive:
        assert "MANIFEST.sha256" in archive.namelist()
    print(tuple(result.format.value for result in results))
    print(bundle.valid, len(bundle.members))
```

Observed output:

```
('json', 'csv', 'markdown', 'latex')
True 4
```

The member count includes the internal `MANIFEST.sha256` record.

60.4 Local LaTeX compilation

PDF export renders a `.tex` companion and invokes a local compiler. The supported engines are `auto`, `pdflatex`, `xelatex`, `lualatex`, and `latexmk`. `available_latex_engines()` reports executable availability, while `resolve_latex_engine()` selects the first supported installed engine for `auto` or rejects a missing requested engine.

`LatexCompileOptions` controls engine, positive pass count, finite positive timeout, auxiliary retention, optional job name, and `shell_escape`. Shell escape is disabled by default. The direct engines receive `-no-shell-escape`. The `latexmk` route uses the corresponding safe compiler configuration. The result records source, PDF, log, engine, command,

return code, elapsed time, and a certificate. A successful process code is not enough: the expected PDF must also exist and be nonempty.

PDF export keeps the generated `.tex` file by default and always records the compiler log as a companion. Set `keep_tex=False` only when the source was not already present and the caller does not need it. Compilation is a local tool contract. Missing engines raise `BackendUnavailableError` rather than silently pretending that a PDF was produced.

60.5 Manifested bundles and their limit

`export_bundle()` writes the requested formats in a temporary directory, computes SHA-256 lines for the staged members, inserts `MANIFEST.sha256` into the ZIP, and writes the same manifest beside the archive as `<archive>.manifest`. Archive member names are derived from the validated base name and supported suffixes.

The bundle certificate establishes that the primary archive was written and is nonempty under the writer's local checks. It is not a cryptographic proof that a future extraction still matches the manifest. A release or handoff workflow should reopen the ZIP, reject unsafe or duplicate paths, verify its CRC, and replay each digest. This manual's own delivery bundle performs that stronger replay separately.

61. Portable persistence

Portable persistence is the strict reconstruction layer. It accepts only finite JSON primitives, explicit structural tags, and registered Komorebi Math codecs. It never imports a class named by untrusted payload data.

61.1 Portable values, codecs, and migrations

The portable grammar begins with `None`, booleans, integers, finite floats, strings, and lists. Tagged values have exactly three fields:

$$\{\texttt{__komorebi_type__} : t, \texttt{__version__} : n, \texttt{data} : v\}.$$

Built-in structural tags cover `Fraction`, complex numbers, paths, bytes, tuples, sets, frozen sets, mappings, and NumPy arrays. Sets and mapping entries are ordered by canonical encoded JSON so that logically equal values have a deterministic digest. NumPy arrays record dtype, shape, and flattened data and are reconstructed without pickle.

`PortableCodec` binds a stable tag and positive version to one Python type, encoder, and decoder. `register_portable_codec()` rejects duplicate types or tags unless explicit replacement is requested. `PortableMigration` advances exactly one version, from n to $n + 1$. Loads run every registered adjacent step until the active codec version is reached. A missing edge is a hard failure, not permission to guess at an older schema.

61.2 Canonical envelope and digest

`dumps_portable()` wraps the encoded payload in exactly five fields:

```
schema, schema_version, producer_version, payload_sha256, payload
```

The schema is `komorebi-math.portable` and the envelope schema version is 1. The payload digest is

$$d(x) = \mathrm{SHA256}\left(\mathrm{UTF8}(\mathrm{CanonicalJSON}(E(x)))\right),$$

where canonical JSON uses sorted keys, compact separators, UTF-8, and rejects NaN and infinity. The pretty-print indentation of the outer envelope does not change the payload digest. `portable_digest(value)` computes the same digest directly from the registered encoding.

`loads_portable()` rejects invalid UTF-8 JSON, duplicate object keys, nonstandard nonfinite constants, missing or additional envelope fields, an unknown schema, an unsupported schema version, and a digest mismatch before it attempts reconstruction.

```python
import json
from fractions import Fraction

import numpy as np

from komorebi_math.exceptions import ValidationError
from komorebi_math.export import dumps_portable, loads_portable, portable_digest

state = {
    "weights": (Fraction(1, 3), Fraction(2, 3)),
    "matrix": np.arange(6).reshape(2, 3),
}
encoded = dumps_portable(state)
restored = loads_portable(encoded)
assert restored["weights"] == state["weights"]
```

```
assert np.array_equal(restored["matrix"], state["matrix"])

envelope = json.loads(encoded)
envelope["payload_sha256"] = "0" * 64
try:
    loads_portable(json.dumps(envelope))
except ValidationError:
    tamper_status = "rejected"
else:
    raise AssertionError("tampered payload was accepted")

print(portable_digest(restored))
print(tamper_status)
```

The digest printed by this example is deterministic for the same package codec contract and value. It should be compared as data, not hard-coded across an intentional schema or codec-version change.

61.3 Decode and resource guards

Decoding validates every structural tag. Fractions require exactly a numerator and denominator and reject zero denominators. Byte strings require valid base64. Sets reject unhashable members. Mappings reject malformed pairs, unhashable keys, and duplicates after reconstruction. NumPy shapes must contain nonnegative dimensions, the flattened data length must equal the declared shape product, and the values must convert to the declared dtype.

Unknown codec tags, future versions, missing migrations, decoder failures, and nonfinite floating or complex components are rejected. The default maximum serialization and deserialization depth is 128. Callers may choose a smaller positive limit for externally supplied material.

These checks make the decoder closed over the active codec registry. They do not make arbitrary data trustworthy, private, or authenticated. SHA-256 detects accidental or adversarial payload modification when the expected digest remains part of the untampered envelope. It is not a keyed signature.

61.4 Atomic save and load

`save_portable()` serializes first, writes a temporary sibling, flushes and `fsync`s the file, and then uses `os.replace` to install the destination. An existing path is rejected unless `overwrite=True`. If failure occurs before replacement, the temporary file is removed and the original destination is left in place. `load_portable()` reads bytes and delegates all schema, digest, depth, and codec checks to `loads_portable()`.

```
from fractions import Fraction
from pathlib import Path
from tempfile import TemporaryDirectory

from komorebi_math.export import load_portable, save_portable

with TemporaryDirectory() as temporary:
    path = Path(temporary) / "state.km.json"
    value = (Fraction(5, 8), {"levels": (2, 4, 8)})
    save_portable(value, path)
    assert load_portable(path) == value
    save_portable(value, path, overwrite=True)
    print(path.name, path.stat().st_size > 0)
```

61.5 Frozen package codec contract

The live registry is dynamic because extensions can add codecs. The release contract separately freezes the package-owned inventory. For `1.0.0b4` it contains 51 Komorebi Math codec entries in deterministic tag order and one registered migration. `nonlinear.packet_jet_snapshot` is at version 2 with the adjacent migration from version 1.

`compare_portable_codec_contract()` reports added and removed tags, changed implementation types, decreased or increased versions, and missing adjacent migrations. Added codecs are compatible. Removed tags, changed types, version decreases, and incomplete migration chains invalidate the certificate.

An extension codec is not silently added to the stable package contract. An extension that promises long-term reconstruction needs its own frozen identity, versioning policy, migration tests, and compatibility record.

62. Provenance, registries, and extensions

The provenance and registry modules answer different questions. Provenance describes the claim attached to a public object. The feature registry describes the implementation status of a mathematical domain. The extension API lets an installed distribution contribute behavior through a standard Python entry point. None of these records substitutes for a mathematical certificate.

62.1 Mathematical provenance

`ClaimStatus` is a claim-kind alphabet:

```
definition, proved, classical input, conditional theorem,
finite certificate, heuristic, conjecture, planned
```

It is not a scalar confidence ordering. In particular, `finite certificate` does not imply a proved global theorem, and `classical input` identifies dependency on established material rather than a lower numerical score.

`ProvenanceRecord` stores an immutable identifier, title, status, source, assumptions, limitations, and optional verification-suite name. The `documented()` decorator attaches a record to a function or class and registers its qualified name. `register_record()` supports explicit records, while `describe()` accepts an object or qualified name and returns a record or `None`. `records()` returns a copy of the registry.

```
import komorebi_math as km

record = km.describe(km.PacketSystem)
assert record is not None
assert record.identifier == "PSC-I-T20"
assert record.status.value == "proved"
print(record.identifier, record.verification_suite)
```

Observed output:

```
PSC-I-T20 core.packets
```

62.2 Feature registry

`FeatureStatus` contains `implemented`, `partial`, `experimental`, `planned`, and `external theorem required`. `FeatureSpec` records a unique key, module, title, status, summary, papers, dependencies, and public object names. `FeatureRegistry.register()` rejects an existing key unless `replace=True`. `all()` returns features in sorted key order, and `by_status()` filters by enum identity.

The package-level `FEATURES` registry backs `register_feature()`, `feature()`, and `features()`. A domain marked implemented means its declared finite API is present. It does not upgrade every associated research program to a theorem.

62.3 Extension contract and discovery

`ExtensionSpec` records name, version, API version, contributed modules, optional dependencies, description, and an optional zero-argument registration callback. `activate()` calls that callback once per explicit activation call. The API does not attempt to infer idempotence, undo registration, or modify the stable namespace automatically.

Installed extensions advertise entry points in the group `komorebi_math.extensions`. `discover_extensions(activate=False)` loads each entry point, accepts either an `ExtensionSpec` or a zero-argument factory that returns one, and produces one `ExtensionLoadResult` per candidate. With `activate=True`, the registration callback runs before the result is marked loaded.

Import, factory, type, and activation failures are caught per entry point. A failed result has `loaded=False` and an error string of the form `ExceptionType: message`. Discovery then continues to the next candidate. This is failure isolation, not a security sandbox. Extension code executes in the current Python process with that process's permissions.

```
from komorebi_math.extensions import ExtensionSpec
from komorebi_math.registry import (
    FeatureRegistry,
    FeatureSpec,
    FeatureStatus,
)

activated = []
extension = ExtensionSpec(
    name="miniature-demo",
    version="0.1",
    api_version="1",
    modules=("miniature_demo",),
    register=lambda: activated.append("ready"),
)
extension.activate()

registry = FeatureRegistry(
    (
        FeatureSpec(
            key="demo",
            module="miniature_demo",
            title="Miniature extension",
            status=FeatureStatus.EXPERIMENTAL,
            summary="A local extension example.",
        ),
    )
)
assert activated == ["ready"]
assert registry.get("demo").status is FeatureStatus.EXPERIMENTAL
print(extension.name, registry.get("demo").status.value)
```

An installable extension would expose a factory under the entry-point group in its own `pyproject.toml`. Merely constructing `ExtensionSpec` does not install or discover anything.

62.4 Stable-core and persistence boundaries

Extensions may register features, adapters, provenance records, or codecs through documented APIs, but those additions do not become stable package symbols by implication. They also do not enter the 51-codec package contract unless a later package release intentionally freezes them. Downstream code should record the extension name, version, API version, and optional dependencies alongside any extension-owned portable state.

The command `komorebi describe QUALIFIED_NAME` exposes a provenance record as JSON and returns a failure status when no record exists. `komorebi doctor` reports optional dependency and extension status. These are diagnostic views. They do not activate extensions unless the underlying command explicitly asks the discovery layer to do so.

63. Complete CLI reference

Using the command reference. Begin with the package identity command from Chapter 4, using the same interpreter that will run the actual operation. Command names in the tables are followed by arguments; names such as `PATH` and `OBJECT` stand for values you supply. Quote paths containing spaces in the syntax of your shell. PowerShell's continuation character is a backtick, while the POSIX examples use a backslash. Copy a command from the matching shell listing rather than mixing those forms.

Choose a new output path for a first run so that a refusal to overwrite is easy to distinguish from a mathematical failure. After a command completes, check its exit status and the expected output file or structured result. For a command's complete option set, use its entry in Appendix F; the short tables here explain purpose and relationships.

The console entry point `komorebi` and `python -m komorebi_math` use the same `build_parser()` and command functions under one interpreter. This equivalence does not cross environments: two shells can resolve different installations, optional backends, or LaTeX executables.

63.1 Identity, verification, API, and release commands

Command	Contract
`info`	print package identity and summary
`doctor`	inspect optional dependencies and discovered extensions
`features`	print registered mathematical domains and statuses
`describe OBJECT`	print one provenance record for a qualified object
`verify SUITE`	run one of the 51 frozen verification-suite names
`api check`	compare research, beta, or stable public API identity
`api snapshot --output PATH`	write a selected API manifest. `--force` replaces
`golden`	run committed behavioral semantics
`release contract`	validate and print the frozen release contract
`release environment`	print the current runtime qualification record
`release qualify`	run installed freeze qualification, optionally probing GPU
`release upgrade`	check predecessor API, fixtures, codecs, and migrations
`release evidence`	validate digest-checked platform evidence
`release documentation`	validate exact stable documentation coverage
`release readiness`	run public-beta or stricter final readiness

`api check` accepts `--manifest`, `--strict-signatures`, and mutually exclusive `--beta` or `--stable` modes. Without a tier flag it checks the research surface. `api snapshot` requires `--output` and uses the same tier selection.

The release commands that can write JSON accept `--output` and refuse an existing destination unless `--force` is present. `--gpu` executes optional CUDA probes. `--require-gpu` makes a successful GPU gate mandatory. The `--final` readiness flag additionally requires current-version evidence across every declared platform family.

63.2 Streams, sequences, and mathematical domains

Family	Subcommands and essential inputs
`stream`	`inspect PATH` with optional incomplete/chunk checks. `verify PATH`
`sequence`	`NAME`, optional term count, index, modulus, and strongest compilation
`coordinates`	`euler-fibonacci`, `recurrence`, `catalog`, `basis`, `model`, `polynomial`, `combinatorial`, `spectral`, `packet`, `formal`

Family	Subcommands and essential inputs
`generating`	`mask`, `cartier`, `kernel`, `bell`
`arithmetic`	`standard-window`, `euler`
`deformation`	`count` for smooth, weighted, nilpotent, or normal-crossing charts
`langlands`	`tame-orbit`, `heisenberg`, `completion`

The parser validates enumerated choices such as spectral coordinate kind, packet index kind, deformation chart, and LaTeX engine. Structured numeric inputs use explicit comma, semicolon, rational, matrix, or JSON decoders in the command function. A syntactically valid string can still fail semantic validation when dimensions, moduli, primes, or mathematical preconditions are invalid.

The completion command accepts a comma-separated subset of the five gate names and returns the conditional completion report. Supplying every gate records that the finite input claims all gates satisfied. It does not independently prove the external automorphic or realization theorems named by those gates.

63.3 Export and LaTeX commands

`export formats` prints the eleven public format names. `export sequence`, `export standard-window`, `export euler`, and `export json` convert their domain values to one requested output. `export bundle` reads JSON and writes a multi-format archive. `--base-name` and comma-separated `--formats` control its members.

All value-export commands share these options:

```
--output, --format, --title, --author, --date, --abstract,
--document-class, --toc, --mathjax, --engine, --passes, --timeout,
--keep-auxiliary, --no-keep-tex, --no-type-metadata, --force
```

The output path is required. Its suffix selects the format unless `--format` overrides it. `--force` is the CLI translation of `overwrite=True`. `--no-type-metadata` affects presentation serialization and is not a switch to portable persistence.

`latex engines` prints availability for `pdflatex`, `xelatex`, `lualatex`, and `latexmk`. `latex compile SOURCE` accepts an optional PDF output, engine, pass count, timeout, and auxiliary-retention flag. A non-PDF output suffix is a usage error.

```
python -m komorebi_math export formats
python -m komorebi_math verify export
python -m komorebi_math describe komorebi_math.core.packets.PacketSystem
python -m komorebi_math export sequence fibonacci --terms 12 --output fibonacci.tex --title "Fibonacci report"
python -m komorebi_math export bundle --input data.json --output report.zip --formats json,markdown,latex --force
```

63.4 Output, exit, and scripting discipline

Commands that promise structured output print JSON followed by a newline. The verification runner also prints one readable line per check and a final count. Scripts should use the exit status as the primary success signal and parse JSON only for fields promised by that command.

The intended exit convention is:

- 0 for a completed command whose requested predicate passed.
- 1 for a completed verification or required capability that failed.
- 2 for parser usage, invalid choices, or command-specific usage errors.

Some lower-level `ValidationError` or backend failures are intentionally not converted into false success records. Callers should capture stderr and a nonzero process status. Filesystem-writing commands refuse replacement unless their `--force` option is present.

`komorebi verify all` is the historical compatibility aggregate. It does not run the entire pytest suite, `verify block20`, or the source publication gate. For release qualification, run the named release command or the bundled handoff wrapper whose scope is explicitly recorded.

63.5 End-to-end command replay

The installed export smoke path for this part is:

```
python -m komorebi_math verify export
```

For `1.0.0b4`, the expected final line is:

```
verification passed 5/5 checks
```

Those checks cover presentation serialization, LaTeX rendering, the portable file formats, manifested multi-format bundles, and local PDF compilation when an engine is installed. The shipped `examples/export_reports.py` adds a fuller report and bundle replay, while `examples/portable_nonlinear_state.py` checks a registered nonlinear snapshot roundtrip and rejects a tampered payload.

Part XI. Connected recipes

The earlier parts document objects one domain at a time. Part XI instead documents complete finite journeys. Every recipe crosses at least two API layers and ends at an observable result, a certificate, or a replay record. This is where the library becomes a working calculus rather than a catalog of constructors.

A recipe has the evidence tuple

$$\mathcal{E} = (I, H, A, O, C, F, R),$$

where I is the input, H the hypotheses, A the ordered actions, O the output, C the certificate predicates, F the failure variants, and R the replay record. A successful numerical output without its checked hypotheses is not a completed recipe. Conversely, an exact finite identity may need no tolerance, but it still needs enough input and version information to be reproduced.

Choose one connected task. These chapters are intended to be entered from a result you want, rather than completed in sequence.

Desired result	Recipe chapter	Useful background
Reconstruct an object after a coordinate change	64	Chapters 9 through 20, as required by the chosen objects
Evaluate a sequence or finite arithmetic model	65	Chapters 21 through 26
Analyze, filter, or resample a signal	66	Chapters 31 through 36
Compose derivatives or reduce finite dynamics	67	Chapters 37 through 46
Integrate or evaluate a typed expression	68	Chapters 47 through 52
Explore a finite quantum, deformation, or Langlands model	69	Chapters 53 through 58
Export and replay a result	70	Chapters 59 through 63

For each recipe, first identify the inputs, dependencies, and expected output. Run the supplied setup and calculation together, then inspect the certificate before changing the example. Make one change at a time, such as a dimension, input sequence, or tolerance. If the change fails, compare the new input with the recipe's stated domain and assumptions before changing another setting. This keeps the example useful as a diagnostic reference.

A printed value is only one checkpoint. Also retain the parameters that define the calculation: for example, the finite degree of a polynomial model or the window and boundary rule of a signal transform. The failure variants explain where a recipe stops applying; they are part of learning the operation, not extra steps required for every ordinary run.

64. Exact algebra and coordinate recipes

Exact algebra recipes begin with a typed domain and end with a reconstruction. The middle objects may be operator paths, seed orbits, basis connections, recurrence defects, or redundant coefficients. The common invariant is that the final physical object agrees with the input under the declared backend.

64.1 Grammar, realization, and seed hull

An `OperatorGrammar` fixes vertices, typed arrows, and parallel path relations. `OperatorRealization` then assigns a dimension to every vertex and a matrix to every arrow. Construction checks shapes and, by default, requires all declared relations. The realized operators can then act on a `SeedSystem`.

For an operator T with $T^3 = T$, a finite recipe is

$$\{T^3 - T = 0\} \longrightarrow T \longrightarrow \operatorname{span}\{T^k v : k \geq 0\}.$$

The seed hull stops when the rank no longer grows or the ambient dimension is reached. A full hull proves that the supplied seeds are cyclic for this finite realization. It does not prove that an abstract infinite-dimensional model is cyclic.

64.2 Transfer paths and basis connections

A packet recipe analyzes an input into source packets, transports those packets along compatible blocks, and synthesizes the target packets. The essential check is global reconstruction, not the appearance of individual blocks:

$$x \xrightarrow{A} (x_r)_r \xrightarrow{T_{sr}} (y_s)_s \xrightarrow{S} \hat{x}, qquad\hat{x} = x.$$

For exact polynomial families the analogous path uses a connection matrix. If B_s and B_t are two bases of the same truncated polynomial space, then the coordinate change $C_{s\to t}$ is accepted only when

$$B_t C_{s\to t} c_s = B_s c_s$$

on the declared degree range. The `connection_transform()` and coordinate family certificates implement this finite statement. Truncation remains part of the hypothesis. A degree-four connection says nothing about a coefficient outside that five-dimensional space.

64.3 Euler values in Fibonacci recurrence coordinates

`euler_fibonacci_coordinates(count)` keeps the first two Euler values as the initial state and stores the defect against the Fibonacci recurrence

$$d_n = E_{n+2} - E_{n+1} - E_n.$$

The reconstruction is a discrete variation-of-constants formula. For `count=18`, the certified record has 16 defects and reconstructs

```
1, 0, -1, 0, 5, 0, -61, 0, 1385, 0,
-50521, 0, 2702765, 0, -199360981, 0, 19391512145, 0
```

exactly. This does not claim that the Euler sequence satisfies the homogeneous Fibonacci recurrence. The defect stream is precisely the information needed because it does not.

64.4 Canonical duals and coefficient gauge

For a full-column-rank analysis matrix A, `AnalysisSynthesisSystem.canonical_dual(A)` constructs

$$S = A^{+}, qquad SA = I.$$

When A is tall, the coordinates are redundant. `AnalysisSynthesisGauge` splits a coefficient vector into its canonical part in $\mathrm{im}(A)$ and its gauge part in $\ker(S)$. Two coefficient vectors are gauge-equivalent when synthesis cannot distinguish them. The physical reconstruction is unique even though the coefficient representative is not.

```
import numpy as np

from komorebi_math import OperatorGrammar, OperatorRealization
from komorebi_math.coordinates import (
    AnalysisSynthesisGauge,
    AnalysisSynthesisSystem,
    euler_fibonacci_coordinates,
    variation_of_constants_prefix,
)
from komorebi_math.core import SeedSystem

grammar = OperatorGrammar(("X",), {"T": ("X", "X")})
grammar.relation(
    "cubic",
    ((1, grammar.word("T", "T", "T")), (-1, grammar.word("T"))),
)
matrix = np.diag([-1.0, 0.0, 1.0])
realization = OperatorRealization(grammar, {"X": 3}, {"T": matrix})
realization.relation_certificate().require()

seeds = SeedSystem({"T": matrix}, (np.ones(3),))
assert seeds.hull_dimension() == 3

record = euler_fibonacci_coordinates(18)
record.certificate().require()
assert record.reconstruct() == variation_of_constants_prefix(record)

analysis = np.array(((1.0, 0.0), (0.0, 1.0), (1.0, 1.0), (1.0, -1.0)))
system = AnalysisSynthesisSystem.canonical_dual(analysis)
gauge = AnalysisSynthesisGauge(system)
gauge.certificate().require()
source = np.array((3.0, -2.0))
canonical = system.analyze(source)
null_shift = gauge.gauge_part(np.array((1.0, 2.0, 3.0, 4.0)))
assert gauge.gauge_equivalent(canonical, canonical + null_shift)
assert np.allclose(system.synthesize(canonical + null_shift), source)
print(seeds.hull_dimension(), len(record.defects), system.redundant)
```

Observed output:

```
3 16 True
```

The principal failure variants are a noncomposable operator word, a relation residual above tolerance, a seed family with a proper hull, a singular analysis matrix, or a coordinate connection used outside its certified degree. Each failure should be preserved as evidence rather than converted into a guessed reconstruction.

65. Arithmetic and sequence recipes

Arithmetic recipes are exact when their inputs are exact. They replace a long prefix or large index by a finite execution model: recurrence, automaton, Cartier representation, carry plan, valuation decomposition, or residue packet. The certificate must distinguish a model declared by the sequence from one merely inferred from a finite sample.

65.1 Catalog to strongest declared model

`compile_sequence()` inspects a `Sequence` in a fixed priority order. A certified declared linear recurrence is used before a declared finite automaton, which is used before a declared holonomic recurrence. Only when no declared model applies does the compiler attempt bounded detection from sample values.

The distinction is visible in the certificate. For a built-in sequence whose metadata declares and certifies a recurrence, the result is exact. For an arbitrary user prefix, agreement on 24 samples remains conditional because a finite prefix cannot identify every infinite continuation.

For the built-in catalog, the shipped compiler recipe reports:

Sequence	Strategy	First terms
Fibonacci	declared linear recurrence	`0, 1, 1, 2, 3, 5, 8, 13`
Thue-Morse	declared finite automaton	`0, 1, 1, 0, 1, 0, 0, 1`
Apéry	declared holonomic recurrence	`1, 5, 73, 1445, 33001`

65.2 Mahler masks and Cartier execution

A Mahler mask represents finite-difference coordinates for a polynomial or integer-valued function. Affine subsequences $f(mx + r)$ remain computable by an exact mask transformation. Cartier sections perform the parallel operation on generating series by selecting coefficients in one residue class.

`compile_finite_mask_carry_plan()` turns a finite mask and base into a carry state system. `compile_cartier_linear_representation()` turns rational series data into a finite linear representation modulo a selected modulus. Its value at a very large index is obtained by reading the base digits rather than materializing every preceding coefficient. The finite representation is the reproducibility record for that evaluation.

65.3 Bell reductions and prime-power kernels

For a normalized factorial family, `PrimePowerKernelCompiler(p, r, s)` records both the p-adic valuation and the surviving unit of

$$\binom{n}{k}^{s} \pmod{p^r}.$$

If the valuation is at least r, the residue is zero without an unnecessary unit computation. `generalized_bell_digit_reduction()` separately reduces a Bell-type index through its declared digit rule and returns a certificate. `q_binomial_valuation_decomposition()` records the mixed-radix carry data for an integer Gaussian binomial.

For $(n, k, p, r, s) = (137, 52, 3, 5, 2)$, the kernel has valuation 4 and residue 81 modulo 3^5. A direct finite assertion against `pow(comb(137, 52), 2, 3**5)` confirms the residue.

65.4 Exact arithmetic polyphase

`arithmetic.polyphase_analyze(values, q)` splits a finite sequence into residue channels

$$a^{(r)} = (a_{qn+r})_n, qquad 0 \le r < q.$$

`ArithmeticPolyphase.reconstruct()` interleaves them exactly. Refinement is allowed only to a divisible finer modulus, and coarsening only to a divisor of the current modulus. This prevents an apparently convenient but undefined channel relabeling.

```
from math import comb

from komorebi_math.arithmetic import polyphase_analyze
from komorebi_math.generating import (
    PrimePowerKernelCompiler,
    generalized_bell_digit_reduction,
)
from komorebi_math.sequences import compile_sequence, fibonacci_sequence

compiled = compile_sequence(fibonacci_sequence())
compiled.certificate.require()
prefix = compiled.first(12)

packet = polyphase_analyze(prefix, 3)
assert packet.reconstruct() == prefix
assert packet.refine(6).coarsen(3).reconstruct() == prefix

kernel = PrimePowerKernelCompiler(3, 5, 2).kernel(137, 52)
assert kernel.residue == pow(comb(137, 52), 2, 3**5)
bell = generalized_bell_digit_reduction(137, 5, 9)
bell.require()
print(compiled.strategy, tuple(map(len, packet.channels)))
print(kernel.valuation, kernel.residue, bell.digit_sum)
```

Observed output:

```
declared linear recurrence (4, 4, 4)
4 81 5
```

Invalid primes, nonpositive exponents, out-of-range subindices, nonunit custom factors, malformed residue addresses, and unjustified detected recurrences are hard boundaries. A congruence certificate applies to the stated modulus and index family only.

66. Signal-processing recipes

Signal recipes combine numerical transforms with finite reconstruction or risk checks. They should record the sampling rate, window, frame and hop lengths, filter coefficients, stream partition, resampling ratio, boundary convention, dtype, and tolerance. Those values are part of the mathematical input, not incidental implementation details.

66.1 Windowed analysis and inverse reconstruction

`stft()` returns frequencies, frame times, complex coefficients, window data, and the exact framing convention needed by its inverse. A roundtrip certificate checks the reconstructed samples against the original signal. Coverage and normalization fail visibly when the chosen window and hop do not support the declared finite reconstruction.

Streaming STFT uses the same frame rule while receiving an explicit chunk partition. Chunk boundaries may change buffering, but they must not change the completed frame values. The shipped production recipe checks both batch and streaming forms on a deterministic 1,024-sample signal.

66.2 Filter design and stateful application

`design_lowpass()` produces an FIR design with a certificate for its declared symmetry and finite response checks. `stream_fir_filter()` then carries the filter state across a supplied sequence of chunk sizes and compares the joined output with batch filtering. Recursive biquad designs use a separate stability certificate and `stream_lfilter()` state replay.

The stream partition belongs in R. A test using only one chunk does not exercise state continuity. Useful adversarial partitions include a one-sample first chunk, uneven interior chunks, and a final chunk shorter than the filter memory.

66.3 Rational resampling

`resample_poly_result(x, L, M)` performs the finite upsample, filter, and downsample path. The result records the rational rate ratio, output signal, and certificate. The recipe must check the expected length and must not describe the operation as lossless inversion: anti-alias filtering and endpoint policy matter, especially when returning to the original rate.

66.4 Packet selection, denoising, and singular recovery

The Haar packet path builds a finite tree, evaluates a declared additive cost, selects a best leaf set, and reconstructs from those leaves. Best means best for that tree, signal, and cost. It is not a universal optimality claim.

`wavelet_denoise()` applies a threshold rule to packet or wavelet coefficients. `denoising_risk_certificate(clean, noisy, estimate)` is an observed finite risk comparison because the clean reference is supplied. It does not certify risk on unseen data. Singular packet recovery is stronger only under its declared separation, sampling, kernel, and sparsity hypotheses. Its result therefore keeps detected cells, locations, amplitudes, and an assumption audit together.

```
import numpy as np

from komorebi_math.signals import (
    denoising_risk_certificate,
    design_lowpass,
    resample_poly_result,
    stft,
    stream_fir_filter,
    wavelet_denoise,
)

rng = np.random.default_rng(1212)
```

```
sample_rate = 1024.0
index = np.arange(1024)
clean = np.sin(2.0 * np.pi * 73.0 * index / sample_rate)
noisy = clean + rng.normal(scale=0.15, size=clean.size)

transform = stft(noisy, sample_rate=sample_rate, frame_length=128, hop_length=32)
transform.roundtrip_certificate(noisy).require()

lowpass = design_lowpass(120.0, num_taps=63, sample_rate=sample_rate)
lowpass.certificate(tolerance=1e-9).require()
streamed = stream_fir_filter(noisy, lowpass, (113, 287, 19, 605))
streamed.certificate.require()

resampled = resample_poly_result(streamed.value, 5, 4)
resampled.certificate.require()

piecewise = np.repeat(np.array((0.0, 2.0, -1.0, 1.5)), 256)
observed = piecewise + rng.normal(scale=0.3, size=piecewise.size)
denoised = wavelet_denoise(observed, levels=5, rule="universal", mode="soft")
denoised.certificate.require()
risk = denoising_risk_certificate(piecewise, observed, denoised.signal)
assert risk.valid
print(transform.frame_count, streamed.value.size, resampled.signal.size, risk.valid)
```

Observed output:

```
33 1024 1280 True
```

The full `examples/production_dsp.py` recipe also checks periodogram frequency, Welch averaging, cross spectra, adaptive NLMS identification, streaming STFT, recursive filtering, and overlap-add convolution. Its deterministic run finds the 73 Hz line, recovers adaptive weights approximately `[0.7, -0.35, 0.15]`, and passes every included certificate.

67. Nonlinear and dynamics recipes

Nonlinear recipes are layered because higher derivatives, correction trees, and reduced dynamics amplify hidden assumptions. The practical rule is to certify each layer before it becomes input to the next one.

67.1 Provider to jet to Faà di Bruno composition

A derivative provider declares source and target dimensions, maximum available order, backend, and exactness. `PacketJetFamily` resolves its multilinear derivatives through source and target packets. `faa_di_bruno()` composes two providers by enumerating set partitions of the requested directions.

For the one-dimensional polynomial providers in the example below, the second directional derivative is exactly 888 and is assembled from two set-partition terms. `packet_jet_support()` separately records which packet addresses are nonzero. Numerical pruning uses the declared tolerance and therefore must not be reported as exact algebraic vanishing.

67.2 Fixed-point trees and majorants

The fixed-point tree workflow expands a finite rooted-tree family, attaches elementary differentials, and compares their norms with a scalar majorant. A majorant certificate gives a finite bound under its supplied coefficient and radius hypotheses. It does not establish convergence beyond the certified order or radius.

67.3 Obstruction, lifting, and holonomy

At each lifting stage the current defect is projected to the obstruction cokernel. A zero obstruction permits the solver to enumerate corrected children. A nonzero obstruction records a stopped branch. The resulting `LiftTree` distinguishes three outcomes that a single success flag would conflate: no lift, one lift, or several compatible lifts.

Holonomy is computed only after a loop of compatible transports exists. The symbolic `examples/obstruction_lifting.py` route uses the optional SymPy profile. Without that dependency, the core NumPy and exact finite verification suites remain available, but that symbolic example should be reported as unavailable rather than silently downgraded.

67.4 Filtered correction and spectral-sequence pages

A filtered complex recipe builds page E_r, computes the induced differential d_r, and advances only after checking the filtration and chain conditions. In the shipped finite example, page dimensions are 2, 2, and 0, with differential ranks 0, 1, and 0. A vanished terminal page is a property of that finite filtered complex, not a general degeneration theorem.

67.5 Markov lumping and Bayesian sufficiency

`MarkovLumping(generator, partition)` checks whether states in one block have the same total rate into every target block. If valid, it produces a coarse generator. `BayesianPartition` uses the same partition and aggregates a prior and likelihood. Fixed sufficiency requires each likelihood to be constant on every block. Thus one partition can support both dynamical and inferential coarse models without identifying the two constructions.

67.6 Feshbach reduction and memory realization

For a block operator

$$H = \begin{bmatrix} A & B \\ C & D \end{bmatrix},$$

the effective operator at spectral parameter z uses the Schur-Feshbach term $A - B(D - zI)^{-1}C$. The eliminated block also defines a memory kernel in time. A complete recipe records the projection, the admissible spectral region, resolvent conditioning, and the state-space realization used for the kernel. Near the spectrum of D, apparent large effects may be conditioning artifacts and must remain visible in the certificate.

```
import numpy as np

from komorebi_math import Exactness, PacketSystem
from komorebi_math.dynamics import BayesianPartition, MarkovLumping
from komorebi_math.nonlinear import PolynomialDerivativeProvider, faa_di_bruno

outer = PolynomialDerivativeProvider(
    {2: np.array([[[2]]], dtype=object)}, exactness=Exactness.EXACT
)
inner = PolynomialDerivativeProvider(
    {1: np.array([[1]], dtype=object), 2: np.array([[[2]]], dtype=object)},
    exactness=Exactness.EXACT,
)
composition = faa_di_bruno(
    outer,
    inner,
    np.array([2], dtype=object),
    (np.array([3], dtype=object), np.array([4], dtype=object)),
)
composition.certificate.require()

generator = np.array(
    ((-0.4, 0.2, 0.0, 0.0), (0.3, -0.3, 0.0, 0.0),
     (0.1, 0.1, -0.6, 0.4), (0.0, 0.0, 0.6, -0.4))
)
partition = (0, 0, 1, 1)
lumping = MarkovLumping(generator, partition)
lumping.certificate().require()
bayes = BayesianPartition(partition)
posterior = bayes.coarse_posterior(
    np.array((0.1, 0.2, 0.3, 0.4)),
    np.array((2.0, 2.0, 0.5, 0.5)),
)
posterior.certificate.require()
assert bayes.is_fixed_sufficient((np.array((2.0, 2.0, 0.5, 0.5)),))
print(composition.value[0], composition.raw_term_count)
print(np.round(posterior.value, 8))
```

Observed output:

```
888 2
[0.63157895 0.36842105]
```

68. Integration and expression recipes

Integration and typed expressions meet at a useful boundary. The integration layer supplies exact measures, polynomial integrals, and error-bounded quadrature. The expression layer records how coordinate changes, derivatives, antiderivatives, substitutions, and integration maps compose. Together they can verify both a scalar result and the operator path that produced it.

68.1 Exact polynomial integration

`IntervalMeasure(a, b)` with rational endpoints and density is an exact finite measure. `ExactPolynomial` stores finite rational coefficients. `integrate(polynomial, measure)` returns an exact `IntegralResult` when exact polynomial coefficients and exact measure moments support the moment contraction.

For

$$f(y) = y^4 - 2y + 1, \qquad \mu = \tfrac{1}{2}\,dy \text{ on } [1, 3],$$

the exact result is $106/5$. Monomial, Euler-polynomial, and Fibonacci-polynomial coordinate pairings all return the same scalar when their connection maps and integration covectors are used consistently.

68.2 Certified Simpson evaluation

`CompositeSimpson(subintervals, derivative_bound)` combines sampled values with a supplied fourth-derivative bound. On the same polynomial, 16 panels produce `21.200032552083332`. The observed error and rigorous absolute bound are both approximately 3.255×10^{-5}.

The derivative provider is part of the hypothesis. The library intentionally tests a degree-six polynomial that vanishes at the three Simpson nodes but has true integral $1/840$. The raw three-node functional returns zero, while an attempt to certify exactness is rejected. Node agreement alone is not an integration theorem.

68.3 Pushforwards and affine change of variables

For $T(x) = 2x + 1$ and Lebesgue measure on $[0, 1]$, `PushforwardMeasure` represents the image measure, whose density is $1/2$ on $[1, 3]$. The recipe checks

$$\int_{[1,3]} f(y)\,\frac{dy}{2} = \int_{[0,1]} f(2x + 1)\,dx.$$

The absolute Jacobian belongs to the pushed measure. Omitting it can preserve the shape of a formula while doubling the integral.

68.4 Typed normalization, planning, and replay

An expression node carries its domain and codomain. Invalid compositions fail before matrix multiplication. `normalize_expression()` computes a canonical finite representation, and `simplify_expression()` applies recorded rewrite steps. Equality is established by matching normal forms under the implemented finite rules, not by comparing display strings.

`compile_expression()` selects executable instructions and uses dynamic programming for matrix chains. In the full worked recipe, the selected cost is 244 scalar multiplications rather than 260 for the left-associated chain. Direct evaluation and planned execution share the same normal-form digest.

68.5 Portable expression boundary

`expression_to_json()` uses the frozen expression schema and `expression_from_json()` validates it before reconstruction. `expression_digest()` binds the normalized portable content. Unknown node types, malformed spaces, invalid rational values, excessive nesting, and digest changes are rejected. As with general portable persistence, the digest detects modification but is not a keyed signature.

```
from fractions import Fraction

from komorebi_math.expression import (
    PolynomialCoordinateSpace,
    affine_substitution,
    apply,
    evaluate_expression,
    exact_value,
    expression_digest,
    expression_from_json,
    expression_to_json,
    interval_integration,
)
from komorebi_math.integration import (
    ExactAffineMap,
    ExactPolynomial,
    IntervalMeasure,
    PushforwardMeasure,
    integrate,
)

Q = Fraction
base = IntervalMeasure(0, 1)
chart = ExactAffineMap(((2,),), (1,))
pushed = PushforwardMeasure(base, chart)
polynomial = ExactPolynomial.univariate((1, -2, 0, 0, 1))
assert integrate(polynomial, pushed).require() == Q(106, 5)
assert integrate(chart.pullback(polynomial), base).require() == Q(106, 5)

monomials = PolynomialCoordinateSpace(
    "y", 4,
    tuple(tuple(Q(int(i == degree)) for i in range(degree + 1))
          for degree in range(5)),
    "monomials",
)
value = exact_value(monomials, (1, -2, 0, 0, 1))
pulled = apply(affine_substitution(monomials, 2, 1), value)
expression = apply(interval_integration(monomials, 0, 1), pulled)
assert evaluate_expression(expression).scalar == Q(106, 5)

encoded = expression_to_json(expression)
restored = expression_from_json(encoded)
assert expression_digest(restored) == expression_digest(expression)
print(evaluate_expression(expression).scalar, len(expression_digest(expression)))
```

Observed output:

```
106/5 64
```

69. Quantum, deformation, and Langlands recipes

These recipes connect finite linear-algebra models while preserving the line between an implemented certificate and an external theorem. The package can verify a finite symmetry decomposition, channel identity, error-correction condition, residual support computation, local packet, or completion gate record. It does not turn a satisfied finite model into an unconditional global Langlands realization.

69.1 Symmetry packets and circuit expansion

A finite group action on $\mathcal{H}$ yields character projectors P_ρ. The symmetry recipe checks projector idempotence, orthogonality, and completeness before converting packet-supported operators into a circuit expansion. The shipped two-qubit example completes with reconstruction error at floating-point scale and reports an overlap of approximately 0.5 for its selected state.

69.2 Channels and Knill-Laflamme conditions

`amplitude_damping(gamma)` constructs a channel from Kraus operators and checks trace preservation. At $\gamma = 0.2$, the excited-state density has diagonal `[0.2, 0.8]` after the channel.

`QuantumCode(projector, errors)` evaluates

$$PE_a^* E_b P = \alpha_{ab} P$$

for every declared error pair. `knill_laflamme_report()` records the scalar matrix and residuals. `recovered_channel_certificate()` then checks the finite recovery construction. Both must pass. A channel certificate alone says nothing about a particular code, and a code certificate covers only the supplied error family.

69.3 Residual forests and visible support

A deformation forest records residual states, children, chart labels, and support data. Visibility selects branches that survive the declared support tests. The result is finite and combinatorial. A missing branch may mean a failed local lift, an excluded chart, or a visibility cutoff, so the diagnostic reason must travel with the support packet.

69.4 Tame packets and Heisenberg models

A Frobenius orbit produces a tame packet whose dimension is the orbit length. Alternating forms and quadratic refinements define finite Heisenberg data and symplectic diagnostics. In the shipped prime-three example, the Frobenius orbit is `(1, 2, 4)`, the tame and Heisenberg dimensions are both 3, and the selected packet projector has rank 1.

These are exact finite representation statements. Naming the objects after local or Langlands structures does not assert a global correspondence beyond the constructors and certificates documented in Part IX.

69.5 Ramification towers and conditional completion

`RamificationCliffordTower` assembles finite stages and reports breaks, dimensions, packet phases, and Clifford data. `AutomorphicCompletionReport` then evaluates five named gates: residual, patching, comparison, fiber, and realization.

The boolean completion result is the conjunction of supplied gate statuses. In the example below, four gates are explicitly supplied as satisfied and the realization gate remains false. The correct result is therefore `completion_ready=False`, with `realization` preserved as the unmet gate. This is the intended boundary: the object tracks what would still be required and does not infer the external theorem.

```
import numpy as np

from komorebi_math.langlands.completion import (
    AutomorphicCompletionReport,
    CompletionGate,
    GateStatus,
)
from komorebi_math.langlands.local import AlternatingForm, QuadraticRefinement
from komorebi_math.langlands.ramification import (
    ProjectiveMultiplicityPacket,
    RamificationCliffordTower,
    RamificationStage,
)
from komorebi_math.quantum import QuantumCode, amplitude_damping

channel = amplitude_damping(0.2)
channel.certificate().require()
excited = np.diag((0, 1)).astype(complex)
assert np.allclose(np.diag(channel.apply_density(excited)), (0.2, 0.8))

identity = np.eye(2)
x = np.array(((0, 1), (1, 0)), dtype=complex)
zero = np.zeros(8)
zero[0] = 1
one = np.zeros(8)
one[-1] = 1
projector = np.outer(zero, zero) + np.outer(one, one)
errors = (
    np.eye(8), np.kron(np.kron(x, identity), identity),
    np.kron(np.kron(identity, x), identity),
    np.kron(np.kron(identity, identity), x),
)
code = QuantumCode(projector, errors)
code.knill_laflamme_report().certificate.require()
code.recovered_channel_certificate().require()

form = AlternatingForm(((0, 1), (1, 0)), prime=2)
packet = ProjectiveMultiplicityPacket(
    2, 2, form, QuadraticRefinement(form, (0, 0))
)
tower = RamificationCliffordTower((
    RamificationStage(0, 8, 4, 2, 2, packet, "wild"),
    RamificationStage(1, 4, 2, 2, 1, None, "deeper"),
))

completion = AutomorphicCompletionReport({
    CompletionGate.RESIDUAL: GateStatus(True, "supplied"),
    CompletionGate.PATCHING: GateStatus(True, "supplied"),
    CompletionGate.COMPARISON: GateStatus(True, "supplied"),
    CompletionGate.FIBER: GateStatus(True, "supplied"),
    CompletionGate.REALIZATION: GateStatus(False, "external"),
})
print(tuple(float(value) for value in np.round(
    np.diag(channel.apply_density(excited)).real, 1
)))
print(tower.report().breaks, bool(completion.result().value),
      tuple(gate.value for gate in completion.unmet_gates))
```

Observed output:

```
(0.2, 0.8)
(0, 1) False ('realization',)
```

70. Export and reproducibility recipes

The final connected recipe moves from an in-memory result to a replayable handoff. It uses several contracts because no single format proves every property.

70.1 Result to document to rendered formats

`document_from_data()` or a domain-specific report builder turns a supported value into `MathDocument`. Text, Markdown, HTML, and LaTeX renderers consume the same ordered block model. PDF export adds a local LaTeX compiler and its log. A rendering certificate establishes that the declared local write completed. It does not certify the mathematical claims inside arbitrary prose.

70.2 Portable object replay

When reconstruction matters, use `dumps_portable()` or `save_portable()` rather than presentation JSON. The portable envelope carries a schema version, producer version, registered typed payload, and SHA-256 payload digest. A roundtrip recipe checks both the reconstructed type and its domain certificate. The active codec contract should be recorded when long-lived files or extension-owned codecs are involved.

70.3 Manifested multi-format bundle

`export_bundle()` renders a selected format family in a staging directory, writes `MANIFEST.sha256`, and packages the members in one ZIP. The manifest is also written beside the archive. A consumer should reopen the ZIP, reject duplicate and unsafe names, verify the CRC, and compare every listed digest. The writer's success certificate alone does not prove that a later copy or extraction is unchanged.

```
from pathlib import Path
from tempfile import TemporaryDirectory
from zipfile import ZipFile

from komorebi_math.export import (
    ExportOptions,
    dumps_portable,
    export_bundle,
    loads_portable,
    portable_digest,
)

rows = tuple({"n": n, "square": n * n} for n in range(6))
with TemporaryDirectory() as temporary:
    root = Path(temporary)
    bundle = export_bundle(
        rows,
        root / "squares.zip",
        base_name="squares",
        formats=("json", "markdown", "latex"),
        options=ExportOptions(overwrite=True, title="Square table"),
    )
    bundle.certificate.require()
    with ZipFile(bundle.path) as archive:
        names = tuple(sorted(archive.namelist()))
        assert "MANIFEST.sha256" in names

    encoded = dumps_portable(rows)
    restored = loads_portable(encoded)
    assert restored == rows
```

```
    assert portable_digest(restored) == portable_digest(rows)
    print(names)
    print(bundle.valid, len(portable_digest(rows)))
```

Observed output:

```
('MANIFEST.sha256', 'squares.json', 'squares.md', 'squares.tex')
True 64
```

70.4 Installed wheel verification

A wheel recipe begins in a fresh environment, installs the bundled wheel and the declared dependency profile, and runs identity plus stable-contract checks:

```
python -m pip install .\komorebi_math-1.0.0b4-py3-none-any.whl
python -m komorebi_math info
python -m komorebi_math verify stable
python -m pip check
```

For the recorded reference baseline, `verify stable` ends with `verification passed 6/6 checks`. This establishes the installed stable surface under that interpreter. It is not a substitute for source tests, strict documentation, platform evidence, or optional GPU qualification.

70.5 Source gate and clean handoff replay

The complete publication path starts from the source tree, runs the source gate, builds the wheel and source distribution, and creates a deterministic handoff archive. The handoff verifier then runs once in staging and again from a new extraction. A release recipe should record at least:

- Source and package version.
- Interpreter, platform, dependency profile, and optional backends.
- Test, documentation, and publication-gate results.
- Artifact paths, byte counts, and SHA-256 digests.
- Archive member count, path-safety audit, and CRC result.
- Deterministic rebuild comparison.
- Clean-extraction verifier result.

The cumulative archive workflow recorded in the reference baseline follows that stronger pattern: it writes the ZIP twice and requires byte equality, audits every member, extracts without trusting member paths, and replays the bundle manifest from the clean root. Such a result applies to the exact archive identified by its record. For the present manual files, consult their supplied build and review records rather than transferring an earlier archive's result to new bytes. Two separately timestamped or intentionally revised editions need not have the same digest.

70.6 Recipe replay matrix

The installed finite smoke suites for Part XI are:

Connected area	Verification command	Expected final line
algebra and coordinates	`python -m komorebi_math verify coordinates`	`verification passed 24/24 checks`
arithmetic sequences	`python -m komorebi_math verify sequences`	`verification passed 5/5 checks`
generating compilers	`python -m komorebi_math verify generating`	`verification passed 14/14 checks`
signal processing	`python -m komorebi_math verify dsp`	`verification passed 11/11 checks`
nonlinear calculus	`python -m komorebi_math verify nonlinear`	`verification passed 14/14 checks`
finite dynamics	`python -m komorebi_math verify dynamics`	`verification passed 11/11 checks`
exact integration	`python -m komorebi_math verify integration`	`verification passed 12/12 checks`
typed expressions	`python -m komorebi_math verify expression`	`verification passed 22/22 checks`
quantum systems	`python -m komorebi_math verify quantum`	`verification passed 9/9 checks`
deformation systems	`python -m komorebi_math verify deformation`	`verification passed 4/4 checks`
finite Langlands models	`python -m komorebi_math verify langlands`	`verification passed 12/12 checks`
export and persistence	`python -m komorebi_math verify export`	`verification passed 5/5 checks`

These suites localize domain regressions. The source publication gate remains the canonical full source release route.

Part XII. Verification, release, and reproducibility

Choose a check that answers your question. Most readers need a focused check while learning a feature. Release maintainers need the wider collection of records described in the later chapters.

Question	Starting point	What a pass applies to
Does this installed feature pass its finite checks?	Chapter 71, named domain suite	the selected suite in the interpreter that ran it
Does the public interface match its contract?	Chapter 72	the selected API, semantic, or persistence contract
Has this package run on the required platforms?	Chapter 73	the version and environment named in each record
Can the delivered source and packages be rebuilt and replayed?	Chapter 74	the source and output bytes identified by the build records
Where is a test or verification program documented?	Appendix O	the static source and reference mapping

This part preserves the reference baseline's commands, digests, counts, and observed outcomes. They explain how the evidence is interpreted. When checking a different release, compare against that release's own contract and records. A changed count or digest is a reason to identify the source version before diagnosing a failure. It is not, by itself, proof that either run is wrong.

For an unsuccessful check, keep its exact invocation, package and interpreter identity, first failing check, and diagnostic. Repeat the smallest relevant check after correcting the cause. This makes failures easier to explain than a single large log with no version or command context.

A trustworthy release claim is a conjunction of narrower claims, not one large green check. Komorebi Math uses five layers: an installed verification suite tests finite package behavior. A frozen contract compares the live package to committed compatibility artifacts. A platform record says where a particular execution occurred. The source publication gate checks the publication-facing source tree, and the handoff builder proves that the distributed bytes can be rebuilt and replayed from a clean extraction. Passing an earlier layer never implies a later one.

In symbols, the strongest local handoff claim has the shape

$$Q_{handoff} = V_{installed} \wedge C_{frozen} \wedge E_{platform} \wedge G_{publication} \wedge A_{replay}.$$

External publication is intentionally outside this expression. A qualified wheel or ZIP is not evidence that a PyPI upload, GitHub release, or authenticated tag exists.

71. Verification suites

71.1 Domain suites

The command-line registry contains exactly 51 accepted names. Each name maps to one callable returning a `VerificationReport`. The final `all` name is retained for compatibility and maps to the historical compatibility runner. The registry divides as follows:

Family	Exact accepted names
finite domain and focused suites	`core`, `refinement`, `nonlinear`, `algorithms`, `signals`, `dynamics`, `analytic`, `quantum`, `arithmetic`, `sequences`, `deformation`, `langlands-local`, `langlands-finite-image`, `langlands-completion`, `langlands`, `export`, `generating`, `coordinates`, `frame-algebra`, `integration`, `expression`, `dsp`, `hardening`, `streaming-beta`
cumulative package suites	`block2`, `block3`, `block4`, `block5`, `block6`, `block7`, `block8`, `block9`, `block10`, `block11`, `block12`, `block13`, `block14`, `block15`, `block16`, `block17`, `block18`, `block19`, `block20`
compatibility and release suites	`stable`, `release`, `gpu`, `upgrade`, `evidence`, `documentation`, `beta`
historical compatibility alias	`all`

A verification check is the immutable triple

$$o = (\text{name}, \text{passed}, \text{detail}),$$

and a `VerificationReport` is a tuple of those checks. Its `passed` property is the conjunction of every check, `passed_count` and `total_count` expose the finite cardinalities, and `certificate()` converts the report to the common certificate vocabulary. The certificate is numerical because many suites mix exact identities with finite floating comparisons. Individual checks remain responsible for their own stronger evidence.

71.2 Cumulative suites

Choose the smallest suite that localizes the question. A domain suite is useful while developing one subsystem. A cumulative `blockN` route checks the graph installed by that development block. Contract routes answer different questions: `stable` combines API, semantic, and persistence checks. `release` checks the beta release contract. `upgrade` replays predecessor relations. `evidence` checks committed platform records. `documentation` checks stable symbol coverage, and `beta` aggregates public-beta readiness. `gpu` is a hardware-facing route and must not be treated as a required base-wheel check.

`komorebi verify all` is a historical compatibility alias. It does not run the complete cumulative verification, source publication gate, or full pytest suite. For the reference installed cumulative graph, use `python -m komorebi_math verify block20`. For the complete source release path, use the source publication gate in full mode.

71.3 Reading verification output

The CLI prints one normalized line per check followed by the aggregate certificate message:

```
[PASS] stable public API manifest
[PASS] stable semantic fixture
...
verification passed 6/6 checks
```

The marker reflects only `check.passed`. A nonempty detail is appended after two spaces and is especially important on failure. The process returns 0 only when the report passes, 1 for a known suite with at least one failed check, and 2 for an unknown suite name. This makes the route safe for shell gates without requiring log scraping.

The recorded qualification environment produced these focused results:

Command suffix after `verify`	Observed result
`stable`	6/6 passed
`release`	10/10 passed
`upgrade`	1/1 passed
`evidence`	1/1 passed
`documentation`	1/1 passed
`beta`	1/1 passed
`block20`	46/46 passed

This installed-Python check uses the report object directly and therefore fails at the same certificate boundary as the CLI:

```python
from komorebi_math.verify import run_stable_verification

report = run_stable_verification()
report.certificate().require()
assert report.passed_count == report.total_count == 6
print(f"stable verification: {report.passed_count}/{report.total_count}")
```

Expected output:

```
stable verification: 6/6
```

71.4 Failure localization

`_capture()` converts an exception raised by one check into a failed `VerificationCheck` whose detail begins with the exception type. This localizes assertion failures, validation errors, stale digests, environment mismatches, and resource refusals without losing the rest of the suite. Native crashes and timeouts require an isolated launcher. They cannot be converted by an in-process `try` block after the interpreter has stopped.

Optional-backend absence is not globally a pass or a failure. A suite may record it as non-gating when the backend was not requested. Once the command or release claim requires that capability, `--require-gpu`, for example, the same absence is a failed requirement. Always read the named check, its detail, the aggregate return code, and the invocation flags together.

> **Chapter 71 boundary.** A passing suite proves the finite checks selected by that suite under the current interpreter. It does not freeze an API, prove a predecessor upgrade, establish another platform, run the full source tests, or qualify an artifact archive.

72. API, semantic, persistence, and upgrade contracts

72.1 Public API manifests

The API checker snapshots exported names, broad object kinds, implementation owners, qualified names, and reflected signatures. It has three intentionally different scopes:

Tier	Namespaces	Entries	Canonical manifest digest
stable	`komorebi_math.stable`	131	`23cd9e47a1663f2d 4b3c0fef50f9f7d8 c88d4af2f8bbc57e 7ba76461e6e69276`
beta	`komorebi_math.beta`	83	`311f2bf7cbcf0a45 bcbe2af433d73a8f 597c0fbf71337508 82314d6e0edb16b2`
research	six broad public namespaces	1,312	`473c73e1a0563fe0 b2569c8be384f7c9 f947570bea2f300e f611db351136847a`

These are canonical object digests calculated from normalized JSON. The release contract separately stores the SHA-256 of each committed JSON file. That file digest also covers whitespace and serialization. Do not compare one kind of digest to the other and call the mismatch a failure.

Stable aliases are stronger than equal spellings. For every stable export `name`, the three supported routes must resolve to the same Python object:

$$\mathrm{id}(stable.name) = \mathrm{id}(v1.name) = \mathrm{id}(api.v1.name).$$

The release and readiness gates check both the identical `__all__` sequences and object identity for every one of the 131 names.

72.2 Closed stable semantic fixture

A structural manifest cannot detect a function that keeps its signature while changing its mathematics. The closed stable fixture therefore executes ten committed cases spanning analysis/synthesis, signal and arithmetic polyphase, lattice refinement, operator grammar, basis coordinates, normalized series, document rendering, settings scope, and portable refinement.

Each result is canonicalized and compared with the committed expected value. The fixture digest is `02d05d0cd59e2e9d 3cd5a72dbeab7223319cf8cbb25b96e738d94d5c9cedd870`. The registry is closed: an unknown case kind is an error, not an ignored extension. The report proves those ten laws only. It is not an exhaustive semantic specification of the research namespace.

72.3 Portable codec contract

The persistence contract freezes the package-owned portable registry at 51 codec tags. For each tag it records the positive codec version and fully qualified implementation type. Comparison rejects a removed tag, a changed implementation type, a version decrease, or a version increase lacking every adjacent migration step.

The live registry contains one adjacent migration: `nonlinear.packet_jet_snapshot` from version 1 to version 2. Additive extension codecs are not silently promoted into the package-owned stable contract. The aggregate stable predicate is therefore

$$C_{stable} = C_{API} \wedge C_{semantics} \wedge C_{persistence}.$$

In the audited tree all three components pass under theorem record `KM-STABLE-CONTRACT-016`.

72.4 Release contract

The current release contract binds package identity, runtime policy, required platforms, stable aliases, CLI routes, and eight committed artifacts. Its artifact rows have the exact shape `(filename, sha256, count)`:

Artifact	Count	Committed file SHA-256
`public_api_stable_1_0.json`	131	`74e94269f875943861cb815f9acdb5eb0289d9a0fab8e8b55ff59e7e15483e67`
`public_api_beta_1_0.json`	83	`c0f4cf27d4a47b86d1ea5b79c6c2fe883368e6ab7f8a640e527f916b271ba000`
`public_api_1_0.json`	1,312	`04a6c1218bb016b2bbd09f551a7866d1aab47efd5efb753710dde322f32f6357`
`stable_semantics_1_0.json`	10	`445668c79fce5eccf4fd3d5f8aebf66a340afff7d58983ec7c48c06201f7aa6e`
`portable_codec_contract_1_0.json`	51	`5f8522edf0dd56c6d3a23be4625e72a33fe0ee7182c13060a9b09f93035a7c05`
`upgrade_contract_1_0.json`	7	`d80de9c2b6913df3386a776519fefffb47b2820a57678b53ed19afae87f3e84d`
`validation_evidence_1_0.json`	2	`7aea0d877dbd1e896567199b9f6a857aa53a0bf40189c6aa17a05827115deaf2`
`stable_documentation_1_0.json`	131	`9ffb806d95c979b77f59334265cc5e045dae949cd25c46a5bd37d2b7e0ca8299`

The verifier first checks file existence, bytes, and the expected array count. Then it re-runs live API, semantics, persistence, upgrade, evidence, and documentation checks. It also verifies alias identity, required CLI routes, and the support matrix. The release-contract digest in this tree is `3f46ed8c65861a043f677dad32c2f84b3e7189f9c122a8489f94ae47ebc8bfd3`.

72.5 Predecessor upgrade records

The accepted predecessor set is

$$\{0.15.0a2, 0.16.0a2, 1.0.0b1, 1.0.0b2, 1.0.0b3\}.$$

The contract contains five stable-API baselines, one `0.16.0a2` stable semantic baseline, one `0.16.0a2` 51-codec baseline, and seven digest-bound portable fixtures. It does not claim one separate semantic or codec snapshot for every predecessor. The `0.15.0a2` API comparison has one documented migration allowance for `create_stable_api_manifest`. The later stable baselines require exact name, kind, and signature continuity.

Every fixture must retain its archive digest and portable-payload digest, load through the current codec graph, produce its expected qualified Python type, and round-trip canonically. The aggregate upgrade-contract digest is `f70d9327fafb6fa743e2934ec0144059219c4fe0f490083c50ef80d19c539bbe`.

This executable check reads the three live manifests and then requires the aggregate stable, release, and upgrade certificates:

```
from komorebi_math.compatibility import (
    create_beta_api_manifest,
    create_public_api_manifest,
    create_stable_api_manifest,
)
from komorebi_math.release import check_release_contract, check_upgrade_contract
from komorebi_math.stable_contract import check_stable_contract

manifests = {
    "stable": create_stable_api_manifest(),
    "beta": create_beta_api_manifest(),
    "research": create_public_api_manifest(),
}
assert {name: len(value.symbols) for name, value in manifests.items()} == {
    "stable": 131,
    "beta": 83,
    "research": 1312,
}
for report in (
    check_stable_contract(),
    check_release_contract(),
    check_upgrade_contract(),
):
    report.certificate.require()
print("stable, release, and upgrade contracts passed")
```

Expected output:

```
stable, release, and upgrade contracts passed
```

> **Chapter 72 boundary.** Compatibility is a versioned relation between the current package and exact committed artifacts. It does not prove performance stability, research-tier stability, platform execution, or artifact reproducibility.

73. Platform and release qualification

73.1 Environment records

`release environment` is descriptive evidence about the interpreter that ran the command. It records the package version, Python executable and version, platform string, installed packages, and isolated optional-backend probes. It does not by itself say that a verification suite passed. Keeping environment and result records separate prevents an installed package list from being misread as executed qualification.

Three predicates must therefore remain distinct:

$$\text{DeclaredSupported}(E) \not\equiv \text{ExecutedSuccessfully}(E, R) \not\equiv \text{HardwareQualified}(E, H).$$

The support matrix declares Python 3.11, 3.12, and 3.13 with NumPy 1.26 or newer. That declaration is policy, not proof that every combination has run.

73.2 Linux and Windows evidence

One validation-evidence record contains an identifier, normalized platform key, raw platform string, package, Python and NumPy versions, a source record and its SHA-256, an inheritance flag, finite results, and optional-backend details. The checker verifies the source file digest separately from version currentness.

The committed evidence set contains two records:

Platform key	Record	Package version	Status in `1.0.0b4` policy
`linux-x86_64`	`linux-1.0.0b4-publication-gate`	`1.0.0b4`	current
`windows-x86_64`	`windows-0.16.0a2-user-qualification`	`0.16.0a2`	inherited through the upgrade contract

Both required platform families are covered, at least one current execution exists, and the inherited predecessor is authorized, so the beta evidence policy passes. Only Linux is current. Consequently,

$$\text{current} = \{\text{linux–!x86_64}\}, \qquad \text{missing_current} = \{\text{windows–!x86_64}\}.$$

The evidence object's canonical digest is `cc7ea963e6799320104b84e2d49231b933ee5a3e379909173fa4df349562474e`.

73.3 CPU and optional CUDA qualification

The base wheel requires NumPy only. JAX, PyTorch, CuPy, SciPy, SymPy, and the documentation toolchain are optional profiles. Backend discovery and hardware qualification are also different events: package metadata can find a module that fails to import, imports can work without the required primitive, and a CUDA library can import without executing the intended GPU kernel.

The GPU qualifier therefore isolates PyTorch and CuPy work in child interpreters and records native import failures, timeouts, abnormal exits, device identity, and numerical residuals. With no GPU flag, beta readiness records that current-host CUDA was not requested. `--gpu` observes hardware without making it mandatory. `--require-gpu` turns a missing or failing GPU record into a gate failure. None of these routes changes the NumPy-only base dependency contract.

73.4 Beta versus release-candidate readiness

Beta readiness permits a required platform to inherit a successful predecessor record when the upgrade contract protects the stable API, semantics, persistence codecs, and portable fixtures. Final release-candidate readiness does not. It sets `require_current_all_platforms=True`, so every declared platform family must supply a current-package record.

Command	Audited exit	Meaning
`python -m komorebi_math release evidence`	0	beta evidence passed. Windows is inherited
`python -m komorebi_math release readiness`	0	public-beta readiness passed
`python -m komorebi_math release evidence --current`	1	current Windows evidence is missing
`python -m komorebi_math release readiness --final`	1	release-candidate readiness is not established

The nonzero final result is expected evidence, not a broken command. This short program makes that asymmetry executable:

```
from komorebi_math.release import check_beta_readiness, check_validation_evidence

beta = check_validation_evidence()
current = check_validation_evidence(require_current_all_platforms=True)
readiness = check_beta_readiness()
final = check_beta_readiness(require_current_platforms=True)

assert beta.passed and readiness.passed
assert not current.passed and not final.passed
assert current.missing_current_platforms == ("windows-x86_64",)
print("beta ready; final missing:", *current.missing_current_platforms)
```

Expected output:

```
beta ready; final missing: windows-x86_64
```

73.5 Externally observed Windows qualification transcript

1148 passed, 4 optional backend skips, 0 failed,

with strict MkDocs and report digest `4aed4f725e7592d0783ede586b7940dc80374fbe67123bf1acd507520c26e2e3`.

This successful transcript was supplied from an external Windows replay, but its JSON record is not committed in this handoff. A provenance filename cited by an earlier manual scaffold, `BLOCK21_WINDOWS_HOTFIX1_PROVENANCE.json`, is also absent from the delivered tree and therefore cannot carry evidence here. The committed validation contract continues to inherit Windows evidence from `0.16.0a2`.

Before describing Windows as current, import the actual transcript JSON, validate its internal self-digest and named checks, bind its file digest into `validation_evidence_1_0.json`, and regenerate the release-contract artifact and dependent handoff records. The separate committed Linux gate has report digest `9ece0eef69115b4519cfcc266eacb16d0881bfb3d3bc4b3b4d5c36e900ef46d5`.

> **Chapter 73 boundary.** The recorded reference package satisfied its committed public-beta policy. Those records do not establish final all-current platform readiness or current Windows qualification for a different package version.

74. Source publication handoff

74.1 Public capability tour

`examples/block21_public_capability_tour.py` is the first deterministic public program for a release reviewer. It stays finite and inexpensive while crossing stable and research-tier features. Its record includes:

- Polyphase refinement from order 4 to order 12 with a 29-sample round trip.
- A redundant two-dimensional analysis/synthesis system with four coordinates and a portable round trip.
- Eighteen Euler-Fibonacci coordinates with verified reconstruction.
- The exact finite integral `106/5` and an adversarial false-certificate guard.
- A typed-expression result `5/4`, identity pipeline, portable normal-form round trip, and matrix-chain costs 244 versus 260.
- The 131-symbol stable manifest and its canonical digest.

Canonical JSON over that record, excluding the digest field itself, produced `0e20e32f4ad9004d5248d258813b6acfec7b9e96cc30c001aa6865aba9039fdf` in the recorded audit. The digest makes altered output detectable. It is not a digital signature or proof of who executed the tour.

74.2 Full publication gate

The gate's base mode contains 14 checks: version/citation identity, required repository layout, archive-safe source paths, strict research, beta, and stable API contracts, stable and cumulative verification, release and upgrade contracts, beta evidence and readiness, the capability tour, and local Markdown links. Full mode adds the complete source test suite. MkDocs is a check when required, an automatic check when importable, or a warning when explicitly skipped or unavailable in automatic mode.

Thus the strict handoff prerequisite is

$$G_{21}^{strict} = G_{base} \wedge G_{full\ tests} \wedge G_{MkDocs}.$$

During the recorded publication audit, an explicit quick invocation with MkDocs skipped passed all 14 base checks. Its report correctly carried two non-gating warnings: the strict documentation build was skipped and the complete source tests were not requested. That observation is smoke evidence, not a new full-gate record.

POSIX source review uses:

```
PYTHON=python ./run_block21_publication_gate.sh
```

The POSIX wrapper always requests full tests. It requires MkDocs when the module is installed and otherwise records an explicit skip, so install MkDocs before using the result as the strict handoff prerequisite.

74.3 Strict MkDocs build

The strict site build checks navigation, local documentation structure, and MkDocs warnings:

```
python -m mkdocs build --strict
```

The site uses `mkdocs.yml` and the `docs/` corpus. The technical manual has a separate Markdown and LaTeX production workflow. The reference-baseline PDF build used Pandoc and `latexmk`; the editable manuscript supplied with this edition includes its own build instructions. Use those instructions when rebuilding these files. A passing site can still have a broken LaTeX page, and a clean PDF can still coexist with a broken site link. Publication evidence must name both workflows separately.

74.4 Reproducible wheel and source distribution

The distribution builder constructs the wheel and source distribution twice under the recorded normalization environment and requires exact byte equality between the first and second build. It then audits wheel `RECORD`, archive paths, source completeness, and clean installation behavior. The shipped artifacts audited for the reference baseline are:

Artifact	SHA-256
`komorebi_math-1.0.0b4-py3-none-any.whl`	`461e0f954aaee3b6b996b0dc0a5aa66f0b15114eaddad7ed3c3767187ef911ff`
`komorebi_math-1.0.0b4.tar.gz`	`744574baca52b13f094d2c2877c42e37c7f45e2affa45fe94038793e631281dc`

Byte reproducibility is intentionally stronger than comparing extracted file sets. It detects metadata, member ordering, compression, or timestamp drift that a payload-only comparison could miss.

74.5 Deterministic repository ZIP

The repository handoff builder first consumes a passing full gate record. It walks the source tree, excludes local caches and build state, and writes a single-root ZIP with normalized timestamps and modes. Every member must be a regular file with a relative NFC path. Traversal components, backslashes, symlinks, case-fold collisions, encrypted entries, and unsafe Windows names are rejected.

The ZIP is built twice and the two SHA-256 digests must match. This proves that the same accepted source and normalization inputs produced identical archive bytes. It does not prove that an independently modified source tree will or should have the same digest.

74.6 Manifest, archive safety, and clean-extraction replay

The handoff manifest records every payload path, normalized mode, size, and SHA-256, plus the embedded wheel and source-distribution identities. After ZIP creation, the verifier audits the central directory before extraction, rejects unlisted or unsafe entries, extracts without trusting member paths, and recomputes the complete inventory.

The clean root then replays the quick publication gate. Replay acceptance requires a full-mode prerequisite in the source record, the expected named checks, a valid report self-digest, matching package version, identical manifest content, payload hashes, and encoded modes. This sequence catches a handoff that passed in its build tree but omitted a required source, example, contract, or documentation file.

74.7 Windows isolated qualification

On Windows, the canonical launcher is:

```
.\Run_Block21_Publication_Gate.ps1 -Python "$env:CONDA_PREFIX\python.exe"
```

Without `-Quick`, it runs full tests and, unless `-SkipMkDocs` is explicitly given, requires strict MkDocs. The outer cumulative-manual wrapper goes further: it verifies the manual bundle manifest, copies the project into a new temporary directory, creates a fresh environment unless told otherwise, runs focused integration and expression tests, and then calls the publication-gate launcher. Failed workspaces are retained for diagnosis. Successful workspaces are removed unless preservation was requested.

After a strict gate passes, the repository handoff is built with:

```
.\Build_Block21_Handoff.ps1 -Python "$env:CONDA_PREFIX\python.exe"
```

These commands qualify source and artifact records. They do not upload to PyPI, create a GitHub release, redistribute source contrary to its recorded license, or create an authenticated tag. Those external actions require separate authority and evidence.

> **Chapter 74 boundary.** A replayable handoff binds finite source, documentation, distributions, archive bytes, and clean extraction. It does not imply external publication or final all-platform readiness.

74A. Source reconciliation

A source review distinguishes historical reproduction from active release instructions. Package identities, command options, support matrices, verifier scope, build workflows, and license descriptions must agree with the declared source version.

A reconciliation record identifies the source finding, governing contract, accepted instruction, and retained historical context. License descriptions must match the license supplied with the declared release.

Packet routes and other coordinate routes may use different option names. Check the declared parser before carrying an option from one route to another.

A maintainer can repeat the focused static review with searches such as:

```
rg -n 'support_matrix_0_16|coordinates packet.*--size' docs examples README.md
rg -n 'verify all' docs README.md
rg -n 'open source|OSI' LICENSE.md CONTRIBUTING.md docs README.md
```

Read search results in context. A historical command may remain valid as versioned reproduction evidence while requiring a different command in active instructions. License claims require review against the applicable release.

Part XIII. Exhaustive reference appendices

Appendix A. Stable API: 131-entry frozen reference

Using the stable reference. Start here when you want an interface with the stable compatibility contract. Find the exported name, read its definition, then check the contract before copying the signature. The signature tells you how arguments are supplied; the contract tells you which values, dimensions, and assumptions make the operation meaningful. Follow the chapter links for construction steps and worked examples.

A reading key for the API cards. Appendices A, B, and C use the same fields. You do not need to memorize their letters. Read each card in the following order when using an unfamiliar object.

Card section	What to look for	Practical question
Identity: `q`, `a`, `t`, `k`	Implementation identity, supported import routes, tier, and kind	Which name should my program import, and is it a class, function, or data value?
Signature: `s`	Parameter order, annotations, defaults, and keyword-only arguments	How do I supply the inputs?
Definition and contract: `D`, `C`, `H`, `R`, `X`	Meaning, input and output types, shapes, units, hypotheses, return variants, and failure conditions	Does this operation apply to my data, and what will I receive?
Guarantees: `E`, `P`, `B`, `K`	Exactness, dependencies and platform, backend behavior, and resource costs	Which guarantees and execution requirements apply to this call?
Evidence and links: `V`, `L`	Relevant checks, certificates, chapters, examples, schemas, and tests	Where can I see the operation in context and understand its evidence?

For example, the card for `CoordinateTransform` describes an exact coordinate map, while `NumericCoordinateTransform` describes a numerical map with a tolerance. Their similar purpose does not make their scalar domains or guarantees interchangeable. The contract and guarantees fields tell you which one matches your calculation. Chapters 15 through 20 explain the construction and use of both kinds.

Reading a reflected signature. An ordinary positional or keyword parameter with no default is required. A parameter followed by a default may be omitted, in which case that default is used. Parameters after a bare `*` must be passed by name; parameters before `/` must be supplied positionally. Entries written as `*args` or `**kwargs` collect additional positional or keyword arguments. They do not by themselves require at least one additional argument. An annotation such as `tuple[...]` describes an expected type; it does not replace the shape and value requirements in the contract. Quotation marks around annotations are part of Python's reflected representation and are not quotation marks to add to your argument values. A class card can show an initializer annotation ending in `-> None`; calling the class still constructs an instance. The literal `null` means that the manifest records no callable signature. Check the kind and definition before treating a name as a function.

An alias names the same object through another route. Choose one documented route consistently in application code. A matching implementation owner alone does not establish aliasing: different data values can share a Python type. The identity section states the supported relationship explicitly.

From a returned value to a usable result. Check whether the card returns a plain value, a result wrapper, a report, or a record that contains a certificate. Read the return contract before accessing fields. Where a certificate is supplied, inspect its validity, exactness, assumptions, and diagnostics as described in Chapter 5. A stable import route describes the compatibility promise; it does not turn a numerical result into exact arithmetic or discharge a conditional assumption.

For a dimension or input failure, begin with Chapter 6 and Appendix I. For an optional backend, consult Chapter 8 and Appendix J. For saved objects, check the card's persistence statement and Appendix G before assuming that a record has a portable codec. This keeps the reference useful both when a call succeeds and when it needs correction.

Appendix A records the exported-symbol ledger for the frozen 1.x surface. It covers exactly 131 manifest names: 58 classes, 61 functions, and 12 data exports. "Exhaustive" here means every exported stable name, not every public method or property on the exported classes. Method behavior remains in the chapters linked by each card.

The canonical committed manifest has digest `23cd9e47a1663f2d4b3c0fef50f9f7d8c88d4af2f8bbc57e7ba76461e6e69276`. The platform-neutral first-line documentation inventory has digest `c0702315e6ddafdb5bfa5a4f973370dab83afba5cf356efeb68280f561cf6803`. Those are canonical-JSON digests. Raw-file SHA-256 values are separate release-artifact identities. The documentation inventory proves one summary record per export but explicitly does not prove narrative completeness. The cards below provide that separate editorial layer.

A.0 Reference contract and alias rules

Every card is keyed by the exported stable name and contains the retained row fields `q, a, t, k, s, D, C, H, R, X, E, P, B, K, V, L`. The exact reflected signature is copied verbatim from the manifest in a fenced `text` block. Literal `null` means the manifest does not claim a callable constructor signature. This is correct for all 12 data exports and the seven stable exception classes.

For each name `n`, these supported routes resolve to the same object:

```
komorebi_math.stable.n is komorebi_math.v1.n
komorebi_math.v1.n is komorebi_math.api.v1.n
```

That gives 393 name-preserving qualified routes. A root or domain re-export may also be identity-equal, but importing there does not itself declare a stable-tier dependency. Five source-declared cross-name alias pairs are retained as separate manifest cards: `CoordinateTransform/ExactCoordinateTransform` and the four verb-order refinement pairs. Data values are never deduplicated by Python `id()` or by reflected `(implementation_module, qualname)`: interned integer `1` and shared runtime types would create false aliases among unrelated constants.

Data summaries are fixed semantic strings rather than docstrings inherited from `PosixPath`, `WindowsPath`, `str`, `int`, or `types.UnionType`. The reference-source contract and its `1.0.0b4` documentation snapshots were updated together. Predecessor snapshots and earlier release evidence retain their original scope. They do not establish execution of the source correction.

The compact profile IDs are editorial inheritance only. Each card repeats the profile's complete operational and evidence text so no required field is hidden behind an external lookup. "No frozen codec" is an explicit non-support statement, and "no tighter public bound" is not replaced by a benchmark.

Section	Classes	Functions	Data	Total
A.1	0	0	11	11

A.1 Constants and identity records

A.1 · DEFAULT_PORTABLE_CODEC_CONTRACT

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.DEFAULT_PORTABLE_CODEC_CONTRACT`. Name-preserving aliases `komorebi_math.v1.DEFAULT_PORTABLE_CODEC_CONTRACT` and `komorebi_math.api.v1.DEFAULT_PORTABLE_CODEC_CONTRACT`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `pathlib.Path`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. A `pathlib.Path` resolved from the installed package to `data/portable_codec_contract_1_0.json`. The install prefix is intentionally not frozen.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · DEFAULT_STABLE_SEMANTICS_FIXTURE

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.DEFAULT_STABLE_SEMANTICS_FIXTURE`. Name-preserving aliases `komorebi_math.v1.DEFAULT_STABLE_SEMANTICS_FIXTURE` and `komorebi_math.api.v1.DEFAULT_STABLE_SEMANTICS_FIXTURE`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `pathlib.Path`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. A `pathlib.Path` resolved from the installed package to `data/stable_semantics_1_0.json`. The install prefix is intentionally not frozen.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · PORTABLE_CODEC_CONTRACT_SCHEMA

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PORTABLE_CODEC_CONTRACT_SCHEMA`. Name-preserving aliases `komorebi_math.v1.PORTABLE_CODEC_CONTRACT_SCHEMA` and `komorebi_math.api.v1.PORTABLE_CODEC_CONTRACT_SCHEMA`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `A1-I1`.

Manifest signature (`s`).

```
null
```

Definition. The string `komorebi-math.portable-codec-contract`.

Contract (`D, C, H, R, X`). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (`E, P, B, K`). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (`V, L`). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · `PORTABLE_CODEC_CONTRACT_SCHEMA_VERSION`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PORTABLE_CODEC_CONTRACT_SCHEMA_VERSION`. Name-preserving aliases `komorebi_math.v1.PORTABLE_CODEC_CONTRACT_SCHEMA_VERSION` and `komorebi_math.api.v1.PORTABLE_CODEC_CONTRACT_SCHEMA_VERSION`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `A1-I1`.

Manifest signature (`s`).

```
null
```

Definition. The integer `1` for the codec-contract schema. Identity with other small integers is not an alias relation.

Contract (`D, C, H, R, X`). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (`E, P, B, K`). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (`V, L`). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · `PORTABLE_SCHEMA`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PORTABLE_SCHEMA`. Name-preserving aliases `komorebi_math.v1.PORTABLE_SCHEMA` and `komorebi_math.api.v1.PORTABLE_SCHEMA`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `A1-I1`.

Manifest signature (`s`).

```
null
```

Definition. The string `komorebi-math.portable`.

Contract (`D, C, H, R, X`). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (`E, P, B, K`). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · PORTABLE_SCHEMA_VERSION

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PORTABLE_SCHEMA_VERSION`. Name-preserving aliases `komorebi_math.v1.PORTABLE_SCHEMA_VERSION` and `komorebi_math.api.v1.PORTABLE_SCHEMA_VERSION`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. The integer `1` for portable envelopes. Identity with other small integers is not an alias relation.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · STABLE_API_STABILITY_LEVEL

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.STABLE_API_STABILITY_LEVEL`. Name-preserving aliases `komorebi_math.v1.STABLE_API_STABILITY_LEVEL` and `komorebi_math.api.v1.STABLE_API_STABILITY_LEVEL`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. The string `1.0-frozen-strict-signatures-semantics-and-persistence`.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · STABLE_PUBLIC_NAMESPACES

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.STABLE_PUBLIC_NAMESPACES`. Name-preserving aliases `komorebi_math.v1.STABLE_PUBLIC_NAMESPACES` and `komorebi_math.api.v1.STABLE_PUBLIC_NAMESPACES`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.tuple`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. The tuple `('komorebi_math.stable',)` used by the canonical manifest. The two versioned facades are checked separately.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · STABLE_SEMANTICS_SCHEMA

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.STABLE_SEMANTICS_SCHEMA`. Name-preserving aliases `komorebi_math.v1.STABLE_SEMANTICS_SCHEMA` and `komorebi_math.api.v1.STABLE_SEMANTICS_SCHEMA`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. The string `komorebi-math.stable-semantics`.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · STABLE_SEMANTICS_SCHEMA_VERSION

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.STABLE_SEMANTICS_SCHEMA_VERSION`. Name-preserving aliases `komorebi_math.v1.STABLE_SEMANTICS_SCHEMA_VERSION` and `komorebi_math.api.v1.STABLE_SEMANTICS_SCHEMA_VERSION`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. The integer `1` for semantic fixtures. Identity with other small integers is not an alias relation.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.1 · `__version__`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.__version__`. Name-preserving aliases `komorebi_math.v1.__version__` and `komorebi_math.api.v1.__version__`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `A1-I1`.

Manifest signature (s).

```
null
```

Definition. The string `1.0.0b4`.

Contract (D, C, H, R, X). The domain is the empty argument tuple and the codomain is the recorded literal or package-relative default path. Import is the only hypothesis. The result is an immutable string, integer, tuple, path, or union-type binding. There is no call-time failure, although dereferencing a default path can raise ordinary filesystem errors.

Guarantees (E, P, B, K). These are exact identity values, not mathematical certificates. Schema constants name persistence formats but are not themselves codec payloads. They use the Python standard library and have constant-time binding lookup. File I/O is outside that bound.

Evidence and links (V, L). The stable API and reference-card parsers verify name, kind, and reflected type owner. The platform-neutral documentation inventory verifies the semantic summary. See Chapters 0, 61, and 72 and the corresponding contract loader.

A.2 Certificates, settings, and exceptions

A.2 · `AssumptionError`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.AssumptionError`. Name-preserving aliases `komorebi_math.v1.AssumptionError` and `komorebi_math.api.v1.AssumptionError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.AssumptionError`. Profile `A2-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when a required mathematical assumption is not satisfied.

Contract (D, C, H, R, X). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (E, P, B, K). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (V, L). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · `BackendUnavailableError`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.BackendUnavailableError`. Name-preserving aliases `komorebi_math.v1.BackendUnavailableError` and `komorebi_math.api.v1.BackendUnavailableError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.BackendUnavailableError`. Profile `A2-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when an optional computation backend is not installed.

Contract (D, C, H, R, X). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (E, P, B, K). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (V, L). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · `Certificate`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.Certificate`. Name-preserving aliases `komorebi_math.v1.Certificate` and `komorebi_math.api.v1.Certificate`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.Certificate`. Profile `A2-C1`.

Manifest signature (s).

```
(valid: 'bool', exactness: 'Exactness', residuals: 'dict[str, float]' = <factory>, tolerance: 'float | None' =
    ↪ None, assumptions_checked: 'tuple[str, ...]' = (), assumptions_unchecked: 'tuple[str, ...]' = (),
    ↪ diagnostics: 'dict[str, Any]' = <factory>, theorem_id: 'str | None' = None, message: 'str' = '') -> None
```

Definition. Structured validation record.

Contract (D, C, H, R, X). Constructors map typed evidence fields to immutable evidence or result records. `Exactness` maps one of five string values to an enum member. `ConditionalResult` requires a conditional certificate, and `require()` rejects an invalid certificate. Results are records, wrapped values, or enum members. Malformed conditional records raise `ValueError`, while failed certificate requirements raise `ValidationError`.

Guarantees (E, P, B, K). Exactness is recorded, not inferred from arbitrary payloads. `Certificate` alone has the stable `core.certificate` codec. The two generic wrappers have no separate frozen codec. The base path is standard-library-only and storage is linear in recorded residuals, assumptions, and diagnostics.

Evidence and links (V, L). Stable structural verification covers every export. Chapter 5 supplies executable valid, invalid, exact, numerical, and conditional examples. Related symbols are `ValidationError`, contract reports, and certificate-producing domain operations.

A.2 · `ComputationResult`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ComputationResult`. Name-preserving aliases `komorebi_math.v1.ComputationResult` and `komorebi_math.api.v1.ComputationResult`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.ComputationResult`. Profile `A2-C1`.

Manifest signature (s).

```
(value: 'T', certificate: 'Certificate') -> None
```

Definition. A value paired with its execution certificate.

Contract (D, C, H, R, X). Constructors map typed evidence fields to immutable evidence or result records. `Exactness` maps one of five string values to an enum member. `ConditionalResult` requires a conditional certificate, and `require()` rejects an invalid certificate. Results are records, wrapped values, or enum members. Malformed conditional records raise `ValueError`, while failed certificate requirements raise `ValidationError`.

Guarantees (E, P, B, K). Exactness is recorded, not inferred from arbitrary payloads. `Certificate` alone has the stable `core.certificate` codec. The two generic wrappers have no separate frozen codec. The base path is standard-library-only and storage is linear in recorded residuals, assumptions, and diagnostics.

Evidence and links (V, L). Stable structural verification covers every export. Chapter 5 supplies executable valid, invalid, exact, numerical, and conditional examples. Related symbols are `ValidationError`, contract reports, and certificate-producing domain operations.

A.2 · `ConditionalResult`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ConditionalResult`. Name-preserving aliases `komorebi_math.v1.ConditionalResult` and `komorebi_math.api.v1.ConditionalResult`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.ConditionalResult`. Profile `A2-C1`.

Manifest signature (s).

```
(value: 'T', certificate: 'Certificate') -> None
```

Definition. A value whose conclusion depends on explicit unchecked assumptions.

Contract (D, C, H, R, X). Constructors map typed evidence fields to immutable evidence or result records. `Exactness` maps one of five string values to an enum member. `ConditionalResult` requires a conditional certificate, and `require()` rejects an invalid certificate. Results are records, wrapped values, or enum members. Malformed conditional records raise `ValueError`, while failed certificate requirements raise `ValidationError`.

Guarantees (E, P, B, K). Exactness is recorded, not inferred from arbitrary payloads. `Certificate` alone has the stable `core.certificate` codec. The two generic wrappers have no separate frozen codec. The base path is standard-library-only and storage is linear in recorded residuals, assumptions, and diagnostics.

Evidence and links (V, L). Stable structural verification covers every export. Chapter 5 supplies executable valid, invalid, exact, numerical, and conditional examples. Related symbols are `ValidationError`, contract reports, and certificate-producing domain operations.

A.2 · `DimensionError`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.DimensionError`. Name-preserving aliases `komorebi_math.v1.DimensionError` and `komorebi_math.api.v1.DimensionError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.DimensionError`. Profile `A2-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when matrix, vector, or packet dimensions do not agree.

Contract (D, C, H, R, X). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (E, P, B, K). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (V, L). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · `Exactness`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.Exactness`. Name-preserving aliases `komorebi_math.v1.Exactness` and `komorebi_math.api.v1.Exactness`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.Exactness`. Profile `A2-C1`.

Manifest signature (`s`).

```
(*values)
```

Definition. An enum whose members are strings.

Contract (`D, C, H, R, X`). Constructors map typed evidence fields to immutable evidence or result records. `Exactness` maps one of five string values to an enum member. `ConditionalResult` requires a conditional certificate, and `require()` rejects an invalid certificate. Results are records, wrapped values, or enum members. Malformed conditional records raise `ValueError`, while failed certificate requirements raise `ValidationError`.

Guarantees (`E, P, B, K`). Exactness is recorded, not inferred from arbitrary payloads. `Certificate` alone has the stable `core.certificate` codec. The two generic wrappers have no separate frozen codec. The base path is standard-library-only and storage is linear in recorded residuals, assumptions, and diagnostics.

Evidence and links (`V, L`). Stable structural verification covers every export. Chapter 5 supplies executable valid, invalid, exact, numerical, and conditional examples. Related symbols are `ValidationError`, contract reports, and certificate-producing domain operations.

A.2 · `ExactnessError`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.ExactnessError`. Name-preserving aliases `komorebi_math.v1.ExactnessError` and `komorebi_math.api.v1.ExactnessError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.ExactnessError`. Profile `A2-X1`.

Manifest signature (`s`).

```
null
```

Definition. Raised when an exact operation is requested from an inexact backend.

Contract (`D, C, H, R, X`). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (`E, P, B, K`). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (`V, L`). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · `KomorebiMathError`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.KomorebiMathError`. Name-preserving aliases `komorebi_math.v1.KomorebiMathError` and `komorebi_math.api.v1.KomorebiMathError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.KomorebiMathError`. Profile `A2-X1`.

Manifest signature (`s`).

```
null
```

Definition. Base class for all public package exceptions.

Contract (`D, C, H, R, X`). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (`E, P, B, K`). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (`V, L`). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · ResourceLimitError

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ResourceLimitError`. Name-preserving aliases `komorebi_math.v1.ResourceLimitError` and `komorebi_math.api.v1.ResourceLimitError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.ResourceLimitError`. Profile `A2-X1`.

Manifest signature (s).

```
null
```

Definition. Raised before a computation exceeds an explicit resource contract.

Contract (D, C, H, R, X). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (E, P, B, K). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (V, L). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · Settings

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.Settings`. Name-preserving aliases `komorebi_math.v1.Settings` and `komorebi_math.api.v1.Settings`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.config.Settings`. Profile `A2-S1`.

Manifest signature (s).

```
(backend: 'str' = 'numpy', tolerance: 'float' = 1e-10, validate_on_construction: 'bool' = True) -> None
```

Definition. Settings(backend: ‘str’ = ‘numpy’, tolerance: ‘float’ = 1e-10, validate_on_construction: ‘bool’ = True)

Contract (D, C, H, R, X). A context-local `Settings` value is read, replaced, or temporarily installed. Keyword fields must match the dataclass. `configure` converts tolerance to `float`, and the context manager restores the prior value even on exit. Results are settings records or a yielding iterator. Bad replacement fields and failed conversions raise ordinary `TypeError` or `ValueError`.

Guarantees (E, P, B, K). Configuration state is exact process metadata, not a computation certificate and not a frozen portable payload. It uses `contextvars`, has no optional dependency, and each read or replacement is constant-time apart from keyword conversion.

Evidence and links (V, L). The stable semantic fixture checks context restoration. Chapters 3, 5, and 8 show configuration, backend selection, and failure boundaries. Related symbols are `Settings`, `configure`, `get_settings`, and `settings_context`.

A.2 · ValidationError

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ValidationError`. Name-preserving aliases `komorebi_math.v1.ValidationError` and `komorebi_math.api.v1.ValidationError`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.ValidationError`. Profile `A2-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when a mathematical object fails a declared validation rule.

Contract (D, C, H, R, X). Each export is an exception type with inherited constructor semantics, so the frozen manifest intentionally records `null` rather than inventing a signature. The domain is an error condition and the codomain is a raised exception instance. There is no successful return. The defining predicate is stated in the summary.

Guarantees (E, P, B, K). Exactness, portability, and backend execution are not applicable to exception classes. They use the base runtime. Construction cost is proportional only to supplied exception arguments and traceback creation.

Evidence and links (V, L). Chapter 6 maps each stable exception to producers and recovery actions. Structural API and documentation checks verify the type identity and summary. Domain tests verify the operations that raise them.

A.2 · configure

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.configure`. Name-preserving aliases `komorebi_math.v1.configure` and `komorebi_math.api.v1.configure`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.config.configure`. Profile `A2-S1`.

Manifest signature (s).

```
(*, backend: 'str | None' = None, tolerance: 'float | None' = None, validate_on_construction: 'bool | None' = None)
   ↪  -> 'Settings'
```

Definition. Update and return the runtime settings in the current context.

Contract (D, C, H, R, X). A context-local `Settings` value is read, replaced, or temporarily installed. Keyword fields must match the dataclass. `configure` converts tolerance to `float`, and the context manager restores the prior value even on exit. Results are settings records or a yielding iterator. Bad replacement fields and failed conversions raise ordinary `TypeError` or `ValueError`.

Guarantees (E, P, B, K). Configuration state is exact process metadata, not a computation certificate and not a frozen portable payload. It uses `contextvars`, has no optional dependency, and each read or replacement is constant-time apart from keyword conversion.

Evidence and links (V, L). The stable semantic fixture checks context restoration. Chapters 3, 5, and 8 show configuration, backend selection, and failure boundaries. Related symbols are `Settings`, `configure`, `get_settings`, and `settings_context`.

A.2 · get_settings

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.get_settings`. Name-preserving aliases `komorebi_math.v1.get_settings` and `komorebi_math.api.v1.get_settings`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.config.get_settings`. Profile `A2-S1`.

Manifest signature (s).

```
() -> 'Settings'
```

Definition. Return the active runtime settings for the current context.

Contract (D, C, H, R, X). A context-local `Settings` value is read, replaced, or temporarily installed. Keyword fields must match the dataclass. `configure` converts tolerance to `float`, and the context manager restores the prior value even on exit. Results are settings records or a yielding iterator. Bad replacement fields and failed conversions raise ordinary `TypeError` or `ValueError`.

Guarantees (E, P, B, K). Configuration state is exact process metadata, not a computation certificate and not a frozen portable payload. It uses `contextvars`, has no optional dependency, and each read or replacement is constant-time apart from keyword conversion.

Evidence and links (V, L). The stable semantic fixture checks context restoration. Chapters 3, 5, and 8 show configuration, backend selection, and failure boundaries. Related symbols are `Settings`, `configure`, `get_settings`, and `settings_context`.

A.2 · settings_context

Identity (q, a, t, k). Canonical manifest name komorebi_math.stable.settings_context. Name-preserving aliases komorebi_math.v1.settings_context and komorebi_math.api.v1.settings_context. Tier [STABLE]. Manifest kind function. Reflected implementation komorebi_math.config.settings_context. Profile A2-S1.

Manifest signature (s).

```
(**changes: 'object') -> 'Iterator[Settings]'
```

Definition. Temporarily apply runtime setting changes inside a context manager.

Contract (D, C, H, R, X). A context-local Settings value is read, replaced, or temporarily installed. Keyword fields must match the dataclass. configure converts tolerance to float, and the context manager restores the prior value even on exit. Results are settings records or a yielding iterator. Bad replacement fields and failed conversions raise ordinary TypeError or ValueError.

Guarantees (E, P, B, K). Configuration state is exact process metadata, not a computation certificate and not a frozen portable payload. It uses contextvars, has no optional dependency, and each read or replacement is constant-time apart from keyword conversion.

Evidence and links (V, L). The stable semantic fixture checks context restoration. Chapters 3, 5, and 8 show configuration, backend selection, and failure boundaries. Related symbols are Settings, configure, get_settings, and settings_context.

A.3 Operator and packet foundations

A.3 · Arrow

Identity (q, a, t, k). Canonical manifest name komorebi_math.stable.Arrow. Name-preserving aliases komorebi_math.v1.Arrow and komorebi_math.api.v1.Arrow. Tier [STABLE]. Manifest kind class. Reflected implementation komorebi_math.core.grammar.Arrow. Profile A3-G1.

Manifest signature (s).

```
(name: 'str', source: 'str', target: 'str') -> None
```

Definition. Arrow(name: ‘str’, source: ‘str’, target: ‘str’)

Contract (D, C, H, R, X). Finite vertices, typed arrows, paths, and parallel linear relations map to immutable grammar records. Names, sources, targets, and composability must agree. Malformed paths or relations are rejected by validation. Results are structural records rather than executed matrices.

Guarantees (E, P, B, K). The structural layer is exact for its finite labels and coefficients, has no frozen codec on this stable surface, and uses no optional backend. Work and storage scale with the supplied vertices, arrows, path length, and relation terms. No tighter public bound is promised.

Evidence and links (V, L). The typed-operator semantic fixture and Chapters 9 through 10 exercise construction, composition, and rejection paths. Related symbols are OperatorRealization, PacketSystem, and the grammar recipes in Chapter 64.

A.3 · OperatorGrammar

Identity (q, a, t, k). Canonical manifest name komorebi_math.stable.OperatorGrammar. Name-preserving aliases komorebi_math.v1.OperatorGrammar and komorebi_math.api.v1.OperatorGrammar. Tier [STABLE]. Manifest kind class. Reflected implementation komorebi_math.core.grammar.OperatorGrammar. Profile A3-G1.

Manifest signature (s).

```
(vertices: 'Iterable[str]', arrows: 'Mapping[str, tuple[str, str]] | Iterable[Arrow]', relations:
    ↪ 'Iterable[OperatorRelation]' = ()) -> 'None'
```

Definition. A finite quiver with optional linear path relations.

Contract (D, C, H, R, X). Finite vertices, typed arrows, paths, and parallel linear relations map to immutable grammar records. Names, sources, targets, and composability must agree. Malformed paths or relations are rejected by validation. Results are structural records rather than executed matrices.

Guarantees (E, P, B, K). The structural layer is exact for its finite labels and coefficients, has no frozen codec on this stable surface, and uses no optional backend. Work and storage scale with the supplied vertices, arrows, path length, and relation terms. No tighter public bound is promised.

Evidence and links (V, L). The typed-operator semantic fixture and Chapters 9 through 10 exercise construction, composition, and rejection paths. Related symbols are `OperatorRealization`, `PacketSystem`, and the grammar recipes in Chapter 64.

A.3 · `OperatorRealization`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.OperatorRealization`. Name-preserving aliases `komorebi_math.v1.OperatorRealization` and `komorebi_math.api.v1.OperatorRealization`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.realization.OperatorRealization`. Profile `A3-R1`.

Manifest signature (s).

```
(grammar: 'OperatorGrammar', spaces: 'Mapping[str, int]', operators: 'Mapping[str, Any]', *, backend: 'str |
    ↪ LinearAlgebraBackend | None' = None, validate_relations: 'bool' = True, tolerance: 'float | None' = None) ->
    ↪ 'None'
```

Definition. Assign vector space dimensions and matrices to a typed grammar.

Contract (D, C, H, R, X). A typed grammar, declared space dimensions, and arrow matrices map to an `OperatorRealization`. Evaluating declared relations maps to `RelationResidual` records. Parallel shapes and relations must agree, and optional validation may require residuals within tolerance. Results are realized matrices and named residual records. Dimension, backend, or validation failures are explicit.

Guarantees (E, P, B, K). The certificate meaning is exact on an exact backend and tolerance-qualified on a numerical backend. These records have no frozen stable codec. NumPy is the default with optional exact backends. Dense relation evaluation is bounded by the declared matrix products and relation count.

Evidence and links (V, L). The stable typed-operator semantic case and Chapters 9 through 10 verify relation realization. Related symbols are the grammar records, `Certificate`, `PacketSystem`, and `SeedSystem`.

A.3 · `OperatorRelation`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.OperatorRelation`. Name-preserving aliases `komorebi_math.v1.OperatorRelation` and `komorebi_math.api.v1.OperatorRelation`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.grammar.OperatorRelation`. Profile `A3-G1`.

Manifest signature (s).

```
(name: 'str', terms: 'tuple[tuple[Any, OperatorWord], ...]') -> None
```

Definition. A linear relation among parallel operator words.

Contract (D, C, H, R, X). Finite vertices, typed arrows, paths, and parallel linear relations map to immutable grammar records. Names, sources, targets, and composability must agree. Malformed paths or relations are rejected by validation. Results are structural records rather than executed matrices.

Guarantees (E, P, B, K). The structural layer is exact for its finite labels and coefficients, has no frozen codec on this stable surface, and uses no optional backend. Work and storage scale with the supplied vertices, arrows, path length, and relation terms. No tighter public bound is promised.

Evidence and links (V, L). The typed-operator semantic fixture and Chapters 9 through 10 exercise construction, composition, and rejection paths. Related symbols are `OperatorRealization`, `PacketSystem`, and the grammar recipes in Chapter 64.

A.3 · `OperatorWord`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.OperatorWord`. Name-preserving aliases `komorebi_math.v1.OperatorWord` and `komorebi_math.api.v1.OperatorWord`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.grammar.OperatorWord`. Profile `A3-G1`.

Manifest signature (s).

```
(arrows: 'tuple[str, ...]', source: 'str', target: 'str') -> None
```

Definition. A typed path written in the order in which arrows act.

Contract (D, C, H, R, X). Finite vertices, typed arrows, paths, and parallel linear relations map to immutable grammar records. Names, sources, targets, and composability must agree. Malformed paths or relations are rejected by validation. Results are structural records rather than executed matrices.

Guarantees (E, P, B, K). The structural layer is exact for its finite labels and coefficients, has no frozen codec on this stable surface, and uses no optional backend. Work and storage scale with the supplied vertices, arrows, path length, and relation terms. No tighter public bound is promised.

Evidence and links (V, L). The typed-operator semantic fixture and Chapters 9 through 10 exercise construction, composition, and rejection paths. Related symbols are `OperatorRealization`, `PacketSystem`, and the grammar recipes in Chapter 64.

A.3 · `PacketCoordinates`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PacketCoordinates`. Name-preserving aliases `komorebi_math.v1.PacketCoordinates` and `komorebi_math.api.v1.PacketCoordinates`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.packets.PacketCoordinates`. Profile `A3-P1`.

Manifest signature (s).

```
(system: "'PacketSystem'", values: 'tuple[Any, ...]') -> None
```

Definition. PacketCoordinates(system: “ ‘PacketSystem’ ”, values: ‘tuple[Any, …]’)

Contract (D, C, H, R, X). A complete family of finite projectors, packet coordinates, or a rectangular block operator maps ambient vectors and operators to packet-indexed records. Dimensions, idempotence, annihilation, completeness, names, and source/target systems are checked according to construction options. Results are packet systems, coordinate tuples, or block arrays. Invalid shapes and identities raise validation or dimension errors.

Guarantees (E, P, B, K). Exactness follows the selected backend and tolerance. No stable codec is registered for these three records. NumPy is the default backend, with exact object paths available where supported. Matrix work scales with ambient dimension and packet count.

Evidence and links (V, L). Chapters 8, 11, and 12 provide constructor and transfer examples. Stable semantic cases cover packet transfer through analysis/synthesis. Related symbols are `OperatorRealization`, `TransferPath`, and refinement records.

A.3 · `PacketOperator`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PacketOperator`. Name-preserving aliases `komorebi_math.v1.PacketOperator` and `komorebi_math.api.v1.PacketOperator`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.operators.PacketOperator`. Profile `A3-P1`.

Manifest signature (`s`).

```
(source: 'PacketSystem', target: 'PacketSystem', blocks: 'tuple[tuple[Any, ...], ...]') -> None
```

Definition. An operator represented by all target by source packet blocks.

Contract (`D, C, H, R, X`). A complete family of finite projectors, packet coordinates, or a rectangular block operator maps ambient vectors and operators to packet-indexed records. Dimensions, idempotence, annihilation, completeness, names, and source/target systems are checked according to construction options. Results are packet systems, coordinate tuples, or block arrays. Invalid shapes and identities raise validation or dimension errors.

Guarantees (`E, P, B, K`). Exactness follows the selected backend and tolerance. No stable codec is registered for these three records. NumPy is the default backend, with exact object paths available where supported. Matrix work scales with ambient dimension and packet count.

Evidence and links (`V, L`). Chapters 8, 11, and 12 provide constructor and transfer examples. Stable semantic cases cover packet transfer through analysis/synthesis. Related symbols are `OperatorRealization`, `TransferPath`, and refinement records.

A.3 · `PacketSystem`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PacketSystem`. Name-preserving aliases `komorebi_math.v1.PacketSystem` and `komorebi_math.api.v1.PacketSystem`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.packets.PacketSystem`. Profile `A3-P1`.

Manifest signature (`s`).

```
(projectors: 'Sequence[Any]', *, names: 'Sequence[str] | None' = None, backend: 'str | LinearAlgebraBackend | None'
   ↪  = None, tolerance: 'float | None' = None, validate: 'bool | None' = None) -> 'None'
```

Definition. A complete finite family of pairwise annihilating idempotents.

Contract (`D, C, H, R, X`). A complete family of finite projectors, packet coordinates, or a rectangular block operator maps ambient vectors and operators to packet-indexed records. Dimensions, idempotence, annihilation, completeness, names, and source/target systems are checked according to construction options. Results are packet systems, coordinate tuples, or block arrays. Invalid shapes and identities raise validation or dimension errors.

Guarantees (`E, P, B, K`). Exactness follows the selected backend and tolerance. No stable codec is registered for these three records. NumPy is the default backend, with exact object paths available where supported. Matrix work scales with ambient dimension and packet count.

Evidence and links (`V, L`). Chapters 8, 11, and 12 provide constructor and transfer examples. Stable semantic cases cover packet transfer through analysis/synthesis. Related symbols are `OperatorRealization`, `TransferPath`, and refinement records.

A.3 · `RelationResidual`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.RelationResidual`. Name-preserving aliases `komorebi_math.v1.RelationResidual` and `komorebi_math.api.v1.RelationResidual`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.realization.RelationResidual`. Profile `A3-R1`.

Manifest signature (`s`).

```
(name: 'str', residual: 'float', satisfied: 'bool') -> None
```

Definition. RelationResidual(name: ‘str’, residual: ‘float’, satisfied: ‘bool’)

Contract (`D, C, H, R, X`). A typed grammar, declared space dimensions, and arrow matrices map to an `OperatorRealization`. Evaluating declared relations maps to `RelationResidual` records. Parallel shapes and relations must agree, and optional validation may require residuals within tolerance. Results are realized matrices and named residual records. Dimension, backend, or validation failures are explicit.

Guarantees (E, P, B, K). The certificate meaning is exact on an exact backend and tolerance-qualified on a numerical backend. These records have no frozen stable codec. NumPy is the default with optional exact backends. Dense relation evaluation is bounded by the declared matrix products and relation count.

Evidence and links (V, L). The stable typed-operator semantic case and Chapters 9 through 10 verify relation realization. Related symbols are the grammar records, `Certificate`, `PacketSystem`, and `SeedSystem`.

A.3 · SeedSystem

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.SeedSystem`. Name-preserving aliases `komorebi_math.v1.SeedSystem` and `komorebi_math.api.v1.SeedSystem`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.seeds.SeedSystem`. Profile `A3-SD`.

Manifest signature (s).

```
(operators: 'Mapping[str, Any] | Sequence[Any]', seeds: 'Sequence[Any]', *, backend: 'str | LinearAlgebraBackend |
    ↪ None' = None, tolerance: 'float | None' = None) -> 'None'
```

Definition. A finite family of operators acting on a finite seed family.

Contract (D, C, H, R, X). A finite operator family and finite seed family map to their generated action system. Operator and seed dimensions must agree and backend coercion must succeed. The result stores generated words, vectors, and relations. Invalid dimensions, relations, or unavailable backends fail explicitly.

Guarantees (E, P, B, K). Exactness follows the active backend. The record has no frozen stable codec. Time and memory grow with the finite word horizon, operator count, seed count, and ambient dimension, subject to caller-selected bounds.

Evidence and links (V, L). Chapter 10 supplies generated-action examples and Chapter 64 links them to exact algebra recipes. Stable structural verification covers the symbol. Core and backend tests cover behavior.

A.3 · TransferGraph

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.TransferGraph`. Name-preserving aliases `komorebi_math.v1.TransferGraph` and `komorebi_math.api.v1.TransferGraph`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.graphs.TransferGraph`. Profile `A3-GR`.

Manifest signature (s).

```
(adjacency: 'Sequence[Sequence[bool | int]]', *, names: 'Sequence[str] | None' = None) -> 'None'
```

Definition. A finite directed graph with adjacency stored as source by target.

Contract (D, C, H, R, X). A finite adjacency matrix maps to a directed transfer graph. The matrix must be square and optional names must match its size. The result is a finite graph with path and reachability operations. Invalid shapes or names raise validation errors.

Guarantees (E, P, B, K). Graph structure is exact Boolean data, is not assigned a frozen stable codec, and uses the base numerical stack only for array storage. Construction is quadratic in vertex count for a dense adjacency matrix. Later path work depends on requested length.

Evidence and links (V, L). Chapter 11 connects transfer graphs to packet blocks and path contributions. Structural stable checks cover the export. Graph and transfer tests cover semantics and failures.

A.3 · TransferPath

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.TransferPath`. Name-preserving aliases `komorebi_math.v1.TransferPath` and `komorebi_math.api.v1.TransferPath`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.core.transfer.TransferPath`. Profile `A3-T1`.

Manifest signature (s).

```
(vertices: 'tuple[int, ...]', product: 'Any') -> None
```

Definition. TransferPath(vertices: 'tuple[int, …]', product: 'Any')

Contract (D, C, H, R, X). A packet operator plus source, target, and nonnegative path length maps either to all nonzero `TransferPath` contributions or to their summed block in a certified result. Packet compatibility, index ranges, and length are required. Invalid inputs raise validation or dimension errors. Numerical reconstruction can fail its tolerance certificate.

Guarantees (E, P, B, K). Structural enumeration is exact. Summed block certification follows backend exactness and tolerance. No stable codec is registered for `TransferPath` or the returned wrapper. Cost grows with admissible paths and matrix-product dimensions and is therefore exponential in unconstrained path length in the worst case.

Evidence and links (V, L). The analysis/synthesis/transfer semantic case and Chapter 11 verify path-to-block reconstruction. Related symbols are `PacketOperator`, `TransferGraph`, `ComputationResult`, and Chapter 64 transfer recipes.

A.3 · `block_from_paths`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.block_from_paths`. Name-preserving aliases `komorebi_math.v1.block_from_paths` and `komorebi_math.api.v1.block_from_paths`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.core.transfer.block_from_paths`. Profile `A3-T1`.

Manifest signature (s).

```
(operator: 'PacketOperator', *, source: 'int', target: 'int', length: 'int', tolerance: 'float | None' = None) ->
   ↪ 'ComputationResult[Any]'
```

Definition. Reconstruct one block of an operator power from packet paths.

Contract (D, C, H, R, X). A packet operator plus source, target, and nonnegative path length maps either to all nonzero `TransferPath` contributions or to their summed block in a certified result. Packet compatibility, index ranges, and length are required. Invalid inputs raise validation or dimension errors. Numerical reconstruction can fail its tolerance certificate.

Guarantees (E, P, B, K). Structural enumeration is exact. Summed block certification follows backend exactness and tolerance. No stable codec is registered for `TransferPath` or the returned wrapper. Cost grows with admissible paths and matrix-product dimensions and is therefore exponential in unconstrained path length in the worst case.

Evidence and links (V, L). The analysis/synthesis/transfer semantic case and Chapter 11 verify path-to-block reconstruction. Related symbols are `PacketOperator`, `TransferGraph`, `ComputationResult`, and Chapter 64 transfer recipes.

A.3 · `path_contributions`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.path_contributions`. Name-preserving aliases `komorebi_math.v1.path_contributions` and `komorebi_math.api.v1.path_contributions`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.core.transfer.path_contributions`. Profile `A3-T1`.

Manifest signature (s).

```
(operator: 'PacketOperator', *, source: 'int', target: 'int', length: 'int', tolerance: 'float | None' = None) ->
   ↪ 'tuple[TransferPath, ...]'
```

Definition. Return every nonzero structural path contribution of fixed length.

Contract (D, C, H, R, X). A packet operator plus source, target, and nonnegative path length maps either to all nonzero `TransferPath` contributions or to their summed block in a certified result. Packet compatibility, index ranges, and length are required. Invalid inputs raise validation or dimension errors. Numerical reconstruction can fail its tolerance certificate.

Guarantees (E, P, B, K). Structural enumeration is exact. Summed block certification follows backend exactness and tolerance. No stable codec is registered for `TransferPath` or the returned wrapper. Cost grows with admissible paths and matrix-product dimensions and is therefore exponential in unconstrained path length in the worst case.

Evidence and links (V, L). The analysis/synthesis/transfer semantic case and Chapter 11 verify path-to-block reconstruction. Related symbols are `PacketOperator`, `TransferGraph`, `ComputationResult`, and Chapter 64 transfer recipes.

A.4 Coordinates and analysis-synthesis

A.4 · `AnalysisSynthesisBlocks`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.AnalysisSynthesisBlocks`. Name-preserving aliases `komorebi_math.v1.AnalysisSynthesisBlocks` and `komorebi_math.api.v1.AnalysisSynthesisBlocks`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.analysis_synthesis.AnalysisSynthesisBlocks`. Profile `A4-AS`.

Manifest signature (s).

```
(system: "'AnalysisSynthesisSystem'", groups: 'tuple[tuple[int, ...], ...]', blocks: 'tuple[tuple[np.ndarray,
   ↪  ...], ...]', operator: 'np.ndarray') -> None
```

Definition. Packet blocks of one operator under a declared analysis/synthesis atlas.

Contract (D, C, H, R, X). Finite analysis and synthesis matrices map ambient vectors/operators to redundant coordinates and packet blocks. Matrix shapes must compose and `S A = I` must hold within the declared tolerance. Results are an analysis/synthesis system or grouped block record. Shape or reconstruction failures raise dimension or validation errors.

Guarantees (E, P, B, K). The implementation is tolerance-qualified numerical linear algebra. `AnalysisSynthesisSystem` has codec `coordinates.analysis_synthesis` version 1. `AnalysisSynthesisBlocks` has no separate codec. NumPy is required, and dense costs follow the displayed matrix products and block extraction.

Evidence and links (V, L). The first stable semantic case exercises analysis, synthesis, and transfer blocks. Chapter 20 gives minimal, redundant, adversarial, and portable examples. Related symbols are `PacketSystem`, `CoordinateAtlas`, and `block_from_paths`.

A.4 · `AnalysisSynthesisSystem`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.AnalysisSynthesisSystem`. Name-preserving aliases `komorebi_math.v1.AnalysisSynthesisSystem` and `komorebi_math.api.v1.AnalysisSynthesisSystem`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.analysis_synthesis.AnalysisSynthesisSystem`. Profile `A4-AS`.

Manifest signature (s).

```
(analysis: 'np.ndarray', synthesis: 'np.ndarray', source: 'str' = 'source', coordinates: 'str' = 'coordinates',
   ↪  tolerance: 'float' = 1e-12, theorem: 'str' = 'KM-AS-01') -> None
```

Definition. A finite analysis map `A` and synthesis map `S` with `S A = I`.

Contract (D, C, H, R, X). Finite analysis and synthesis matrices map ambient vectors/operators to redundant coordinates and packet blocks. Matrix shapes must compose and `S A = I` must hold within the declared tolerance. Results are an analysis/synthesis system or grouped block record. Shape or reconstruction failures raise dimension or validation errors.

Guarantees (E, P, B, K). The implementation is tolerance-qualified numerical linear algebra. `AnalysisSynthesisSystem` has codec `coordinates.analysis_synthesis` version 1. `AnalysisSynthesisBlocks` has no separate codec. NumPy is required, and dense costs follow the displayed matrix products and block extraction.

Evidence and links (V, L). The first stable semantic case exercises analysis, synthesis, and transfer blocks. Chapter 20 gives minimal, redundant, adversarial, and portable examples. Related symbols are `PacketSystem`, `CoordinateAtlas`, and `block_from_paths`.

A.4 · CoordinateAtlas

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.CoordinateAtlas`. Name-preserving aliases `komorebi_math.v1.CoordinateAtlas` and `komorebi_math.api.v1.CoordinateAtlas`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.basis.CoordinateAtlas`. Profile `A4-B1`.

Manifest signature (s).

```
(name: 'str' = 'coordinate atlas') -> None
```

Definition. A graph of exact coordinate systems and composable transforms.

Contract (D, C, H, R, X). Rational basis vectors and exact transform edges map to finite bases or an atlas of composable coordinate systems. Vectors must share dimension and be linearly independent. Atlas paths must have compatible endpoints. Results are exact basis and atlas records. Invalid dimensions, dependence, or missing paths fail validation.

Guarantees (E, P, B, K). The finite rational path is exact. `FiniteBasis` and `CoordinateAtlas` have version-1 stable codecs. The base path uses `fractions` and finite matrix operations. Construction and conversion costs are bounded by basis dimension and atlas path length.

Evidence and links (V, L). The exact-basis roundtrip semantic case and Chapters 15 and 20 verify these objects. Related symbols are coordinate transforms, `basis_from_matrix`, `standard_basis`, and exact-coordinate recipes.

A.4 · CoordinateTransform

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.CoordinateTransform`. Name-preserving aliases `komorebi_math.v1.CoordinateTransform` and `komorebi_math.api.v1.CoordinateTransform`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.transform.CoordinateTransform`. Profile `A4-T1`. Deliberate cross-name alias: `komorebi_math.stable.ExactCoordinateTransform`. Both export cards remain present.

Manifest signature (s).

```
(source: 'str', target: 'str', matrix: 'Matrix', theorem: 'str', description: 'str' = '') -> None
```

Definition. An exact matrix that maps source coordinates to target coordinates.

Contract (D, C, H, R, X). A labeled finite matrix maps coordinates from a named source to a named target. Exact transforms require exact matrix entries. Numeric transforms use arrays and a tolerance. Results are transform records with composition and application operations. Incompatible dimensions, singular assumptions, or failed tolerance checks raise explicit errors.

Guarantees (E, P, B, K). `CoordinateTransform` and its deliberate alias `ExactCoordinateTransform` share codec `coordinates.transform` version 1. `NumericCoordinateTransform` uses `coordinates.numeric_transform` version 1. Exact paths use rational arithmetic and numerical paths use NumPy. Dense application and composition have ordinary matrix costs.

Evidence and links (V, L). Chapters 15 through 20 provide exact and numerical transform examples and failure cases. The exact-basis semantic fixture covers a roundtrip. Related constructors are connection, difference, formal, and standard-basis functions.

A.4 · ExactCoordinateTransform

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ExactCoordinateTransform`. Name-preserving aliases `komorebi_math.v1.ExactCoordinateTransform` and `komorebi_math.api.v1.ExactCoordinateTransform`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.transform.CoordinateTransform`. Profile `A4-T1`. Deliberate cross-name alias: `komorebi_math.stable.CoordinateTransform`. Both export cards remain present.

Manifest signature (s).

```
(source: 'str', target: 'str', matrix: 'Matrix', theorem: 'str', description: 'str' = '') -> None
```

Definition. An exact matrix that maps source coordinates to target coordinates.

Contract (D, C, H, R, X). A labeled finite matrix maps coordinates from a named source to a named target. Exact transforms require exact matrix entries. Numeric transforms use arrays and a tolerance. Results are transform records with composition and application operations. Incompatible dimensions, singular assumptions, or failed tolerance checks raise explicit errors.

Guarantees (E, P, B, K). `CoordinateTransform` and its deliberate alias `ExactCoordinateTransform` share codec `coordinates.transform` version 1. `NumericCoordinateTransform` uses `coordinates.numeric_transform` version 1. Exact paths use rational arithmetic and numerical paths use NumPy. Dense application and composition have ordinary matrix costs.

Evidence and links (V, L). Chapters 15 through 20 provide exact and numerical transform examples and failure cases. The exact-basis semantic fixture covers a roundtrip. Related constructors are connection, difference, formal, and standard-basis functions.

A.4 · `FiniteBasis`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.FiniteBasis`. Name-preserving aliases `komorebi_math.v1.FiniteBasis` and `komorebi_math.api.v1.FiniteBasis`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.basis.FiniteBasis`. Profile `A4-B1`.

Manifest signature (s).

```
(name: 'str', vectors: 'tuple[Vector, ...]', labels: 'tuple[str, ...]' = (), description: 'str' = '') -> None
```

Definition. A linearly independent finite basis inside a rational ambient space.

Contract (D, C, H, R, X). Rational basis vectors and exact transform edges map to finite bases or an atlas of composable coordinate systems. Vectors must share dimension and be linearly independent. Atlas paths must have compatible endpoints. Results are exact basis and atlas records. Invalid dimensions, dependence, or missing paths fail validation.

Guarantees (E, P, B, K). The finite rational path is exact. `FiniteBasis` and `CoordinateAtlas` have version-1 stable codecs. The base path uses `fractions` and finite matrix operations. Construction and conversion costs are bounded by basis dimension and atlas path length.

Evidence and links (V, L). The exact-basis roundtrip semantic case and Chapters 15 and 20 verify these objects. Related symbols are coordinate transforms, `basis_from_matrix`, `standard_basis`, and exact-coordinate recipes.

A.4 · `FormalCoordinateChange`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.FormalCoordinateChange`. Name-preserving aliases `komorebi_math.v1.FormalCoordinateChange` and `komorebi_math.api.v1.FormalCoordinateChange`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.formal.FormalCoordinateChange`. Profile `A4-F1`.

Manifest signature (s).

```
(name: 'str', coefficients: 'Vector', source: 'str' = 'source formal coordinate', target: 'str' = 'target formal
   ↪ coordinate') -> None
```

Definition. A finite exact jet `phi(z)=a_1 z+a_2 z^2+...`.

Contract (D, C, H, R, X). A finite exact coefficient vector with nonzero linear term maps to a formal coordinate jet. Coefficients must belong to the accepted exact scalar protocol and satisfy invertibility at first order. The result is a `FormalCoordinateChange`. Malformed or noninvertible data raise validation errors.

Guarantees (E, P, B, K). The declared finite-jet algebra is exact and has codec `coordinates.formal_change` version 1. It uses base exact arithmetic. Composition and inversion costs grow with truncation order and coefficient arithmetic.

Evidence and links (V, L). Chapters 15 through 16 give construction, composition, and failure examples. Stable structural checks cover both exports. Coordinate tests verify finite-jet identities and persistence.

A.4 · NumericCoordinateTransform

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.NumericCoordinateTransform`. Name-preserving aliases `komorebi_math.v1.NumericCoordinateTransform` and `komorebi_math.api.v1.NumericCoordinateTransform`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.coordinates.numeric.NumericCoordinateTransform`. Profile `A4-T1`.

Manifest signature (s).

```
(source: 'str', target: 'str', matrix: 'np.ndarray', theorem: 'str' = 'CC.NM1', description: 'str' = '', tolerance:
   ↪ 'float' = 1e-12) -> None
```

Definition. A finite numerical matrix between coordinate systems.

Contract (D, C, H, R, X). A labeled finite matrix maps coordinates from a named source to a named target. Exact transforms require exact matrix entries. Numeric transforms use arrays and a tolerance. Results are transform records with composition and application operations. Incompatible dimensions, singular assumptions, or failed tolerance checks raise explicit errors.

Guarantees (E, P, B, K). `CoordinateTransform` and its deliberate alias `ExactCoordinateTransform` share codec `coordinates.transform` version 1. `NumericCoordinateTransform` uses `coordinates.numeric_transform` version 1. Exact paths use rational arithmetic and numerical paths use NumPy. Dense application and composition have ordinary matrix costs.

Evidence and links (V, L). Chapters 15 through 20 provide exact and numerical transform examples and failure cases. The exact-basis semantic fixture covers a roundtrip. Related constructors are connection, difference, formal, and standard-basis functions.

A.4 · basis_from_matrix

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.basis_from_matrix`. Name-preserving aliases `komorebi_math.v1.basis_from_matrix` and `komorebi_math.api.v1.basis_from_matrix`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.coordinates.basis.basis_from_matrix`. Profile `A4-B1`.

Manifest signature (s).

```
(name: 'str', matrix: 'Iterable[Iterable[Scalar]]', *, labels: 'Sequence[str]' = (), description: 'str' = '') ->
   ↪ 'FiniteBasis'
```

Definition. Construct a basis from a matrix whose columns are basis vectors.

Contract (D, C, H, R, X). Rational basis vectors and exact transform edges map to finite bases or an atlas of composable coordinate systems. Vectors must share dimension and be linearly independent. Atlas paths must have compatible endpoints. Results are exact basis and atlas records. Invalid dimensions, dependence, or missing paths fail validation.

Guarantees (E, P, B, K). The finite rational path is exact. `FiniteBasis` and `CoordinateAtlas` have version-1 stable codecs. The base path uses `fractions` and finite matrix operations. Construction and conversion costs are bounded by basis dimension and atlas path length.

Evidence and links (V, L). The exact-basis roundtrip semantic case and Chapters 15 and 20 verify these objects. Related symbols are coordinate transforms, `basis_from_matrix`, `standard_basis`, and exact-coordinate recipes.

A.4 · connection_transform

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.connection_transform`. Name-preserving aliases `komorebi_math.v1.connection_transform` and `komorebi_math.api.v1.connection_transform`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.coordinates.polynomials.connection_transform`. Profile `A4-C1`.

Manifest signature (s).

```
(source: 'PolynomialFamily', target: 'PolynomialFamily', degree: 'int', *, budget: 'CoordinateBudget' =
    ↪ CoordinateBudget(maximum_matrix_dimension=512, maximum_polynomial_degree=512, maximum_horizon=4096,
    ↪ maximum_exact_entries=1000000)) -> 'CoordinateTransform'
```

Definition. Return target coordinates of source basis vectors through one degree.

Contract (D, C, H, R, X). A family name, matrix, or finite size/degree maps to a built-in polynomial family or exact connection/difference transform. Names must resolve, sizes and degrees must be nonnegative, matrices must define a basis, and coordinate budgets must permit allocation. Results are families, bases, or transforms. Unknown names and exceeded budgets fail explicitly.

Guarantees (E, P, B, K). The intended combinatorial and polynomial transformations are exact. Returned stable basis/transform types are portable through their own codecs. Base exact arithmetic is used, with optional symbolic support inside family implementations. Dense work is bounded by degree and the declared coordinate budget.

Evidence and links (V, L). Chapters 16 through 17 contain connection and forward-difference examples. The exact-basis semantic case and coordinate tests verify roundtrips. Related symbols are `FiniteBasis`, `CoordinateTransform`, and `get_polynomial_family`.

A.4 · formal_coordinate_from_iterable

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.formal_coordinate_from_iterable`. Name-preserving aliases `komorebi_math.v1.formal_coordinate_from_iterable` and `komorebi_math.api.v1.formal_coordinate_from_iterable`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.coordinates.formal.formal_coordinate_from_iterable`. Profile `A4-F1`.

Manifest signature (s).

```
(coefficients: 'Iterable[Scalar]', *, name: 'str' = 'custom formal coordinate', source: 'str' = 'source formal
    ↪ coordinate', target: 'str' = 'target formal coordinate') -> 'FormalCoordinateChange'
```

Definition. Construct a formal coordinate change from exact coefficients.

Contract (D, C, H, R, X). A finite exact coefficient vector with nonzero linear term maps to a formal coordinate jet. Coefficients must belong to the accepted exact scalar protocol and satisfy invertibility at first order. The result is a `FormalCoordinateChange`. Malformed or noninvertible data raise validation errors.

Guarantees (E, P, B, K). The declared finite-jet algebra is exact and has codec `coordinates.formal_change` version 1. It uses base exact arithmetic. Composition and inversion costs grow with truncation order and coefficient arithmetic.

Evidence and links (V, L). Chapters 15 through 16 give construction, composition, and failure examples. Stable structural checks cover both exports. Coordinate tests verify finite-jet identities and persistence.

A.4 · forward_difference_transform

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.forward_difference_transform`. Name-preserving aliases `komorebi_math.v1.forward_difference_transform` and `komorebi_math.api.v1.forward_difference_transform`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.coordinates.combinatorial.forward_difference_transform`. Profile `A4-C1`.

Manifest signature (`s`).

```
(size: 'int', *, budget: 'CoordinateBudget' = CoordinateBudget(maximum_matrix_dimension=512,
    ↪ maximum_polynomial_degree=512, maximum_horizon=4096, maximum_exact_entries=1000000)) ->
    ↪ 'CoordinateTransform'
```

Definition. Map sampled values `f(0),...,f(N)` to forward differences at zero.

Contract (`D, C, H, R, X`). A family name, matrix, or finite size/degree maps to a built-in polynomial family or exact connection/difference transform. Names must resolve, sizes and degrees must be nonnegative, matrices must define a basis, and coordinate budgets must permit allocation. Results are families, bases, or transforms. Unknown names and exceeded budgets fail explicitly.

Guarantees (`E, P, B, K`). The intended combinatorial and polynomial transformations are exact. Returned stable basis/transform types are portable through their own codecs. Base exact arithmetic is used, with optional symbolic support inside family implementations. Dense work is bounded by degree and the declared coordinate budget.

Evidence and links (`V, L`). Chapters 16 through 17 contain connection and forward-difference examples. The exact-basis semantic case and coordinate tests verify roundtrips. Related symbols are `FiniteBasis`, `CoordinateTransform`, and `get_polynomial_family`.

A.4 · `get_polynomial_family`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.get_polynomial_family`. Name-preserving aliases `komorebi_math.v1.get_polynomial_family` and `komorebi_math.api.v1.get_polynomial_family`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.coordinates.classical.get_polynomial_family`. Profile `A4-C1`.

Manifest signature (`s`).

```
(name: 'str') -> 'PolynomialFamily'
```

Definition. Return one built-in graded polynomial family by name or short alias.

Contract (`D, C, H, R, X`). A family name, matrix, or finite size/degree maps to a built-in polynomial family or exact connection/difference transform. Names must resolve, sizes and degrees must be nonnegative, matrices must define a basis, and coordinate budgets must permit allocation. Results are families, bases, or transforms. Unknown names and exceeded budgets fail explicitly.

Guarantees (`E, P, B, K`). The intended combinatorial and polynomial transformations are exact. Returned stable basis/transform types are portable through their own codecs. Base exact arithmetic is used, with optional symbolic support inside family implementations. Dense work is bounded by degree and the declared coordinate budget.

Evidence and links (`V, L`). Chapters 16 through 17 contain connection and forward-difference examples. The exact-basis semantic case and coordinate tests verify roundtrips. Related symbols are `FiniteBasis`, `CoordinateTransform`, and `get_polynomial_family`.

A.4 · `standard_basis`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.standard_basis`. Name-preserving aliases `komorebi_math.v1.standard_basis` and `komorebi_math.api.v1.standard_basis`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.coordinates.basis.standard_basis`. Profile `A4-B1`.

Manifest signature (`s`).

```
(dimension: 'int', *, name: 'str' = 'standard') -> 'FiniteBasis'
```

Definition. Return the standard basis of a rational vector space.

Contract (`D, C, H, R, X`). Rational basis vectors and exact transform edges map to finite bases or an atlas of composable coordinate systems. Vectors must share dimension and be linearly independent. Atlas paths must have compatible endpoints. Results are exact basis and atlas records. Invalid dimensions, dependence, or missing paths fail validation.

Guarantees (E, P, B, K). The finite rational path is exact. `FiniteBasis` and `CoordinateAtlas` have version-1 stable codecs. The base path uses `fractions` and finite matrix operations. Construction and conversion costs are bounded by basis dimension and atlas path length.

Evidence and links (V, L). The exact-basis roundtrip semantic case and Chapters 15 and 20 verify these objects. Related symbols are coordinate transforms, `basis_from_matrix`, `standard_basis`, and exact-coordinate recipes.

A.5 Refinement, residue, polyphase, and arithmetic polyphase

A.5 · `ArithmeticPolyphase`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ArithmeticPolyphase`. Name-preserving aliases `komorebi_math.v1.ArithmeticPolyphase` and `komorebi_math.api.v1.ArithmeticPolyphase`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.arithmetic.polyphase.ArithmeticPolyphase`. Profile `A5-A1`.

Manifest signature (s).

```
(modulus: 'int', channels: 'tuple[tuple[Number, ...], ...]', length: 'int') -> None
```

Definition. Exact residue channels of one finite arithmetic sequence.

Contract (D, C, H, R, X). Finite exact sequences, moduli, residue channels, mixed-radix digits, or Mahler coefficients map to arithmetic polyphase records and exact address conversions. Moduli/radices must be positive, digits and addresses in range, and channel lengths consistent. Results are integers, tuples, channels, or `MahlerSeries`. Invalid arithmetic data raise validation errors.

Guarantees (E, P, B, K). These operations are exact over their accepted number domain. `ArithmeticPolyphase` has codec `arithmetic.polyphase_coordinates` version 1. Returned Mahler series use their own domain support. No numerical backend is required. Analysis/synthesis are linear in sequence length, and mixed-radix conversion is linear in digit count.

Evidence and links (V, L). The exact-arithmetic polyphase semantic case and Chapters 13 through 14, 23, and 25 verify roundtrips and address laws. Related symbols are residue and signal polyphase operations.

A.5 · `LatticePolyphaseRefinement`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.LatticePolyphaseRefinement`. Name-preserving aliases `komorebi_math.v1.LatticePolyphaseRefinement` and `komorebi_math.api.v1.LatticePolyphaseRefinement`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.refinement.polyphase.LatticePolyphaseRefinement`. Profile `A5-R1`.

Manifest signature (s).

```
(coarse_strides: 'tuple[int, ...]', fine_strides: 'tuple[int, ...]') -> None
```

Definition. Componentwise refinement of rectangular lattice polyphase coordinates.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · PacketRefinement

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PacketRefinement`. Name-preserving aliases `komorebi_math.v1.PacketRefinement` and `komorebi_math.api.v1.PacketRefinement`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.refinement.towers.PacketRefinement`. Profile `A5-T1`.

Manifest signature (s).

```
(coarse: 'PacketSystem', fine: 'PacketSystem', parent_of_fine: 'tuple[int, ...]') -> None
```

Definition. One exact refinement from a coarse packet system to a fine system.

Contract (D, C, H, R, X). Compatible coarse/fine packet systems map to a `PacketRefinement`. A composable finite chain maps to `RefinementTower`. Two commuting systems map to a common refinement and its two arrows. Completeness, commutation, parent maps, and adjacent endpoints must agree. Violations raise validation or dimension errors.

Guarantees (E, P, B, K). Finite projector identities are exact on exact backends and tolerance-qualified otherwise. These packet-tower records have no frozen codec on the stable surface. Dense projector products scale with ambient dimension and packet counts. Tower work sums across levels.

Evidence and links (V, L). Chapter 12 supplies refinement and common-refinement examples and certificates. Core/refinement tests verify identities. Related symbols are `PacketSystem`, `PolyphaseRefinementTower`, and Chapter 64 algebra recipes.

A.5 · PolyphaseCoordinateRecord

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PolyphaseCoordinateRecord`. Name-preserving aliases `komorebi_math.v1.PolyphaseCoordinateRecord` and `komorebi_math.api.v1.PolyphaseCoordinateRecord`. Tier `[STABLE]`. Manifest kind `data`. Reflected implementation `types.UnionType`. Profile `A5-U1`.

Manifest signature (s).

```
null
```

Definition. The union `PolyphaseCoordinates | ResidueCoordinates | ArithmeticPolyphase`. It is keyed by exported name, not collapsed to `types.UnionType`.

Contract (D, C, H, R, X). This data export is the union of `PolyphaseCoordinates`, `ResidueCoordinates`, and `ArithmeticPolyphase`, accepted by the generic one-dimensional refine/coarsen functions. It takes no call arguments and returns no value by itself. The manifest signature is therefore `null`.

Guarantees (E, P, B, K). The union is exact typing metadata, has no codec of its own, and introduces no backend work or runtime complexity. Each concrete member retains its own persistence and exactness contract.

Evidence and links (V, L). The stable reference-card parser verifies the union binding as a distinct data export rather than collapsing it by runtime type owner. Chapters 13 through 14 and the A.5 cards for the three concrete records provide examples and links.

A.5 · PolyphaseRefinement

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PolyphaseRefinement`. Name-preserving aliases `komorebi_math.v1.PolyphaseRefinement` and `komorebi_math.api.v1.PolyphaseRefinement`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.refinement.polyphase.PolyphaseRefinement`. Profile `A5-R1`.

Manifest signature (s).

```
(coarse_order: 'int', fine_order: 'int') -> None
```

Definition. One canonical refinement between divisible one-dimensional packet orders.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · `PolyphaseRefinementTower`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PolyphaseRefinementTower`. Name-preserving aliases `komorebi_math.v1.PolyphaseRefinementTower` and `komorebi_math.api.v1.PolyphaseRefinementTower`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.refinement.polyphase.PolyphaseRefinementTower`. Profile `A5-R1`.

Manifest signature (s).

```
(orders: 'tuple[int, ...]') -> None
```

Definition. A finite chain of compatible polyphase orders.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · `RefinementTower`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.RefinementTower`. Name-preserving aliases `komorebi_math.v1.RefinementTower` and `komorebi_math.api.v1.RefinementTower`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.refinement.towers.RefinementTower`. Profile `A5-T1`.

Manifest signature (s).

```
(refinements: 'tuple[PacketRefinement, ...] | list[PacketRefinement]') -> 'None'
```

Definition. A finite sequence of exact packet refinements.

Contract (D, C, H, R, X). Compatible coarse/fine packet systems map to a `PacketRefinement`. A composable finite chain maps to `RefinementTower`. Two commuting systems map to a common refinement and its two arrows. Completeness, commutation, parent maps, and adjacent endpoints must agree. Violations raise validation or dimension errors.

Guarantees (E, P, B, K). Finite projector identities are exact on exact backends and tolerance-qualified otherwise. These packet-tower records have no frozen codec on the stable surface. Dense projector products scale with ambient dimension and packet counts. Tower work sums across levels.

Evidence and links (V, L). Chapter 12 supplies refinement and common-refinement examples and certificates. Core/refinement tests verify identities. Related symbols are `PacketSystem`, `PolyphaseRefinementTower`, and Chapter 64 algebra recipes.

A.5 · ResidueCoordinates

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ResidueCoordinates`. Name-preserving aliases `komorebi_math.v1.ResidueCoordinates` and `komorebi_math.api.v1.ResidueCoordinates`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.refinement.residue.ResidueCoordinates`. Profile `A5-Z1`.

Manifest signature (s).

```
(modulus: 'int', channels: 'tuple[np.ndarray, ...]', length: 'int') -> None
```

Definition. Ordinary polyphase channels for one finite sequence.

Contract (D, C, H, R, X). A finite sequence and positive modulus map to ordinary residue channels. Nested residue data map to the product modulus and back. Channel counts, dimensions, lengths, and residue ranges must agree. Results are `ResidueCoordinates`, combined addresses, or reconstructed arrays. Invalid inputs raise validation or dimension errors.

Guarantees (E, P, B, K). Address laws are exact. NumPy reconstruction preserves supplied values subject to array dtype. `ResidueCoordinates` has codec `refinement.residue_coordinates` version 1. Analysis and synthesis are linear in sequence length. Nested addressing is constant-time integer arithmetic.

Evidence and links (V, L). Chapters 13 through 14 verify CRT-style addresses, nesting, synthesis, and failure cases. Stable arithmetic/refinement semantic cases cover roundtrips. Related symbols are arithmetic and signal polyphase functions.

A.5 · arithmetic_mixed_radix_address

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.arithmetic_mixed_radix_address`. Name-preserving aliases `komorebi_math.v1.arithmetic_mixed_radix_address` and `komorebi_math.api.v1.arithmetic_mixed_radix_address`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.arithmetic.polyphase.mixed_radix_address`. Profile `A5-A1`.

Manifest signature (s).

```
(digits: 'Iterable[int]', radices: 'Iterable[int]') -> 'int'
```

Definition. Encode nested residue digits in least significant first order.

Contract (D, C, H, R, X). Finite exact sequences, moduli, residue channels, mixed-radix digits, or Mahler coefficients map to arithmetic polyphase records and exact address conversions. Moduli/radices must be positive, digits and addresses in range, and channel lengths consistent. Results are integers, tuples, channels, or `MahlerSeries`. Invalid arithmetic data raise validation errors.

Guarantees (E, P, B, K). These operations are exact over their accepted number domain. `ArithmeticPolyphase` has codec `arithmetic.polyphase_coordinates` version 1. Returned Mahler series use their own domain support. No numerical backend is required. Analysis/synthesis are linear in sequence length, and mixed-radix conversion is linear in digit count.

Evidence and links (V, L). The exact-arithmetic polyphase semantic case and Chapters 13 through 14, 23, and 25 verify roundtrips and address laws. Related symbols are residue and signal polyphase operations.

A.5 · arithmetic_mixed_radix_digits

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.arithmetic_mixed_radix_digits`. Name-preserving aliases `komorebi_math.v1.arithmetic_mixed_radix_digits` and `komorebi_math.api.v1.arithmetic_mixed_radix_digits`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.arithmetic.polyphase.mixed_radix_digits`. Profile `A5-A1`.

Manifest signature (s).

```
(address: 'int', radices: 'Iterable[int]') -> 'tuple[int, ...]'
```

Definition. Decode one mixed radix address in least significant first order.

Contract (D, C, H, R, X). Finite exact sequences, moduli, residue channels, mixed-radix digits, or Mahler coefficients map to arithmetic polyphase records and exact address conversions. Moduli/radices must be positive, digits and addresses in range, and channel lengths consistent. Results are integers, tuples, channels, or `MahlerSeries`. Invalid arithmetic data raise validation errors.

Guarantees (E, P, B, K). These operations are exact over their accepted number domain. `ArithmeticPolyphase` has codec `arithmetic.polyphase_coordinates` version 1. Returned Mahler series use their own domain support. No numerical backend is required. Analysis/synthesis are linear in sequence length, and mixed-radix conversion is linear in digit count.

Evidence and links (V, L). The exact-arithmetic polyphase semantic case and Chapters 13 through 14, 23, and 25 verify roundtrips and address laws. Related symbols are residue and signal polyphase operations.

A.5 · `arithmetic_polyphase_analyze`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.arithmetic_polyphase_analyze`. Name-preserving aliases `komorebi_math.v1.arithmetic_polyphase_analyze` and `komorebi_math.api.v1.arithmetic_polyphase_analyze`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.arithmetic.polyphase.polyphase_analyze`. Profile `A5-A1`.

Manifest signature (s).

```
(values: 'Iterable[Number]', modulus: 'int') -> 'ArithmeticPolyphase'
```

Definition. Split a finite sequence into exact residue channels.

Contract (D, C, H, R, X). Finite exact sequences, moduli, residue channels, mixed-radix digits, or Mahler coefficients map to arithmetic polyphase records and exact address conversions. Moduli/radices must be positive, digits and addresses in range, and channel lengths consistent. Results are integers, tuples, channels, or `MahlerSeries`. Invalid arithmetic data raise validation errors.

Guarantees (E, P, B, K). These operations are exact over their accepted number domain. `ArithmeticPolyphase` has codec `arithmetic.polyphase_coordinates` version 1. Returned Mahler series use their own domain support. No numerical backend is required. Analysis/synthesis are linear in sequence length, and mixed-radix conversion is linear in digit count.

Evidence and links (V, L). The exact-arithmetic polyphase semantic case and Chapters 13 through 14, 23, and 25 verify roundtrips and address laws. Related symbols are residue and signal polyphase operations.

A.5 · `arithmetic_polyphase_synthesize`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.arithmetic_polyphase_synthesize`. Name-preserving aliases `komorebi_math.v1.arithmetic_polyphase_synthesize` and `komorebi_math.api.v1.arithmetic_polyphase_synthesize`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.arithmetic.polyphase.polyphase_synthesize`. Profile `A5-A1`.

Manifest signature (s).

```
(channels: 'Iterable[Iterable[Number]]', length: 'int | None' = None) -> 'tuple[Number, ...]'
```

Definition. Interleave exact residue channels.

Contract (D, C, H, R, X). Finite exact sequences, moduli, residue channels, mixed-radix digits, or Mahler coefficients map to arithmetic polyphase records and exact address conversions. Moduli/radices must be positive, digits and addresses in range, and channel lengths consistent. Results are integers, tuples, channels, or `MahlerSeries`. Invalid arithmetic data raise validation errors.

Guarantees (E, P, B, K). These operations are exact over their accepted number domain. `ArithmeticPolyphase` has codec `arithmetic.polyphase_coordinates` version 1. Returned Mahler series use their own domain support. No numerical backend is required. Analysis/synthesis are linear in sequence length, and mixed-radix conversion is linear in digit count.

Evidence and links (V, L). The exact-arithmetic polyphase semantic case and Chapters 13 through 14, 23, and 25 verify roundtrips and address laws. Related symbols are residue and signal polyphase operations.

A.5 · `coarsen_lattice_polyphase`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.coarsen_lattice_polyphase`. Name-preserving aliases `komorebi_math.v1.coarsen_lattice_polyphase` and `komorebi_math.api.v1.coarsen_lattice_polyphase`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.coarsen_lattice_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.lattice_polyphase_coarsen`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'LatticePolyphaseCoordinates', coarse_strides: 'Iterable[int]', *, copy: 'bool' = True) ->
    ↪ 'LatticePolyphaseCoordinates'
```

Definition. Coarsen rectangular lattice coordinates to componentwise coarser strides.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `Polyphase Refinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · `coarsen_polyphase`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.coarsen_polyphase`. Name-preserving aliases `komorebi_math.v1.coarsen_polyphase` and `komorebi_math.api.v1.coarsen_polyphase`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.coarsen_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.polyphase_coarsen`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'PolyphaseCoordinateRecord', coarse_order: 'int', *, copy: 'bool' = True) ->
    ↪ 'PolyphaseCoordinateRecord'
```

Definition. Coarsen any supported one-dimensional coordinate record to `coarse_order`.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `Polyphase Refinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · common_refinement

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.common_refinement`. Name-preserving aliases `komorebi_math.v1.common_refinement` and `komorebi_math.api.v1.common_refinement`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.towers.common_refinement`. Profile `A5-T1`.

Manifest signature (s).

```
(left: 'PacketSystem', right: 'PacketSystem', *, names: 'tuple[str, ...] | None' = None) -> 'tuple[PacketSystem,
   ↪ PacketRefinement, PacketRefinement]'
```

Definition. Construct the common refinement of two commuting packet systems.

Contract (D, C, H, R, X). Compatible coarse/fine packet systems map to a `PacketRefinement`. A composable finite chain maps to `RefinementTower`. Two commuting systems map to a common refinement and its two arrows. Completeness, commutation, parent maps, and adjacent endpoints must agree. Violations raise validation or dimension errors.

Guarantees (E, P, B, K). Finite projector identities are exact on exact backends and tolerance-qualified otherwise. These packet-tower records have no frozen codec on the stable surface. Dense projector products scale with ambient dimension and packet counts. Tower work sums across levels.

Evidence and links (V, L). Chapter 12 supplies refinement and common-refinement examples and certificates. Core/refinement tests verify identities. Related symbols are `PacketSystem`, `PolyphaseRefinementTower`, and Chapter 64 algebra recipes.

A.5 · lattice_polyphase_coarsen

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.lattice_polyphase_coarsen`. Name-preserving aliases `komorebi_math.v1.lattice_polyphase_coarsen` and `komorebi_math.api.v1.lattice_polyphase_coarsen`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.coarsen_lattice_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.coarsen_lattice_polyphase`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'LatticePolyphaseCoordinates', coarse_strides: 'Iterable[int]', *, copy: 'bool' = True) ->
   ↪ 'LatticePolyphaseCoordinates'
```

Definition. Coarsen rectangular lattice coordinates to componentwise coarser strides.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · lattice_polyphase_refine

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.lattice_polyphase_refine`. Name-preserving aliases `komorebi_math.v1.lattice_polyphase_refine` and `komorebi_math.api.v1.lattice_polyphase_refine`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.refine_lattice_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.refine_lattice_polyphase`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'LatticePolyphaseCoordinates', fine_strides: 'Iterable[int]', *, copy: 'bool' = True) ->
    ↪ 'LatticePolyphaseCoordinates'
```

Definition. Refine rectangular lattice coordinates to componentwise finer strides.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · `mahler_polyphase`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.mahler_polyphase`. Name-preserving aliases `komorebi_math.v1.mahler_polyphase` and `komorebi_math.api.v1.mahler_polyphase`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.arithmetic.polyphase.mahler_polyphase`. Profile `A5-A1`.

Manifest signature (s).

```
(series: 'MahlerSeries', modulus: 'int', address: 'int') -> 'MahlerSeries'
```

Definition. Return the exact Mahler coordinates of `series(modulus*x + address)`.

Contract (D, C, H, R, X). Finite exact sequences, moduli, residue channels, mixed-radix digits, or Mahler coefficients map to arithmetic polyphase records and exact address conversions. Moduli/radices must be positive, digits and addresses in range, and channel lengths consistent. Results are integers, tuples, channels, or `MahlerSeries`. Invalid arithmetic data raise validation errors.

Guarantees (E, P, B, K). These operations are exact over their accepted number domain. `ArithmeticPolyphase` has codec `arithmetic.polyphase_coordinates` version 1. Returned Mahler series use their own domain support. No numerical backend is required. Analysis/synthesis are linear in sequence length, and mixed-radix conversion is linear in digit count.

Evidence and links (V, L). The exact-arithmetic polyphase semantic case and Chapters 13 through 14, 23, and 25 verify roundtrips and address laws. Related symbols are residue and signal polyphase operations.

A.5 · `nested_residue_address`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.nested_residue_address`. Name-preserving aliases `komorebi_math.v1.nested_residue_address` and `komorebi_math.api.v1.nested_residue_address`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.residue.nested_residue_address`. Profile `A5-Z1`.

Manifest signature (s).

```
(outer_residue: 'int', outer_modulus: 'int', inner_residue: 'int', inner_modulus: 'int') -> 'int'
```

Definition. Return the combined address `outer_residue + outer_modulus * inner_residue`.

Contract (D, C, H, R, X). A finite sequence and positive modulus map to ordinary residue channels. Nested residue data map to the product modulus and back. Channel counts, dimensions, lengths, and residue ranges must agree. Results are `ResidueCoordinates`, combined addresses, or reconstructed arrays. Invalid inputs raise validation or dimension errors.

Guarantees (E, P, B, K). Address laws are exact. NumPy reconstruction preserves supplied values subject to array dtype. `ResidueCoordinates` has codec `refinement.residue_coordinates` version 1. Analysis and synthesis are linear in sequence length. Nested addressing is constant-time integer arithmetic.

Evidence and links (V, L). Chapters 13 through 14 verify CRT-style addresses, nesting, synthesis, and failure cases. Stable arithmetic/refinement semantic cases cover roundtrips. Related symbols are arithmetic and signal polyphase functions.

A.5 · `nested_residue_analysis`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.nested_residue_analysis`. Name-preserving aliases `komorebi_math.v1.nested_residue_analysis` and `komorebi_math.api.v1.nested_residue_analysis`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.residue.nested_residue_analysis`. Profile `A5-Z1`.

Manifest signature (s).

```
(values: 'Any', outer_modulus: 'int', inner_modulus: 'int') -> 'ResidueCoordinates'
```

Definition. Analyze twice and return the equivalent channels modulo the product.

Contract (D, C, H, R, X). A finite sequence and positive modulus map to ordinary residue channels. Nested residue data map to the product modulus and back. Channel counts, dimensions, lengths, and residue ranges must agree. Results are `ResidueCoordinates`, combined addresses, or reconstructed arrays. Invalid inputs raise validation or dimension errors.

Guarantees (E, P, B, K). Address laws are exact. NumPy reconstruction preserves supplied values subject to array dtype. `ResidueCoordinates` has codec `refinement.residue_coordinates` version 1. Analysis and synthesis are linear in sequence length. Nested addressing is constant-time integer arithmetic.

Evidence and links (V, L). Chapters 13 through 14 verify CRT-style addresses, nesting, synthesis, and failure cases. Stable arithmetic/refinement semantic cases cover roundtrips. Related symbols are arithmetic and signal polyphase functions.

A.5 · `polyphase_coarsen`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.polyphase_coarsen`. Name-preserving aliases `komorebi_math.v1.polyphase_coarsen` and `komorebi_math.api.v1.polyphase_coarsen`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.coarsen_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.coarsen_polyphase`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'PolyphaseCoordinateRecord', coarse_order: 'int', *, copy: 'bool' = True) ->
    ↪ 'PolyphaseCoordinateRecord'
```

Definition. Coarsen any supported one-dimensional coordinate record to `coarse_order`.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `Polyphase Refinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · polyphase_refine

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.polyphase_refine`. Name-preserving aliases `komorebi_math.v1.polyphase_refine` and `komorebi_math.api.v1.polyphase_refine`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.refine_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.refine_polyphase`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'PolyphaseCoordinateRecord', fine_order: 'int', *, copy: 'bool' = True) ->
    ↪ 'PolyphaseCoordinateRecord'
```

Definition. Refine any supported one-dimensional coordinate record to `fine_order`.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · polyphase_refinement_certificate

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.polyphase_refinement_certificate`. Name-preserving aliases `komorebi_math.v1.polyphase_refinement_certificate` and `komorebi_math.api.v1.polyphase_refinement_certificate`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.polyphase_refinement_certificate`. Profile `A5-R1`.

Manifest signature (s).

```
(coordinates: 'PolyphaseCoordinateRecord', fine_order: 'int', *, tolerance: 'float' = 1e-12) -> 'Certificate'
```

Definition. Certify refinement and direct-analysis equivalence for one coordinate record.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `PolyphaseRefinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · refine_lattice_polyphase

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.refine_lattice_polyphase`. Name-preserving aliases `komorebi_math.v1.refine_lattice_polyphase` and `komorebi_math.api.v1.refine_lattice_polyphase`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.refine_lattice_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.lattice_polyphase_refine`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'LatticePolyphaseCoordinates', fine_strides: 'Iterable[int]', *, copy: 'bool' = True) ->
    ↪ 'LatticePolyphaseCoordinates'
```

Definition. Refine rectangular lattice coordinates to componentwise finer strides.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `Polyphase Refinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · `refine_polyphase`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.refine_polyphase`. Name-preserving aliases `komorebi_math.v1.refine_polyphase` and `komorebi_math.api.v1.refine_polyphase`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.polyphase.refine_polyphase`. Profile `A5-R1`. Deliberate cross-name alias: `komorebi_math.stable.polyphase_refine`. Both export cards remain present.

Manifest signature (s).

```
(coordinates: 'PolyphaseCoordinateRecord', fine_order: 'int', *, copy: 'bool' = True) ->
    ↪ 'PolyphaseCoordinateRecord'
```

Definition. Refine any supported one-dimensional coordinate record to `fine_order`.

Contract (D, C, H, R, X). One-dimensional or rectangular polyphase coordinates plus divisible coarse/fine orders map to refined or coarsened coordinate records. Orders and strides must be positive and componentwise divisible, shapes must match, and certificate tolerances must be nonnegative. Results preserve the supported coordinate-record variant. Invalid relations raise validation or dimension errors.

Guarantees (E, P, B, K). Index regrouping is exact. Array comparison certificates are tolerance-qualified. `Polyphase Refinement`, `LatticePolyphaseRefinement`, and `PolyphaseRefinementTower` have version-1 codecs. NumPy stores signal records. Work and memory are linear in materialized sample count plus channel bookkeeping.

Evidence and links (V, L). Signal, arithmetic, rectangular-lattice, and portable-tower semantic cases cover this family. Chapters 12 through 14 give direct-fine equivalence, alias, and failure examples. Related symbols include analysis/synthesis and `refinement_children`.

A.5 · `residue_analyze`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.residue_analyze`. Name-preserving aliases `komorebi_math.v1.residue_analyze` and `komorebi_math.api.v1.residue_analyze`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.residue.residue_analyze`. Profile `A5-Z1`.

Manifest signature (s).

```
(values: 'Any', modulus: 'int') -> 'ResidueCoordinates'
```

Definition. Split a one dimensional sequence into residue channels.

Contract (D, C, H, R, X). A finite sequence and positive modulus map to ordinary residue channels. Nested residue data map to the product modulus and back. Channel counts, dimensions, lengths, and residue ranges must agree. Results are `ResidueCoordinates`, combined addresses, or reconstructed arrays. Invalid inputs raise validation or dimension errors.

Guarantees (E, P, B, K). Address laws are exact. NumPy reconstruction preserves supplied values subject to array dtype. `ResidueCoordinates` has codec `refinement.residue_coordinates` version 1. Analysis and synthesis are linear in sequence length. Nested addressing is constant-time integer arithmetic.

Evidence and links (V, L). Chapters 13 through 14 verify CRT-style addresses, nesting, synthesis, and failure cases. Stable arithmetic/refinement semantic cases cover roundtrips. Related symbols are arithmetic and signal polyphase functions.

A.5 · `residue_synthesize`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.residue_synthesize`. Name-preserving aliases `komorebi_math.v1.residue_synthesize` and `komorebi_math.api.v1.residue_synthesize`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.refinement.residue.residue_synthesize`. Profile `A5-Z1`.

Manifest signature (s).

```
(channels: 'ResidueCoordinates | tuple[Any, ...]', *, length: 'int | None' = None) -> 'np.ndarray'
```

Definition. Reconstruct a sequence from residue channels.

Contract (D, C, H, R, X). A finite sequence and positive modulus map to ordinary residue channels. Nested residue data map to the product modulus and back. Channel counts, dimensions, lengths, and residue ranges must agree. Results are `ResidueCoordinates`, combined addresses, or reconstructed arrays. Invalid inputs raise validation or dimension errors.

Guarantees (E, P, B, K). Address laws are exact. NumPy reconstruction preserves supplied values subject to array dtype. `ResidueCoordinates` has codec `refinement.residue_coordinates` version 1. Analysis and synthesis are linear in sequence length. Nested addressing is constant-time integer arithmetic.

Evidence and links (V, L). Chapters 13 through 14 verify CRT-style addresses, nesting, synthesis, and failure cases. Stable arithmetic/refinement semantic cases cover roundtrips. Related symbols are arithmetic and signal polyphase functions.

A.6 Generating series

A.6 · `FormalSeries`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.FormalSeries`. Name-preserving aliases `komorebi_math.v1.FormalSeries` and `komorebi_math.api.v1.FormalSeries`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.generating.series.FormalSeries`. Profile `A6-G1`.

Manifest signature (s).

```
(basis: 'WeightedMonomialBasis', coefficients: 'Iterable[int | Fraction]') -> 'None'
```

Definition. A finite exact series `sum a_n z^n/gamma_n`.

Contract (D, C, H, R, X). A positive factorial power or ordinary-basis request produces a weighted monomial basis. A basis plus finite exact coefficients produces a `FormalSeries`. Orders and coefficients must satisfy the exact scalar and finite-iteration contracts. Results are basis descriptors or finite series. Invalid powers or incompatible bases fail validation.

Guarantees (E, P, B, K). Finite coefficient algebra is exact. `FormalSeries` has codec `generating.formal_series` version 1, while returned weighted bases use `generating.weighted_monomial_basis` version 1. Base exact arithmetic is sufficient. Convolution cost is quadratic in truncation length unless a method documents otherwise.

Evidence and links (V, L). The factorial-power product semantic case and Chapter 21 verify basis construction, multiplication, persistence, and failures. Related symbols are generating-function recipes in Chapters 21 through 25.

A.6 · factorial_power_basis

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.factorial_power_basis`. Name-preserving aliases `komorebi_math.v1.factorial_power_basis` and `komorebi_math.api.v1.factorial_power_basis`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.generating.basis.factorial_power_basis`. Profile `A6-G1`.

Manifest signature (s).

```
(power: 'int', *, name: 'str | None' = None) -> 'WeightedMonomialBasis'
```

Definition. Return `z^n/(n!)^power` for a positive integer power.

Contract (D, C, H, R, X). A positive factorial power or ordinary-basis request produces a weighted monomial basis. A basis plus finite exact coefficients produces a `FormalSeries`. Orders and coefficients must satisfy the exact scalar and finite-iteration contracts. Results are basis descriptors or finite series. Invalid powers or incompatible bases fail validation.

Guarantees (E, P, B, K). Finite coefficient algebra is exact. `FormalSeries` has codec `generating.formal_series` version 1, while returned weighted bases use `generating.weighted_monomial_basis` version 1. Base exact arithmetic is sufficient. Convolution cost is quadratic in truncation length unless a method documents otherwise.

Evidence and links (V, L). The factorial-power product semantic case and Chapter 21 verify basis construction, multiplication, persistence, and failures. Related symbols are generating-function recipes in Chapters 21 through 25.

A.6 · ordinary_generating_basis

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.ordinary_generating_basis`. Name-preserving aliases `komorebi_math.v1.ordinary_generating_basis` and `komorebi_math.api.v1.ordinary_generating_basis`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.generating.basis.ordinary_basis`. Profile `A6-G1`.

Manifest signature (s).

```
(*, name: 'str' = 'ordinary') -> 'WeightedMonomialBasis'
```

Definition. Return the ordinary generating-function basis `z^n`.

Contract (D, C, H, R, X). A positive factorial power or ordinary-basis request produces a weighted monomial basis. A basis plus finite exact coefficients produces a `FormalSeries`. Orders and coefficients must satisfy the exact scalar and finite-iteration contracts. Results are basis descriptors or finite series. Invalid powers or incompatible bases fail validation.

Guarantees (E, P, B, K). Finite coefficient algebra is exact. `FormalSeries` has codec `generating.formal_series` version 1, while returned weighted bases use `generating.weighted_monomial_basis` version 1. Base exact arithmetic is sufficient. Convolution cost is quadratic in truncation length unless a method documents otherwise.

Evidence and links (V, L). The factorial-power product semantic case and Chapter 21 verify basis construction, multiplication, persistence, and failures. Related symbols are generating-function recipes in Chapters 21 through 25.

A.7 Signal polyphase

A.7 · `LatticePolyphaseCoordinates`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.LatticePolyphaseCoordinates`. Name-preserving aliases `komorebi_math.v1.LatticePolyphaseCoordinates` and `komorebi_math.api.v1.LatticePolyphaseCoordinates`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.signals.polyphase.LatticePolyphaseCoordinates`. Profile `A7-S1`.

Manifest signature (`s`).

```
(channels: 'dict[tuple[int, ...], np.ndarray]', strides: 'tuple[int, ...]', original_shape: 'tuple[int, ...]') ->
    ↪ None
```

Definition. Rectangular lattice residue channels of a finite multidimensional array.

Contract (`D, C, H, R, X`). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (`E, P, B, K`). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (`V, L`). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · `PolyphaseCoordinates`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PolyphaseCoordinates`. Name-preserving aliases `komorebi_math.v1.PolyphaseCoordinates` and `komorebi_math.api.v1.PolyphaseCoordinates`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.signals.polyphase.PolyphaseCoordinates`. Profile `A7-S1`.

Manifest signature (`s`).

```
(channels: 'tuple[np.ndarray, ...]', order: 'int', axis: 'int', original_shape: 'tuple[int, ...]') -> None
```

Definition. Residue channels of a finite array along one axis.

Contract (`D, C, H, R, X`). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (`E, P, B, K`). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (`V, L`). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · PolyphaseSystem

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PolyphaseSystem`. Name-preserving aliases `komorebi_math.v1.PolyphaseSystem` and `komorebi_math.api.v1.PolyphaseSystem`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.signals.polyphase.PolyphaseSystem`. Profile `A7-S1`.

Manifest signature (s).

```
(order: 'int', axis: 'int' = -1) -> None
```

Definition. Reusable one axis polyphase analysis and synthesis system.

Contract (D, C, H, R, X). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (E, P, B, K). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (V, L). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · lattice_polyphase_analyze

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.lattice_polyphase_analyze`. Name-preserving aliases `komorebi_math.v1.lattice_polyphase_analyze` and `komorebi_math.api.v1.lattice_polyphase_analyze`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.lattice_polyphase_analyze`. Profile `A7-S1`.

Manifest signature (s).

```
(signal: 'Any', strides: 'Iterable[int]', *, copy: 'bool' = True) -> 'LatticePolyphaseCoordinates'
```

Definition. Split an array into channels indexed by a rectangular lattice quotient.

Contract (D, C, H, R, X). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (E, P, B, K). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (V, L). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · lattice_polyphase_synthesize

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.lattice_polyphase_synthesize`. Name-preserving aliases `komorebi_math.v1.lattice_polyphase_synthesize` and `komorebi_math.api.v1.lattice_polyphase_synthesize`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.lattice_polyphase_synthesize`. Profile `A7-S1`.

Manifest signature (`s`).

```
(coordinates: 'LatticePolyphaseCoordinates') -> 'np.ndarray'
```

Definition. Reconstruct an array from rectangular lattice packet coordinates.

Contract (`D, C, H, R, X`). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (`E, P, B, K`). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (`V, L`). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · `polyphase_roundtrip_certificate`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.polyphase_roundtrip_certificate`. Name-preserving aliases `komorebi_math.v1.polyphase_roundtrip_certificate` and `komorebi_math.api.v1.polyphase_roundtrip_certificate`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.polyphase_roundtrip_certificate`. Profile `A7-S1`.

Manifest signature (`s`).

```
(signal: 'Any', order: 'int', *, axis: 'int' = -1, tolerance: 'float' = 1e-12) -> 'ComputationResult[np.ndarray]'
```

Definition. Analyze and reconstruct a finite signal with a numerical certificate.

Contract (`D, C, H, R, X`). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (`E, P, B, K`). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (`V, L`). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · `refinement_children`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.refinement_children`. Name-preserving aliases `komorebi_math.v1.refinement_children` and `komorebi_math.api.v1.refinement_children`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.refinement_children`. Profile `A7-S1`.

Manifest signature (`s`).

```
(coarse_order: 'int', fine_order: 'int', residue: 'int') -> 'tuple[int, ...]'
```

Definition. Return fine residues whose reduction modulo the coarse order is `residue`.

Contract (`D, C, H, R, X`). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes,

and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (E, P, B, K). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (V, L). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · `residue_project`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.residue_project`. Name-preserving aliases `komorebi_math.v1.residue_project` and `komorebi_math.api.v1.residue_project`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.residue_project`. Profile `A7-S1`.

Manifest signature (s).

```
(signal: 'Any', order: 'int', residue: 'int', *, axis: 'int' = -1) -> 'np.ndarray'
```

Definition. Return the full shaped signal supported on one residue class.

Contract (D, C, H, R, X). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (E, P, B, K). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (V, L). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · `signal_polyphase_analyze`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.signal_polyphase_analyze`. Name-preserving aliases `komorebi_math.v1.signal_polyphase_analyze` and `komorebi_math.api.v1.signal_polyphase_analyze`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.polyphase_analyze`. Profile `A7-S1`.

Manifest signature (s).

```
(signal: 'Any', order: 'int', *, axis: 'int' = -1, copy: 'bool' = True) -> 'PolyphaseCoordinates'
```

Definition. Split a finite array into residue channels along `axis`.

Contract (D, C, H, R, X). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (E, P, B, K). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (V, L). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.7 · signal_polyphase_synthesize

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.signal_polyphase_synthesize`. Name-preserving aliases `komorebi_math.v1.signal_polyphase_synthesize` and `komorebi_math.api.v1.signal_polyphase_synthesize`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.signals.polyphase.polyphase_synthesize`. Profile `A7-S1`.

Manifest signature (s).

```
(coordinates: 'PolyphaseCoordinates') -> 'np.ndarray'
```

Definition. Reconstruct a finite array from polyphase coordinates.

Contract (D, C, H, R, X). A finite NumPy-compatible signal and order/axis or rectangular strides map to residue-channel coordinates. Synthesis maps those records back to the original shape. Orders, axes, strides, channel shapes, and stored original shape must agree. Results are coordinate records, reconstructed arrays, projections, child-index tuples, or certified roundtrips. Invalid shapes raise validation or dimension errors.

Guarantees (E, P, B, K). Index splitting and child arithmetic are exact. Floating roundtrip certificates are numerical with explicit tolerance. `PolyphaseCoordinates` and `LatticePolyphaseCoordinates` have version-1 codecs. NumPy is required. Analysis, synthesis, and projection are linear in sample count with channel-view/copy behavior controlled by arguments.

Evidence and links (V, L). The signal and rectangular-lattice semantic cases and Chapters 14 and 35 verify roundtrips, refinement children, projections, aliases, and adversarial shapes. Related symbols are A.5 refinement and arithmetic polyphase cards.

A.8 Document model and portable persistence

A.8 · DocumentMetadata

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.DocumentMetadata`. Name-preserving aliases `komorebi_math.v1.DocumentMetadata` and `komorebi_math.api.v1.DocumentMetadata`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.export.model.DocumentMetadata`. Profile `A8-D1`.

Manifest signature (s).

```
(title: 'str' = 'Komorebi Math Export', author: 'str | None' = None, date: 'str | None' = None, abstract: 'str |
    ↪ None' = None, keywords: 'tuple[str, ...]' = ()) -> None
```

Definition. Metadata used by Markdown, HTML, and LaTeX document renderers.

Contract (D, C, H, R, X). Metadata and typed prose/equation blocks map to a renderer-independent `MathDocument`. Text, labels, numbering flags, and metadata fields must have the declared types. Results are mutable document assemblies or immutable block records. Malformed construction raises ordinary dataclass/type errors and renderer validation errors.

Guarantees (E, P, B, K). Document structure is exact editorial data, not a mathematical certificate. These four records have no frozen portable codec. Their supported public export is rendering. The base model uses the standard library and storage is linear in block and text size.

Evidence and links (V, L). The portable-document-rendering semantic case and Chapters 59 through 60 exercise assembly and output. Related symbols are `render_markdown`, `render_latex`, and the report-builder APIs outside the frozen stable tier.

A.8 · Equation

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.Equation`. Name-preserving aliases `komorebi_math.v1.Equation` and `komorebi_math.api.v1.Equation`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.export.model.Equation`. Profile `A8-D1`.

Manifest signature (s).

```
(latex: 'str', label: 'str | None' = None, numbered: 'bool' = False, description: 'str | None' = None) -> None
```

Definition. One LaTeX mathematical expression.

Contract (D, C, H, R, X). Metadata and typed prose/equation blocks map to a renderer-independent `MathDocument`. Text, labels, numbering flags, and metadata fields must have the declared types. Results are mutable document assemblies or immutable block records. Malformed construction raises ordinary dataclass/type errors and renderer validation errors.

Guarantees (E, P, B, K). Document structure is exact editorial data, not a mathematical certificate. These four records have no frozen portable codec. Their supported public export is rendering. The base model uses the standard library and storage is linear in block and text size.

Evidence and links (V, L). The portable-document-rendering semantic case and Chapters 59 through 60 exercise assembly and output. Related symbols are `render_markdown`, `render_latex`, and the report-builder APIs outside the frozen stable tier.

A.8 · MathDocument

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.MathDocument`. Name-preserving aliases `komorebi_math.v1.MathDocument` and `komorebi_math.api.v1.MathDocument`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.export.model.MathDocument`. Profile `A8-D1`.

Manifest signature (s).

```
(metadata: 'DocumentMetadata' = <factory>, blocks: 'list[DocumentBlock]' = <factory>) -> None
```

Definition. A renderer independent mathematical document.

Contract (D, C, H, R, X). Metadata and typed prose/equation blocks map to a renderer-independent `MathDocument`. Text, labels, numbering flags, and metadata fields must have the declared types. Results are mutable document assemblies or immutable block records. Malformed construction raises ordinary dataclass/type errors and renderer validation errors.

Guarantees (E, P, B, K). Document structure is exact editorial data, not a mathematical certificate. These four records have no frozen portable codec. Their supported public export is rendering. The base model uses the standard library and storage is linear in block and text size.

Evidence and links (V, L). The portable-document-rendering semantic case and Chapters 59 through 60 exercise assembly and output. Related symbols are `render_markdown`, `render_latex`, and the report-builder APIs outside the frozen stable tier.

A.8 · Paragraph

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.Paragraph`. Name-preserving aliases `komorebi_math.v1.Paragraph` and `komorebi_math.api.v1.Paragraph`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.export.model.Paragraph`. Profile `A8-D1`.

Manifest signature (`s`).

```
(text: 'str') -> None
```

Definition. One prose paragraph whose text is escaped by each renderer.

Contract (`D, C, H, R, X`). Metadata and typed prose/equation blocks map to a renderer-independent `MathDocument`. Text, labels, numbering flags, and metadata fields must have the declared types. Results are mutable document assemblies or immutable block records. Malformed construction raises ordinary dataclass/type errors and renderer validation errors.

Guarantees (`E, P, B, K`). Document structure is exact editorial data, not a mathematical certificate. These four records have no frozen portable codec. Their supported public export is rendering. The base model uses the standard library and storage is linear in block and text size.

Evidence and links (`V, L`). The portable-document-rendering semantic case and Chapters 59 through 60 exercise assembly and output. Related symbols are `render_markdown`, `render_latex`, and the report-builder APIs outside the frozen stable tier.

A.8 · `PortableCodec`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PortableCodec`. Name-preserving aliases `komorebi_math.v1.PortableCodec` and `komorebi_math.api.v1.PortableCodec`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.export.persistence.PortableCodec`. Profile `A8-P1`.

Manifest signature (`s`).

```
(tag: 'str', version: 'int', type_: 'type[Any]', encoder: 'Encoder', decoder: 'Decoder') -> None
```

Definition. One explicit type codec in the portable persistence registry.

Contract (`D, C, H, R, X`). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (`E, P, B, K`). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (`V, L`). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · `PortableMigration`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PortableMigration`. Name-preserving aliases `komorebi_math.v1.PortableMigration` and `komorebi_math.api.v1.PortableMigration`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.export.persistence.PortableMigration`. Profile `A8-P1`.

Manifest signature (`s`).

```
(tag: 'str', from_version: 'int', to_version: 'int', migrator: 'Migrator') -> None
```

Definition. One explicit, adjacent codec-data migration.

Contract (`D, C, H, R, X`). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · `dumps_portable`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.dumps_portable`. Name-preserving aliases `komorebi_math.v1.dumps_portable` and `komorebi_math.api.v1.dumps_portable`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.dumps_portable`. Profile `A8-P1`.

Manifest signature (s).

```
(value: 'Any', *, indent: 'int | None' = 2, max_depth: 'int' = 128) -> 'str'
```

Definition. Serialize one value into a complete digest-checked JSON envelope.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · `from_portable_data`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.from_portable_data`. Name-preserving aliases `komorebi_math.v1.from_portable_data` and `komorebi_math.api.v1.from_portable_data`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.from_portable_data`. Profile `A8-P1`.

Manifest signature (s).

```
(value: 'Any', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Decode one previously encoded portable payload tree.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · load_portable

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.load_portable`. Name-preserving aliases `komorebi_math.v1.load_portable` and `komorebi_math.api.v1.load_portable`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.load_portable`. Profile `A8-P1`.

Manifest signature (s).

```
(path: 'str | os.PathLike[str]', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Read and validate a portable envelope from disk.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · loads_portable

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.loads_portable`. Name-preserving aliases `komorebi_math.v1.loads_portable` and `komorebi_math.api.v1.loads_portable`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.loads_portable`. Profile `A8-P1`.

Manifest signature (s).

```
(text: 'str | bytes', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Validate and deserialize one complete portable JSON envelope.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · portable_codecs

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.portable_codecs`. Name-preserving aliases `komorebi_math.v1.portable_codecs` and `komorebi_math.api.v1.portable_codecs`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.portable_codecs`. Profile `A8-P1`.

Manifest signature (s).

```
() -> 'tuple[PortableCodec, ...]'
```

Definition. Return the active codecs ordered by stable tag.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · `portable_digest`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.portable_digest`. Name-preserving aliases `komorebi_math.v1.portable_digest` and `komorebi_math.api.v1.portable_digest`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.portable_digest`. Profile `A8-P1`.

Manifest signature (s).

```
(value: 'Any', *, max_depth: 'int' = 128) -> 'str'
```

Definition. Return the canonical SHA256 digest of one encoded payload.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · `portable_migrations`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.portable_migrations`. Name-preserving aliases `komorebi_math.v1.portable_migrations` and `komorebi_math.api.v1.portable_migrations`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.portable_migrations`. Profile `A8-P1`.

Manifest signature (s).

```
() -> 'tuple[PortableMigration, ...]'
```

Definition. Return registered codec migrations in deterministic order.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · render_latex

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.render_latex`. Name-preserving aliases `komorebi_math.v1.render_latex` and `komorebi_math.api.v1.render_latex`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.renderers.render_latex`. Profile `A8-R1`.

Manifest signature (s).

```
(document: 'MathDocument', *, options: 'LatexRenderOptions | None' = None) -> 'str'
```

Definition. Render a complete compilable LaTeX document.

Contract (D, C, H, R, X). A valid `MathDocument` maps to Markdown text or a complete LaTeX document. Content is escaped according to renderer context and LaTeX options. The result is text. Malformed blocks, unsupported content, or invalid renderer options raise validation/export errors.

Guarantees (E, P, B, K). Rendering is deterministic text generation for fixed inputs, not a proof of successful external compilation. It is not a portable codec. The stable renderer path is base-only. Runtime and memory are linear in emitted document size apart from escaping.

Evidence and links (V, L). The portable-document-rendering semantic case and Chapters 59 through 60 compare Markdown and LaTeX output. Related symbols are the four document-model records and external writer/compilation interfaces.

A.8 · render_markdown

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.render_markdown`. Name-preserving aliases `komorebi_math.v1.render_markdown` and `komorebi_math.api.v1.render_markdown`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.renderers.render_markdown`. Profile `A8-R1`.

Manifest signature (s).

```
(document: 'MathDocument') -> 'str'
```

Definition. Render a document as Markdown with TeX equations.

Contract (D, C, H, R, X). A valid `MathDocument` maps to Markdown text or a complete LaTeX document. Content is escaped according to renderer context and LaTeX options. The result is text. Malformed blocks, unsupported content, or invalid renderer options raise validation/export errors.

Guarantees (E, P, B, K). Rendering is deterministic text generation for fixed inputs, not a proof of successful external compilation. It is not a portable codec. The stable renderer path is base-only. Runtime and memory are linear in emitted document size apart from escaping.

Evidence and links (V, L). The portable-document-rendering semantic case and Chapters 59 through 60 compare Markdown and LaTeX output. Related symbols are the four document-model records and external writer/compilation interfaces.

A.8 · save_portable

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.save_portable`. Name-preserving aliases `komorebi_math.v1.save_portable` and `komorebi_math.api.v1.save_portable`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.save_portable`. Profile `A8-P1`.

Manifest signature (s).

```
(value: 'Any', path: 'str | os.PathLike[str]', *, overwrite: 'bool' = False, indent: 'int | None' = 2, max_depth:
   ↪  'int' = 128) -> 'Path'
```

Definition. Atomically write a portable envelope to disk.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.8 · to_portable_data

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.to_portable_data`. Name-preserving aliases `komorebi_math.v1.to_portable_data` and `komorebi_math.api.v1.to_portable_data`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.to_portable_data`. Profile `A8-P1`.

Manifest signature (s).

```
(value: 'Any', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Encode one value into the versioned portable payload tree.

Contract (D, C, H, R, X). Registered codecs map supported objects to versioned payload trees. Envelope functions map payloads to canonical digest-checked JSON or atomic files and back. Tags must be unique, migrations adjacent, schemas exact, depths within budget, digests valid, and overwrite policy explicit. Results are codecs, migrations, payloads, text, paths, or decoded values. Schema, tamper, resource, path, and overwrite failures are explicit.

Guarantees (E, P, B, K). Canonical encoding and SHA-256 comparison are exact. Portability exists only for registered types. Unsupported values are rejected. The base route uses JSON, hashing, and filesystem primitives with NumPy used by array codecs. Work is linear in encoded payload size, bounded by `max_depth`, with atomic file replacement for writes.

Evidence and links (V, L). Chapter 61 provides envelope, tamper, depth, overwrite, and roundtrip examples. The persistence contract checks all 51 codecs and one migration. Related symbols are A.9 codec-contract records and `Certificate`.

A.9 API, semantic, persistence, and aggregate contract functions

A.9 · `ApiCompatibilityReport`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.ApiCompatibilityReport`. Name-preserving aliases `komorebi_math.v1.ApiCompatibilityReport` and `komorebi_math.api.v1.ApiCompatibilityReport`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.compatibility.ApiCompatibilityReport`. Profile `A9-A1`.

Manifest signature (`s`).

```
(reference_digest: 'str', current_digest: 'str', added: 'tuple[tuple[str, str], ...]', removed: 'tuple[tuple[str,
   ↪ str], ...]', kind_changed: 'tuple[tuple[str, str, str, str], ...]', signature_changed: 'tuple[tuple[str,
   ↪ str, str | None, str | None], ...]', strict_signatures: 'bool', certificate: 'Certificate') -> None
```

Definition. Structural differences between a reference and current API manifest.

Contract (`D, C, H, R, X`). Stable namespace reflection maps to a deterministic `PublicApiManifest`. Loading and checking map committed JSON plus live reflection to an `ApiCompatibilityReport`. Schemas, package identity, unique names, kinds, owners, and strict signatures must agree. Results are manifests or reports. Malformed JSON and incompatible surfaces raise validation or failed-certificate paths.

Guarantees (`E, P, B, K`). Comparison is exact structural evidence and does not prove every symbol's mathematics. Manifests/reports have no frozen stable codec. Reflection and JSON use the base runtime. Work is linearithmic in export count because entries are normalized and sorted.

Evidence and links (`V, L`). Chapter 72 and `verify stable` cover the 131-name manifest and the three name-preserving alias facades. The stable reference-card parser independently checks every card signature. Related symbols are semantic, persistence, and aggregate contracts.

A.9 · `PortableCodecCompatibilityReport`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.PortableCodecCompatibilityReport`. Name-preserving aliases `komorebi_math.v1.PortableCodecCompatibilityReport` and `komorebi_math.api.v1.PortableCodecCompatibilityReport`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.persistence_contract.PortableCodecCompatibilityReport`. Profile `A9-P1`.

Manifest signature (`s`).

```
(reference_version: 'str', current_version: 'str', added: 'tuple[str, ...]', removed: 'tuple[str, ...]',
   ↪ type_changed: 'tuple[tuple[str, str, str], ...]', version_decreased: 'tuple[tuple[str, int, int], ...]',
   ↪ version_increased: 'tuple[tuple[str, int, int], ...]', missing_migrations: 'tuple[tuple[str, int, int],
   ↪ ...]', certificate: 'Certificate') -> None
```

Definition. Comparison of a committed codec contract with the active registry.

Contract (`D, C, H, R, X`). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (`E, P, B, K`). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (`V, L`). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · PortableCodecContract

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PortableCodecContract`. Name-preserving aliases `komorebi_math.v1.PortableCodecContract` and `komorebi_math.api.v1.PortableCodecContract`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.persistence_contract.PortableCodecContract`. Profile `A9-P1`.

Manifest signature (s).

```
(package_version: 'str', entries: 'tuple[PortableCodecContractEntry, ...]', schema: 'str' =
    ↪ 'komorebi-math.portable-codec-contract', schema_version: 'int' = 1) -> None
```

Definition. Deterministic package-owned portable codec inventory.

Contract (D, C, H, R, X). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (E, P, B, K). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (V, L). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · PortableCodecContractEntry

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PortableCodecContractEntry`. Name-preserving aliases `komorebi_math.v1.PortableCodecContractEntry` and `komorebi_math.api.v1.PortableCodecContractEntry`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.persistence_contract.PortableCodecContractEntry`. Profile `A9-P1`.

Manifest signature (s).

```
(tag: 'str', version: 'int', implementation_type: 'str') -> None
```

Definition. One codec identity frozen by the persistence compatibility contract.

Contract (D, C, H, R, X). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (E, P, B, K). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (V, L). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · PublicApiManifest

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PublicApiManifest`. Name-preserving aliases `komorebi_math.v1.PublicApiManifest` and `komorebi_math.api.v1.PublicApiManifest`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.compatibility.PublicApiManifest`. Profile `A9-A1`.

Manifest signature (s).

```
(package_version: 'str', namespaces: 'tuple[str, ...]', symbols: 'tuple[PublicApiSymbol, ...]', schema: 'str' =
    ↪ 'komorebi-math.public-api', schema_version: 'int' = 1, stability_level: 'str' = 'pre-beta-additive') -> None
```

Definition. A deterministic snapshot of selected `__all__` namespaces.

Contract (D, C, H, R, X). Stable namespace reflection maps to a deterministic `PublicApiManifest`. Loading and checking map committed JSON plus live reflection to an `ApiCompatibilityReport`. Schemas, package identity, unique names, kinds, owners, and strict signatures must agree. Results are manifests or reports. Malformed JSON and incompatible surfaces raise validation or failed-certificate paths.

Guarantees (E, P, B, K). Comparison is exact structural evidence and does not prove every symbol's mathematics. Manifests/reports have no frozen stable codec. Reflection and JSON use the base runtime. Work is linearithmic in export count because entries are normalized and sorted.

Evidence and links (V, L). Chapter 72 and `verify stable` cover the 131-name manifest and the three name-preserving alias facades. The stable reference-card parser independently checks every card signature. Related symbols are semantic, persistence, and aggregate contracts.

A.9 · `PublicApiSymbol`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.PublicApiSymbol`. Name-preserving aliases `komorebi_math.v1.PublicApiSymbol` and `komorebi_math.api.v1.PublicApiSymbol`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.compatibility.PublicApiSymbol`. Profile `A9-A1`.

Manifest signature (s).

```
(namespace: 'str', name: 'str', kind: 'str', implementation_module: 'str', qualname: 'str', signature: 'str |
    ↪ None') -> None
```

Definition. One exported public symbol in a deterministic API manifest.

Contract (D, C, H, R, X). Stable namespace reflection maps to a deterministic `PublicApiManifest`. Loading and checking map committed JSON plus live reflection to an `ApiCompatibilityReport`. Schemas, package identity, unique names, kinds, owners, and strict signatures must agree. Results are manifests or reports. Malformed JSON and incompatible surfaces raise validation or failed-certificate paths.

Guarantees (E, P, B, K). Comparison is exact structural evidence and does not prove every symbol's mathematics. Manifests/reports have no frozen stable codec. Reflection and JSON use the base runtime. Work is linearithmic in export count because entries are normalized and sorted.

Evidence and links (V, L). Chapter 72 and `verify stable` cover the 131-name manifest and the three name-preserving alias facades. The stable reference-card parser independently checks every card signature. Related symbols are semantic, persistence, and aggregate contracts.

A.9 · `StableContractReport`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.StableContractReport`. Name-preserving aliases `komorebi_math.v1.StableContractReport` and `komorebi_math.api.v1.StableContractReport`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.stable_contract.StableContractReport`. Profile `A9-C1`.

Manifest signature (s).

```
(api: 'ApiCompatibilityReport', semantics: 'StableSemanticReport', persistence:
    ↪ 'PortableCodecCompatibilityReport', certificate: 'Certificate') -> None
```

Definition. Complete 1.0-candidate compatibility report.

Contract (D, C, H, R, X). The API, semantic, and portable-codec reports map to one `StableContractReport`. `check_stable_contract` executes all three with optional alternate committed paths. All child certificates must be valid. The result is an aggregate report. Any child incompatibility is retained and makes the aggregate certificate invalid.

Guarantees (E, P, B, K). The aggregate is exact conjunction over finite contract checks. It is not a codec payload and does not establish platform qualification, narrative completeness, or all research semantics. Runtime is the sum of the three child checks and their bounded fixtures.

Evidence and links (V, L). `verify stable` reports 6/6 when the API, aliases, semantics, persistence, aggregate contract, and facade imports pass. Chapter 72 explains the boundary. Related release readiness and platform evidence remain separate Chapter 73 gates.

A.9 · StableSemanticCaseResult

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.StableSemanticCaseResult`. Name-preserving aliases `komorebi_math.v1.StableSemanticCaseResult` and `komorebi_math.api.v1.StableSemanticCaseResult`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.stable_semantics.StableSemanticCaseResult`. Profile `A9-S1`.

Manifest signature (s).

```
(name: 'str', kind: 'str', expected: 'Any', observed: 'Any', passed: 'bool', detail: 'str' = '') -> None
```

Definition. Observed and expected canonical values for one semantic law.

Contract (D, C, H, R, X). A committed stable-semantics fixture maps to a validated path, JSON mapping, digest, individual case results, and an aggregate report. The fixture schema and ten closed expected values must match, and every case must execute. Results preserve expected/observed values and detail. Malformed fixtures or mismatches produce validation failures or an invalid certificate.

Guarantees (E, P, B, K). The ten comparisons are exact for their declared canonical forms. They remain finite regression laws, not universal theorems. Reports have no frozen stable codec. The base path plus domain operations is used. Cost is the sum of the ten bounded cases.

Evidence and links (V, L). Chapter 72 names all semantic-contract layers. The ten cases cover analysis/synthesis, signal/arithmetic/lattice refinement, operator realization, basis roundtrip, generating products, rendering, settings restoration, and portable refinement towers.

A.9 · StableSemanticReport

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.StableSemanticReport`. Name-preserving aliases `komorebi_math.v1.StableSemanticReport` and `komorebi_math.api.v1.StableSemanticReport`. Tier `[STABLE]`. Manifest kind `class`. Reflected implementation `komorebi_math.stable_semantics.StableSemanticReport`. Profile `A9-S1`.

Manifest signature (s).

```
(source: 'Path', fixture_digest: 'str', results: 'tuple[StableSemanticCaseResult, ...]', certificate:
   ↪ 'Certificate') -> None
```

Definition. Aggregate result for the committed stable semantic fixture.

Contract (D, C, H, R, X). A committed stable-semantics fixture maps to a validated path, JSON mapping, digest, individual case results, and an aggregate report. The fixture schema and ten closed expected values must match, and every case must execute. Results preserve expected/observed values and detail. Malformed fixtures or mismatches produce validation failures or an invalid certificate.

Guarantees (E, P, B, K). The ten comparisons are exact for their declared canonical forms. They remain finite regression laws, not universal theorems. Reports have no frozen stable codec. The base path plus domain operations is used. Cost is the sum of the ten bounded cases.

Evidence and links (V, L). Chapter 72 names all semantic-contract layers. The ten cases cover analysis/synthesis, signal/arithmetic/lattice refinement, operator realization, basis roundtrip, generating products, rendering, settings restoration, and portable refinement towers.

A.9 · check_portable_codec_contract

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.check_portable_codec_contract`. Name-preserving aliases `komorebi_math.v1.check_portable_codec_contract` and `komorebi_math.api.v1.check_portable_codec_contract`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.persistence_contract.check_portable_codec_contract`. Profile `A9-P1`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'PortableCodecCompatibilityReport'
```

Definition. Compare the active registry with the committed codec contract.

Contract (D, C, H, R, X). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (E, P, B, K). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (V, L). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · check_stable_api

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.check_stable_api`. Name-preserving aliases `komorebi_math.v1.check_stable_api` and `komorebi_math.api.v1.check_stable_api`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.compatibility.check_stable_api`. Profile `A9-A1`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'ApiCompatibilityReport'
```

Definition. Check the 1.0-candidate namespace under strict signature compatibility.

Contract (D, C, H, R, X). Stable namespace reflection maps to a deterministic `PublicApiManifest`. Loading and checking map committed JSON plus live reflection to an `ApiCompatibilityReport`. Schemas, package identity, unique names, kinds, owners, and strict signatures must agree. Results are manifests or reports. Malformed JSON and incompatible surfaces raise validation or failed-certificate paths.

Guarantees (E, P, B, K). Comparison is exact structural evidence and does not prove every symbol's mathematics. Manifests/reports have no frozen stable codec. Reflection and JSON use the base runtime. Work is linearithmic in export count because entries are normalized and sorted.

Evidence and links (V, L). Chapter 72 and `verify stable` cover the 131-name manifest and the three name-preserving alias facades. The stable reference-card parser independently checks every card signature. Related symbols are semantic, persistence, and aggregate contracts.

A.9 · check_stable_contract

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.check_stable_contract`. Name-preserving aliases `komorebi_math.v1.check_stable_contract` and `komorebi_math.api.v1.check_stable_contract`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.stable_contract.check_stable_contract`. Profile `A9-C1`.

Manifest signature (s).

```
(*, api_manifest: 'str | Path | None' = None, semantic_fixture: 'str | Path | None' = None, persistence_contract:
   ↪  'str | Path | None' = None) -> 'StableContractReport'
```

Definition. Run every compatibility layer required by the frozen 1.0 surface.

Contract (D, C, H, R, X). The API, semantic, and portable-codec reports map to one `StableContractReport`. `check_stable_contract` executes all three with optional alternate committed paths. All child certificates must be valid. The result is an aggregate report. Any child incompatibility is retained and makes the aggregate certificate invalid.

Guarantees (E, P, B, K). The aggregate is exact conjunction over finite contract checks. It is not a codec payload and does not establish platform qualification, narrative completeness, or all research semantics. Runtime is the sum of the three child checks and their bounded fixtures.

Evidence and links (V, L). `verify stable` reports 6/6 when the API, aliases, semantics, persistence, aggregate contract, and facade imports pass. Chapter 72 explains the boundary. Related release readiness and platform evidence remain separate Chapter 73 gates.

A.9 · `compare_portable_codec_contract`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.compare_portable_codec_contract`. Name-preserving aliases `komorebi_math.v1.compare_portable_codec_contract` and `komorebi_math.api.v1.compare_portable_codec_contract`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.persistence_contract.compare_portable_codec_contract`. Profile `A9-P1`.

Manifest signature (s).

```
(reference: 'PortableCodecContract', current: 'PortableCodecContract | None' = None) ->
   ↪  'PortableCodecCompatibilityReport'
```

Definition. Check tag, type, version, and adjacent migration compatibility.

Contract (D, C, H, R, X). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (E, P, B, K). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (V, L). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · `create_portable_codec_contract`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.create_portable_codec_contract`. Name-preserving aliases `komorebi_math.v1.create_portable_codec_contract` and `komorebi_math.api.v1.create_portable_codec_contract`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.persistence_contract.create_portable_codec_contract`. Profile `A9-P1`.

Manifest signature (s).

```
(*, package_version: 'str | None' = None) -> 'PortableCodecContract'
```

Definition. Snapshot every package-owned codec in deterministic tag order.

Contract (D, C, H, R, X). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (E, P, B, K). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (V, L). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · `create_stable_api_manifest`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.create_stable_api_manifest`. Name-preserving aliases `komorebi_math.v1.create_stable_api_manifest` and `komorebi_math.api.v1.create_stable_api_manifest`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.compatibility.create_stable_api_manifest`. Profile `A9-A1`.

Manifest signature (s).

```
(*, package_version: 'str | None' = None) -> 'PublicApiManifest'
```

Definition. Build the curated 1.0-candidate namespace manifest.

Contract (D, C, H, R, X). Stable namespace reflection maps to a deterministic `PublicApiManifest`. Loading and checking map committed JSON plus live reflection to an `ApiCompatibilityReport`. Schemas, package identity, unique names, kinds, owners, and strict signatures must agree. Results are manifests or reports. Malformed JSON and incompatible surfaces raise validation or failed-certificate paths.

Guarantees (E, P, B, K). Comparison is exact structural evidence and does not prove every symbol's mathematics. Manifests/reports have no frozen stable codec. Reflection and JSON use the base runtime. Work is linearithmic in export count because entries are normalized and sorted.

Evidence and links (V, L). Chapter 72 and `verify stable` cover the 131-name manifest and the three name-preserving alias facades. The stable reference-card parser independently checks every card signature. Related symbols are semantic, persistence, and aggregate contracts.

A.9 · `load_portable_codec_contract`

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.load_portable_codec_contract`. Name-preserving aliases `komorebi_math.v1.load_portable_codec_contract` and `komorebi_math.api.v1.load_portable_codec_contract`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.persistence_contract.load_portable_codec_contract`. Profile `A9-P1`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'PortableCodecContract'
```

Definition. Load and validate the committed codec compatibility contract.

Contract (D, C, H, R, X). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (E, P, B, K). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (V, L). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

A.9 · load_stable_api_manifest

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.load_stable_api_manifest`. Name-preserving aliases `komorebi_math.v1.load_stable_api_manifest` and `komorebi_math.api.v1.load_stable_api_manifest`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.compatibility.load_stable_api_manifest`. Profile `A9-A1`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'PublicApiManifest'
```

Definition. Load and validate the committed 1.0-candidate API manifest.

Contract (D, C, H, R, X). Stable namespace reflection maps to a deterministic `PublicApiManifest`. Loading and checking map committed JSON plus live reflection to an `ApiCompatibilityReport`. Schemas, package identity, unique names, kinds, owners, and strict signatures must agree. Results are manifests or reports. Malformed JSON and incompatible surfaces raise validation or failed-certificate paths.

Guarantees (E, P, B, K). Comparison is exact structural evidence and does not prove every symbol's mathematics. Manifests/reports have no frozen stable codec. Reflection and JSON use the base runtime. Work is linearithmic in export count because entries are normalized and sorted.

Evidence and links (V, L). Chapter 72 and `verify stable` cover the 131-name manifest and the three name-preserving alias facades. The stable reference-card parser independently checks every card signature. Related symbols are semantic, persistence, and aggregate contracts.

A.9 · load_stable_semantics_fixture

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.load_stable_semantics_fixture`. Name-preserving aliases `komorebi_math.v1.load_stable_semantics_fixture` and `komorebi_math.api.v1.load_stable_semantics_fixture`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.stable_semantics.load_stable_semantics_fixture`. Profile `A9-S1`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'tuple[Path, Mapping[str, Any], str]'
```

Definition. Load, validate, and digest one stable semantic fixture.

Contract (D, C, H, R, X). A committed stable-semantics fixture maps to a validated path, JSON mapping, digest, individual case results, and an aggregate report. The fixture schema and ten closed expected values must match, and every case must execute. Results preserve expected/observed values and detail. Malformed fixtures or mismatches produce validation failures or an invalid certificate.

Guarantees (E, P, B, K). The ten comparisons are exact for their declared canonical forms. They remain finite regression laws, not universal theorems. Reports have no frozen stable codec. The base path plus domain operations is used. Cost is the sum of the ten bounded cases.

Evidence and links (V, L). Chapter 72 names all semantic-contract layers. The ten cases cover analysis/synthesis, signal/arithmetic/lattice refinement, operator realization, basis roundtrip, generating products, rendering, settings restoration, and portable refinement towers.

A.9 · run_stable_semantics_fixture

Identity (q, a, t, k). Canonical manifest name `komorebi_math.stable.run_stable_semantics_fixture`. Name-preserving aliases `komorebi_math.v1.run_stable_semantics_fixture` and `komorebi_math.api.v1.run_stable_semantics_fixture`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.stable_semantics.run_stable_semantics_fixture`. Profile `A9-S1`.

Manifest signature (`s`).

```
(path: 'str | Path | None' = None) -> 'StableSemanticReport'
```

Definition. Execute every committed 1.0-candidate semantic case.

Contract (`D, C, H, R, X`). A committed stable-semantics fixture maps to a validated path, JSON mapping, digest, individual case results, and an aggregate report. The fixture schema and ten closed expected values must match, and every case must execute. Results preserve expected/observed values and detail. Malformed fixtures or mismatches produce validation failures or an invalid certificate.

Guarantees (`E, P, B, K`). The ten comparisons are exact for their declared canonical forms. They remain finite regression laws, not universal theorems. Reports have no frozen stable codec. The base path plus domain operations is used. Cost is the sum of the ten bounded cases.

Evidence and links (`V, L`). Chapter 72 names all semantic-contract layers. The ten cases cover analysis/synthesis, signal/arithmetic/lattice refinement, operator realization, basis roundtrip, generating products, rendering, settings restoration, and portable refinement towers.

A.9 · `save_portable_codec_contract`

Identity (`q, a, t, k`). Canonical manifest name `komorebi_math.stable.save_portable_codec_contract`. Name-preserving aliases `komorebi_math.v1.save_portable_codec_contract` and `komorebi_math.api.v1.save_portable_codec_contract`. Tier `[STABLE]`. Manifest kind `function`. Reflected implementation `komorebi_math.persistence_contract.save_portable_codec_contract`. Profile `A9-P1`.

Manifest signature (`s`).

```
(contract: 'PortableCodecContract', path: 'str | Path', *, overwrite: 'bool' = False) -> 'Path'
```

Definition. Write a canonical portable-codec contract.

Contract (`D, C, H, R, X`). The active codec registry maps to a deterministic contract. Load/save/compare/check map contract JSON and registry state to a compatibility report. Tags, type names, versions, and adjacent migrations must satisfy the frozen schema. Results are entries, contracts, paths, or reports. Malformed files, removed tags, type changes, version regressions, and missing migrations fail validation.

Guarantees (`E, P, B, K`). Compatibility comparison and canonical contract writing are exact. Contract records are metadata about portability, not themselves assigned stable codecs. Base JSON/filesystem operations suffice. Work is linear in the 51 sorted codec entries and migration set.

Evidence and links (`V, L`). Chapters 61 and 72 and the stable verification suite check 51 codecs and one adjacent migration. Related symbols are A.8 registry/envelope functions and the aggregate stable contract.

> **Stable-reference coverage.** The recorded validation found 131/131 unique export cards, 131/131 unique anchors, exact agreement with all 112 non-null manifest signatures and all 19 manifest `null` values, and runtime identity across all 393 name-preserving versioned routes. This establishes stable exported-symbol coverage only. Appendix B records the curated beta surface, and Appendix C records the research surface.

Appendix B. Beta API: 83-entry reference

Using the beta reference. Use this appendix when the object you need is listed in the curated beta namespace. Read the card-reading key at the start of Appendix A, then use the canonical `komorebi_math.beta` route given on the card. A convenient root re-export does not express the same compatibility dependency in your source code. If the object also has a stable route, compare the stable card and its contract before choosing an import.

The beta compatibility check and a computation's certificate answer different questions. The former compares the public interface with its recorded contract. The latter reports evidence for the computation or validation that produced it. Run and interpret each check for its stated purpose. A compatible manifest does not establish that every input to every function has been tested.

Choose the section by the task.

If you want to…	Begin with	Then read
Inspect certificates, manifests, or regression reports	B.1	Chapters 5, 7, and 72
Build or execute packet jets and understand their work estimates	B.2	Chapters 38 and 43
Capture, resume, or read a finite packet-jet stream	B.3	Chapter 43 and the stream contracts in Appendix G
Encode or recover a supported portable object	B.4	Chapter 61 and Appendix G

For execution, read the input and resource limits before allocating a full family or snapshot. For streaming, distinguish opening a bounded reader from loading the entire snapshot: the cards state their different memory and completion requirements. A partial stream can be useful progress, but it is not a complete snapshot. For persistence, retain the schema and codec version with the data and use the declared decoding route rather than reconstructing an object from a display representation.

The shared card fields are repeated intentionally so that a card can be read on its own. Use the linked chapters when you need the sequence of operations, and return to the card when you need an exact parameter or failure boundary.

Appendix B records the curated beta exported-symbol ledger for the reference `komorebi_math==1.0.0b4` package. It covers exactly 83 manifest names: 45 classes, 28 functions, and 10 data exports. The beta tier is intentionally distinct from the frozen stable tier: it permits additive growth, but the committed `1.0-beta-additive-strict-signatures` contract treats removal, broad kind change, and reflected signature change as release failures.

The canonical committed manifest has compact canonical-JSON digest `311f2bf7cbcf0a45bcbe2af433d73a8f597c0fbf7133750882314d6e0edb16b2`. Its two committed filename variants, `public_api_beta_1_0.json` and `public_api_beta_1_0_0b4.json`, are byte-identical in the reference source and have raw SHA-256 `c0f4cf27d4a47b86d1ea5b79c6c2fe883368e6ab7f8a640e527f916b271ba000`. Canonical and raw digests have different meanings and are not interchangeable.

B.0 Reference contract, maturity rule, and route audit

Every card implements the Chapter 76 fields `q, a, t, k, s, D, C, H, R, X, E, P, B, K, V, L`. Exact manifest signatures appear verbatim in fenced `text` blocks. Literal `null` is preserved for the ten data exports and six exception classes. The manual does not manufacture constructor signatures the manifest does not freeze.

The canonical tier-declaring route is always `komorebi_math.beta.<name>`. The reference root and domain namespaces expose 125 additional identity-equal routes, for 208 audited qualified identities across the 83 names. Those re-exports are convenience routes. Only the `komorebi_math.beta` import explicitly declares the beta compatibility dependency. Unlike the stable tier, there is no `komorebi_math.api.beta` or versioned `v1` beta facade in this source snapshot.

Six names are available only through the canonical beta namespace, 29 have one audited convenience route, and 48 have two.

The cards distinguish structural compatibility, finite regression evidence, mathematical certificates, local runtime observations, persistence integrity, and authenticity. In particular, the strict beta manifest check does not prove behavioral equivalence. The 15-case golden fixture is representative rather than exhaustive. Profiler samples are local observations rather than asymptotic bounds, and SHA-256 stream or portable digests detect corruption but do not authenticate the producer.

Section	Classes	Functions	Data	Total
B.1	16	5	4	25
B.2	19	7	0	26
B.3	8	5	4	17
B.4	2	11	2	15
Total	**45**	**28**	**10**	**83**

A short canonical import pattern is:

```
from komorebi_math import beta

report = beta.check_beta_api()
report.certificate.require()
assert report.strict_signatures
```

B.1 Foundational records, golden fixtures, and compatibility

B.1 · BEHAVIORAL_GOLDEN_SCHEMA

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.BEHAVIORAL_GOLDEN_SCHEMA`. Identity-equal audited re-exports `komorebi_math.BEHAVIORAL_GOLDEN_SCHEMA`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `B1-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `komorebi-math.behavioral-golden`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the recorded immutable string or integer. Importing the package is the only precondition. The value is returned by ordinary attribute access. It has no call-time exception path and does not by itself validate a payload, fixture, or compatibility report.

Guarantees (E, P, B, K). The binding is an exact package identity or schema identifier. It requires no optional backend, performs no fallback, and has constant-time lookup. A schema name and version identify a format. They are not proof that arbitrary data conforms to that format.

Evidence and links (V, L). Verified by the beta manifest parser, runtime identity audit, beta regression tests, and the Appendix B reference-card parser. See Chapters 0, 7, 61, and 72 and the related loader or codec functions.

B.1 · BEHAVIORAL_GOLDEN_SCHEMA_VERSION

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.BEHAVIORAL_GOLDEN_SCHEMA_VERSION`. Identity-equal audited re-exports `komorebi_math.BEHAVIORAL_GOLDEN_SCHEMA_VERSION`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `B1-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `1`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the recorded immutable string or integer. Importing the package is the only precondition. The value is returned by ordinary attribute access. It has no call-time exception path and does not by itself validate a payload, fixture, or compatibility report.

Guarantees (E, P, B, K). The binding is an exact package identity or schema identifier. It requires no optional backend, performs no fallback, and has constant-time lookup. A schema name and version identify a format. They are not proof that arbitrary data conforms to that format.

Evidence and links (V, L). Verified by the beta manifest parser, runtime identity audit, beta regression tests, and the Appendix B reference-card parser. See Chapters 0, 7, 61, and 72 and the related loader or codec functions.

B.1 · `BETA_API_STABILITY_LEVEL`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.BETA_API_STABILITY_LEVEL`. Identity-equal audited re-exports `komorebi_math.BETA_API_STABILITY_LEVEL`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `B1-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `1.0-beta-additive-strict-signatures`: additions are allowed, while removal, kind drift, and reflected signature drift fail the beta compatibility gate.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the recorded immutable string or integer. Importing the package is the only precondition. The value is returned by ordinary attribute access. It has no call-time exception path and does not by itself validate a payload, fixture, or compatibility report.

Guarantees (E, P, B, K). The binding is an exact package identity or schema identifier. It requires no optional backend, performs no fallback, and has constant-time lookup. A schema name and version identify a format. They are not proof that arbitrary data conforms to that format.

Evidence and links (V, L). Verified by the beta manifest parser, runtime identity audit, beta regression tests, and the Appendix B reference-card parser. See Chapters 0, 7, 61, and 72 and the related loader or codec functions.

B.1 · `__version__`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.__version__`. Identity-equal audited re-exports `komorebi_math.__version__`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `B1-I1`.

Manifest signature (s).

```
null
```

Definition. The recorded package version is `1.0.0b4`, as stated in the reference manifest.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the recorded immutable string or integer. Importing the package is the only precondition. The value is returned by ordinary attribute access. It has no call-time exception path and does not by itself validate a payload, fixture, or compatibility report.

Guarantees (E, P, B, K). The binding is an exact package identity or schema identifier. It requires no optional backend, performs no fallback, and has constant-time lookup. A schema name and version identify a format. They are not proof that arbitrary data conforms to that format.

Evidence and links (V, L). Verified by the beta manifest parser, runtime identity audit, beta regression tests, and the Appendix B reference-card parser. See Chapters 0, 7, 61, and 72 and the related loader or codec functions.

B.1 · Exactness

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.Exactness`. Identity-equal audited re-exports `komorebi_math.Exactness`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.Exactness`. Profile `B1-C1`.

Manifest signature (s).

```
(*values)
```

Definition. A string-valued evidence classification enum. The five string values are `exact`, `numerical`, `conditional`, `heuristic`, and `planned`. Members: `EXACT=exact`, `NUMERICAL=numerical`, `CONDITIONAL=conditional`, `HEURISTIC=heuristic`, `PLANNED=planned`.

Contract (D, C, H, R, X). These records classify and carry validation evidence. Inputs are the declared fields in the manifest signature. The codomain is an immutable enum member or frozen result record. Construction requires type-consistent values. `Certificate.require()` and `ComputationResult.require()` raise `ValidationError` when the certificate is invalid. `ConditionalResult` rejects a certificate whose exactness is not conditional.

Guarantees (E, P, B, K). The classes preserve the supplied evidence exactly and make exact, numerical, conditional, heuristic, and planned states machine-visible. They do not independently prove the theorem named in a record. They use only the Python standard library, have no backend fallback, and require storage linear in the number of residual, assumption, and diagnostic entries.

Evidence and links (V, L). Covered by certificate unit tests, portable certificate round-trips, negative invalid-certificate tests, and aggregate verification reports. See Chapters 1, 5, 6, 37, 43, 61, and 71.

B.1 · Certificate

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.Certificate`. Identity-equal audited re-exports `komorebi_math.Certificate`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.Certificate`. Profile `B1-C1`.

Manifest signature (s).

```
(valid: 'bool', exactness: 'Exactness', residuals: 'dict[str, float]' = <factory>, tolerance: 'float | None' =
    ↪ None, assumptions_checked: 'tuple[str, ...]' = (), assumptions_unchecked: 'tuple[str, ...]' = (),
    ↪ diagnostics: 'dict[str, Any]' = <factory>, theorem_id: 'str | None' = None, message: 'str' = '') -> None
```

Definition. Structured validation record. The record carries validity, exactness, residuals, tolerance, checked and unchecked assumptions, diagnostics, an optional theorem identifier, and a message. Stored fields: `valid`, `exactness`, `residuals`, `tolerance`, `assumptions_checked`, `assumptions_unchecked`, `diagnostics`, `theorem_id`, `message`. Runtime-visible operational members: `require`, `to_dict`, `to_json`.

Contract (D, C, H, R, X). These records classify and carry validation evidence. Inputs are the declared fields in the manifest signature. The codomain is an immutable enum member or frozen result record. Construction requires type-consistent values. `Certificate.require()` and `ComputationResult.require()` raise `ValidationError` when the certificate is invalid. `ConditionalResult` rejects a certificate whose exactness is not conditional.

Guarantees (E, P, B, K). The classes preserve the supplied evidence exactly and make exact, numerical, conditional, heuristic, and planned states machine-visible. They do not independently prove the theorem named in a record. They use only the Python standard library, have no backend fallback, and require storage linear in the number of residual, assumption, and diagnostic entries.

Evidence and links (V, L). Covered by certificate unit tests, portable certificate round-trips, negative invalid-certificate tests, and aggregate verification reports. See Chapters 1, 5, 6, 37, 43, 61, and 71.

B.1 · ComputationResult

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.ComputationResult`. Identity-equal audited re-exports `komorebi_math.ComputationResult`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.ComputationResult`. Profile `B1-C1`.

Manifest signature (s).

```
(value: 'T', certificate: 'Certificate') -> None
```

Definition. A value paired with its execution certificate. Properties expose certificate validity and exactness. `require()` validates and returns the value. Stored fields: `value`, `certificate`. Runtime-visible operational members: `exact`, `valid`, `require`.

Contract (D, C, H, R, X). These records classify and carry validation evidence. Inputs are the declared fields in the manifest signature. The codomain is an immutable enum member or frozen result record. Construction requires type-consistent values. `Certificate.require()` and `ComputationResult.require()` raise `ValidationError` when the certificate is invalid. `ConditionalResult` rejects a certificate whose exactness is not conditional.

Guarantees (E, P, B, K). The classes preserve the supplied evidence exactly and make exact, numerical, conditional, heuristic, and planned states machine-visible. They do not independently prove the theorem named in a record. They use only the Python standard library, have no backend fallback, and require storage linear in the number of residual, assumption, and diagnostic entries.

Evidence and links (V, L). Covered by certificate unit tests, portable certificate round-trips, negative invalid-certificate tests, and aggregate verification reports. See Chapters 1, 5, 6, 37, 43, 61, and 71.

B.1 · ConditionalResult

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.ConditionalResult`. Identity-equal audited re-exports `komorebi_math.ConditionalResult`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.certificates.ConditionalResult`. Profile `B1-C1`.

Manifest signature (s).

```
(value: 'T', certificate: 'Certificate') -> None
```

Definition. A value whose conclusion depends on explicit unchecked assumptions. Construction enforces `Exactness.CONDITIONAL`, preventing an unconditional certificate from being wrapped as assumption-dependent output. Stored fields: `value`, `certificate`.

Contract (D, C, H, R, X). These records classify and carry validation evidence. Inputs are the declared fields in the manifest signature. The codomain is an immutable enum member or frozen result record. Construction requires type-consistent values. `Certificate.require()` and `ComputationResult.require()` raise `ValidationError` when the certificate is invalid. `ConditionalResult` rejects a certificate whose exactness is not conditional.

Guarantees (E, P, B, K). The classes preserve the supplied evidence exactly and make exact, numerical, conditional, heuristic, and planned states machine-visible. They do not independently prove the theorem named in a record. They use only the Python standard library, have no backend fallback, and require storage linear in the number of residual, assumption, and diagnostic entries.

Evidence and links (V, L). Covered by certificate unit tests, portable certificate round-trips, negative invalid-certificate tests, and aggregate verification reports. See Chapters 1, 5, 6, 37, 43, 61, and 71.

B.1 · KomorebiMathError

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.KomorebiMathError`. No identity-equal re-export in the six audited root/domain namespaces. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.KomorebiMathError`. Profile `B1-X1`.

Manifest signature (`s`).

```
null
```

Definition. Base class for all public package exceptions.

Contract (`D, C, H, R, X`). The domain is an error condition raised by a public Komorebi operation. The codomain is an exception object carrying the caller-supplied message and ordinary Python exception context. There are no mathematical hypotheses. Constructing an exception does not raise package-specific errors. The originating operation determines when it is emitted.

Guarantees (`E, P, B, K`). The hierarchy provides deterministic error classification, not recovery or proof. It has no optional dependencies or backend behavior and constant construction cost apart from the message and traceback. `ValidationError` also derives from `ValueError`. Specialized classes retain the public `KomorebiMathError` lineage.

Evidence and links (`V, L`). Negative-path tests assert the specific classes for malformed structures, dimension mismatches, unavailable optional backends, exactness violations, and unmet assumptions. See Chapters 6, 8, 37, 43, 61, and Appendix I.

B.1 · `ValidationError`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.ValidationError`. No identity-equal re-export in the six audited root/domain namespaces. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.ValidationError`. Profile `B1-X1`.

Manifest signature (`s`).

```
null
```

Definition. Raised when a mathematical object fails a declared validation rule. This class derives from both `KomorebiMathError` and `ValueError`.

Contract (`D, C, H, R, X`). The domain is an error condition raised by a public Komorebi operation. The codomain is an exception object carrying the caller-supplied message and ordinary Python exception context. There are no mathematical hypotheses. Constructing an exception does not raise package-specific errors. The originating operation determines when it is emitted.

Guarantees (`E, P, B, K`). The hierarchy provides deterministic error classification, not recovery or proof. It has no optional dependencies or backend behavior and constant construction cost apart from the message and traceback. `ValidationError` also derives from `ValueError`. Specialized classes retain the public `KomorebiMathError` lineage.

Evidence and links (`V, L`). Negative-path tests assert the specific classes for malformed structures, dimension mismatches, unavailable optional backends, exactness violations, and unmet assumptions. See Chapters 6, 8, 37, 43, 61, and Appendix I.

B.1 · `DimensionError`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.DimensionError`. No identity-equal re-export in the six audited root/domain namespaces. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.DimensionError`. Profile `B1-X1`.

Manifest signature (`s`).

```
null
```

Definition. Raised when matrix, vector, or packet dimensions do not agree.

Contract (`D, C, H, R, X`). The domain is an error condition raised by a public Komorebi operation. The codomain is an exception object carrying the caller-supplied message and ordinary Python exception context. There are no mathematical hypotheses. Constructing an exception does not raise package-specific errors. The originating operation determines when it is emitted.

Guarantees (E, P, B, K). The hierarchy provides deterministic error classification, not recovery or proof. It has no optional dependencies or backend behavior and constant construction cost apart from the message and traceback. `ValidationError` also derives from `ValueError`. Specialized classes retain the public `KomorebiMathError` lineage.

Evidence and links (V, L). Negative-path tests assert the specific classes for malformed structures, dimension mismatches, unavailable optional backends, exactness violations, and unmet assumptions. See Chapters 6, 8, 37, 43, 61, and Appendix I.

B.1 · `BackendUnavailableError`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.BackendUnavailableError`. No identity-equal re-export in the six audited root/domain namespaces. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.BackendUnavailableError`. Profile `B1-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when an optional computation backend is not installed.

Contract (D, C, H, R, X). The domain is an error condition raised by a public Komorebi operation. The codomain is an exception object carrying the caller-supplied message and ordinary Python exception context. There are no mathematical hypotheses. Constructing an exception does not raise package-specific errors. The originating operation determines when it is emitted.

Guarantees (E, P, B, K). The hierarchy provides deterministic error classification, not recovery or proof. It has no optional dependencies or backend behavior and constant construction cost apart from the message and traceback. `ValidationError` also derives from `ValueError`. Specialized classes retain the public `KomorebiMathError` lineage.

Evidence and links (V, L). Negative-path tests assert the specific classes for malformed structures, dimension mismatches, unavailable optional backends, exactness violations, and unmet assumptions. See Chapters 6, 8, 37, 43, 61, and Appendix I.

B.1 · `ExactnessError`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.ExactnessError`. No identity-equal re-export in the six audited root/domain namespaces. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.ExactnessError`. Profile `B1-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when an exact operation is requested from an inexact backend.

Contract (D, C, H, R, X). The domain is an error condition raised by a public Komorebi operation. The codomain is an exception object carrying the caller-supplied message and ordinary Python exception context. There are no mathematical hypotheses. Constructing an exception does not raise package-specific errors. The originating operation determines when it is emitted.

Guarantees (E, P, B, K). The hierarchy provides deterministic error classification, not recovery or proof. It has no optional dependencies or backend behavior and constant construction cost apart from the message and traceback. `ValidationError` also derives from `ValueError`. Specialized classes retain the public `KomorebiMathError` lineage.

Evidence and links (V, L). Negative-path tests assert the specific classes for malformed structures, dimension mismatches, unavailable optional backends, exactness violations, and unmet assumptions. See Chapters 6, 8, 37, 43, 61, and Appendix I.

B.1 · AssumptionError

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.AssumptionError`. No identity-equal re-export in the six audited root/domain namespaces. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.exceptions.AssumptionError`. Profile `B1-X1`.

Manifest signature (s).

```
null
```

Definition. Raised when a required mathematical assumption is not satisfied.

Contract (D, C, H, R, X). The domain is an error condition raised by a public Komorebi operation. The codomain is an exception object carrying the caller-supplied message and ordinary Python exception context. There are no mathematical hypotheses. Constructing an exception does not raise package-specific errors. The originating operation determines when it is emitted.

Guarantees (E, P, B, K). The hierarchy provides deterministic error classification, not recovery or proof. It has no optional dependencies or backend behavior and constant construction cost apart from the message and traceback. `ValidationError` also derives from `ValueError`. Specialized classes retain the public `KomorebiMathError` lineage.

Evidence and links (V, L). Negative-path tests assert the specific classes for malformed structures, dimension mismatches, unavailable optional backends, exactness violations, and unmet assumptions. See Chapters 6, 8, 37, 43, 61, and Appendix I.

B.1 · PacketSystem

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketSystem`. Identity-equal audited re-exports `komorebi_math.PacketSystem`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.core.packets.PacketSystem`. Profile `B1-P1`.

Manifest signature (s).

```
(projectors: 'Sequence[Any]', *, names: 'Sequence[str] | None' = None, backend: 'str | LinearAlgebraBackend | None'
    ↪  = None, tolerance: 'float | None' = None, validate: 'bool | None' = None) -> 'None'
```

Definition. A complete finite family of pairwise annihilating idempotents. Runtime-visible operational members: `aggregate`, `analyze`, `block_diagonal_projection`, `certificate`, `dual`, `equivalent`, `hilbert_certificate`, `index`, `packet_dimensions`, `quotient`, `restrict`, `support`, `synthesize`, `tensor`, `transport`.

Contract (D, C, H, R, X). A finite sequence of square projectors, optional names, backend selection, tolerance, and validation policy maps to a complete packet decomposition. Projectors must share dimension, be idempotent, annihilate pairwise, and sum to identity under the selected exact or numerical policy. Invalid shapes, duplicate names, failed algebraic checks, or unavailable backends raise the documented validation, dimension, or backend errors.

Guarantees (E, P, B, K). With exact arithmetic the packet identities are exact. Numerical backends certify residuals against the selected tolerance. The object supports analysis, synthesis, support, restriction, quotient, dual, tensor, transport, and block operations. Construction and validation scale with the packet count and matrix products. Materialized matrices require ambient quadratic storage.

Evidence and links (V, L). The constructor certificate uses theorem identifier `PSC-I-T20`. Packet analysis-synthesis, equivalence, tensor, and transport tests cover the public operations. See Chapters 10 through 12, 38, 43, and 64.

B.1 · PublicApiSymbol

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PublicApiSymbol`. Identity-equal audited re-exports `komorebi_math.PublicApiSymbol`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.compatibility.PublicApiSymbol`. Profile `B1-A1`.

Manifest signature (s).

```
(namespace: 'str', name: 'str', kind: 'str', implementation_module: 'str', qualname: 'str', signature: 'str |
   ↪ None') -> None
```

Definition. One exported public symbol in a deterministic API manifest. Stored fields: `namespace`, `name`, `kind`, `implementation_module`, `qualname`, `signature`. Runtime-visible operational members: `to_dict`.

Contract (D, C, H, R, X). The records map reflected public exports to deterministic manifest rows, aggregate rows into a validated manifest, and report structural differences between reference and current manifests. Namespaces must be nonempty and unique. Symbols must be unique, sorted, and inside the declared namespace set. Malformed fields, duplicate symbols, unstable ordering, namespace mismatch, or incompatible changes raise `ValidationError` or produce an invalid report certificate.

Guarantees (E, P, B, K). Canonical dictionaries and SHA-256 digests are deterministic under compact sorted-key JSON. The report policy distinguishes additions, removals, broad kind changes, and reflected signature changes. Structural equality is not mathematical or behavioral equivalence. Work and memory are linear in the number of exported symbols plus sorting cost.

Evidence and links (V, L). The strict beta check is exercised by API tests and `verify streaming-beta`. The reference 83-name manifest reports zero added, removed, kind-changed, or signature-changed entries under theorem identifier `KM-API-010`. See Chapters 7, 72, 75, and 76.

B.1 · `PublicApiManifest`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PublicApiManifest`. Identity-equal audited re-exports `komorebi_math.PublicApiManifest`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.compatibility.PublicApiManifest`. Profile `B1-A1`.

Manifest signature (s).

```
(package_version: 'str', namespaces: 'tuple[str, ...]', symbols: 'tuple[PublicApiSymbol, ...]', schema: 'str' =
   ↪ 'komorebi-math.public-api', schema_version: 'int' = 1, stability_level: 'str' = 'pre-beta-additive') -> None
```

Definition. A deterministic snapshot of selected `__all__` namespaces. The `digest` property hashes canonical compact JSON. `symbol_map()` keys rows by `(namespace, name)`. Stored fields: `package_version`, `namespaces`, `symbols`, `schema`, `schema_version`, `stability_level`. Runtime-visible operational members: `digest`, `symbol_map`, `to_dict`.

Contract (D, C, H, R, X). The records map reflected public exports to deterministic manifest rows, aggregate rows into a validated manifest, and report structural differences between reference and current manifests. Namespaces must be nonempty and unique. Symbols must be unique, sorted, and inside the declared namespace set. Malformed fields, duplicate symbols, unstable ordering, namespace mismatch, or incompatible changes raise `ValidationError` or produce an invalid report certificate.

Guarantees (E, P, B, K). Canonical dictionaries and SHA-256 digests are deterministic under compact sorted-key JSON. The report policy distinguishes additions, removals, broad kind changes, and reflected signature changes. Structural equality is not mathematical or behavioral equivalence. Work and memory are linear in the number of exported symbols plus sorting cost.

Evidence and links (V, L). The strict beta check is exercised by API tests and `verify streaming-beta`. The reference 83-name manifest reports zero added, removed, kind-changed, or signature-changed entries under theorem identifier `KM-API-010`. See Chapters 7, 72, 75, and 76.

B.1 · `ApiCompatibilityReport`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.ApiCompatibilityReport`. Identity-equal audited re-exports `komorebi_math.ApiCompatibilityReport`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.compatibility.ApiCompatibilityReport`. Profile `B1-A1`.

Manifest signature (s).

```
(reference_digest: 'str', current_digest: 'str', added: 'tuple[tuple[str, str], ...]', removed: 'tuple[tuple[str,
    ↪ str], ...]', kind_changed: 'tuple[tuple[str, str, str, str], ...]', signature_changed: 'tuple[tuple[str,
    ↪ str, str | None, str | None], ...]', strict_signatures: 'bool', certificate: 'Certificate') -> None
```

Definition. Structural differences between a reference and current API manifest. The `compatible` property mirrors the certificate verdict. `to_dict()` preserves all four change ledgers and both digests. Stored fields: `reference_digest`, `current_digest`, `added`, `removed`, `kind_changed`, `signature_changed`, `strict_signatures`, `certificate`. Runtime-visible operational members: `compatible`, `to_dict`.

Contract (D, C, H, R, X). The records map reflected public exports to deterministic manifest rows, aggregate rows into a validated manifest, and report structural differences between reference and current manifests. Namespaces must be nonempty and unique. Symbols must be unique, sorted, and inside the declared namespace set. Malformed fields, duplicate symbols, unstable ordering, namespace mismatch, or incompatible changes raise `ValidationError` or produce an invalid report certificate.

Guarantees (E, P, B, K). Canonical dictionaries and SHA-256 digests are deterministic under compact sorted-key JSON. The report policy distinguishes additions, removals, broad kind changes, and reflected signature changes. Structural equality is not mathematical or behavioral equivalence. Work and memory are linear in the number of exported symbols plus sorting cost.

Evidence and links (V, L). The strict beta check is exercised by API tests and `verify streaming-beta`. The reference 83-name manifest reports zero added, removed, kind-changed, or signature-changed entries under theorem identifier `KM-API-010`. See Chapters 7, 72, 75, and 76.

B.1 · `create_beta_api_manifest`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.create_beta_api_manifest`. Identity-equal audited re-exports `komorebi_math.create_beta_api_manifest`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.compatibility.create_beta_api_manifest`. Profile `B1-A2`.

Manifest signature (s).

```
(*, package_version: 'str | None' = None) -> 'PublicApiManifest'
```

Definition. Build the curated beta namespace manifest with strict signatures.

Contract (D, C, H, R, X). The creation route reflects the curated `komorebi_math.beta.__all__` namespace. The loader reads and validates the committed manifest. The checker compares that reference with the installed package using strict signatures. Optional paths must identify a valid public-API JSON document. Invalid schema, duplicate keys or symbols, wrong namespace or stability level, unreadable files, and incompatible removals, kind changes, or signatures are reported through `ValidationError` or an invalid compatibility certificate.

Guarantees (E, P, B, K). The beta policy permits additive exports while treating removal, broad kind change, and reflected signature change as release failures. Canonical manifest generation is deterministic, but it intentionally leaves behavior and undocumented implementation details unchecked. The implementation uses reflection, JSON, SHA-256, and sorting. Cost is quasilinear in the 83-row inventory.

Evidence and links (V, L). The recorded reference audit reran `check_beta_api()` and required theorem `KM-API-010`, strict signatures, the canonical digest `311f2bf7cbcf0a45bcbe2af433d73a8f597c0fbf7133750882314d6e0edb16b2`, and zero incompatible changes. See Chapters 7, 72, 75, and 76.

B.1 · `load_beta_api_manifest`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.load_beta_api_manifest`. Identity-equal audited re-exports `komorebi_math.load_beta_api_manifest`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.compatibility.load_beta_api_manifest`. Profile `B1-A2`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'PublicApiManifest'
```

Definition. Load and validate the committed curated beta API manifest.

Contract (D, C, H, R, X). The creation route reflects the curated `komorebi_math.beta.__all__` namespace. The loader reads and validates the committed manifest. The checker compares that reference with the installed package using strict signatures. Optional paths must identify a valid public-API JSON document. Invalid schema, duplicate keys or symbols, wrong namespace or stability level, unreadable files, and incompatible removals, kind changes, or signatures are reported through `ValidationError` or an invalid compatibility certificate.

Guarantees (E, P, B, K). The beta policy permits additive exports while treating removal, broad kind change, and reflected signature change as release failures. Canonical manifest generation is deterministic, but it intentionally leaves behavior and undocumented implementation details unchecked. The implementation uses reflection, JSON, SHA-256, and sorting. Cost is quasilinear in the 83-row inventory.

Evidence and links (V, L). The recorded reference audit reran `check_beta_api()` and required theorem `KM-API-010`, strict signatures, the canonical digest `311f2bf7cbcf0a45bcbe2af433d73a8f597c0fbf7133750882314d6e0edb16b2`, and zero incompatible changes. See Chapters 7, 72, 75, and 76.

B.1 · `check_beta_api`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.check_beta_api`. Identity-equal audited re-exports `komorebi_math.check_beta_api`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.compatibility.check_beta_api`. Profile `B1-A2`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'ApiCompatibilityReport'
```

Definition. Check the curated beta namespace under strict signature compatibility. The default reference is the committed curated beta manifest, and strict signatures are always enabled.

Contract (D, C, H, R, X). The creation route reflects the curated `komorebi_math.beta.__all__` namespace. The loader reads and validates the committed manifest. The checker compares that reference with the installed package using strict signatures. Optional paths must identify a valid public-API JSON document. Invalid schema, duplicate keys or symbols, wrong namespace or stability level, unreadable files, and incompatible removals, kind changes, or signatures are reported through `ValidationError` or an invalid compatibility certificate.

Guarantees (E, P, B, K). The beta policy permits additive exports while treating removal, broad kind change, and reflected signature change as release failures. Canonical manifest generation is deterministic, but it intentionally leaves behavior and undocumented implementation details unchecked. The implementation uses reflection, JSON, SHA-256, and sorting. Cost is quasilinear in the 83-row inventory.

Evidence and links (V, L). The recorded reference audit reran `check_beta_api()` and required theorem `KM-API-010`, strict signatures, the canonical digest `311f2bf7cbcf0a45bcbe2af433d73a8f597c0fbf7133750882314d6e0edb16b2`, and zero incompatible changes. See Chapters 7, 72, 75, and 76.

B.1 · `BehavioralGoldenCaseResult`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.BehavioralGoldenCaseResult`. Identity-equal audited re-exports `komorebi_math.BehavioralGoldenCaseResult`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.golden.BehavioralGoldenCaseResult`. Profile `B1-G1`.

Manifest signature (`s`).

```
(name: 'str', kind: 'str', observed: 'Any', expected: 'Any', certificate: 'Certificate') -> None
```

Definition. Observed and expected data for one closed golden case. Stored fields: `name`, `kind`, `observed`, `expected`, `certificate`. Runtime-visible operational members: `passed`, `to_dict`.

Contract (`D, C, H, R, X`). A case result stores one closed case name and kind, observed and expected canonical values, and its certificate. A report stores fixture path and digest, the ordered case results, and an aggregate certificate. Inputs must already satisfy the closed fixture evaluator contract. Serialization exposes JSON-compatible mappings. A failed case yields `passed == False`. Malformed fixture data is rejected before these records are returned.

Guarantees (`E, P, B, K`). The records preserve deterministic finite regression evidence. They prove only the enumerated committed cases and explicitly do not make the fixture exhaustive. No optional backend is required for the committed fixture. Storage is linear in the number and size of the case records.

Evidence and links (`V, L`). The reference fixture contains 15 cases and has digest `13bd8c499838593c9d9242ac10210f0695e16a690c9270d68f321c41d85835ea`. The aggregate certificate uses `KM-GOLDEN-011`. See Chapters 72 and 75 and `tests/test_block11_golden_profiling_beta.py`.

B.1 · `BehavioralGoldenReport`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.BehavioralGoldenReport`. Identity-equal audited re-exports `komorebi_math.BehavioralGoldenReport`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.golden.BehavioralGoldenReport`. Profile `B1-G1`.

Manifest signature (`s`).

```
(fixture_path: 'Path', fixture_digest: 'str', results: 'tuple[BehavioralGoldenCaseResult, ...]', certificate:
    ↪ 'Certificate') -> None
```

Definition. Aggregate deterministic semantic regression report. The `passed` property requires the aggregate certificate and every case result to pass. Stored fields: `fixture_path`, `fixture_digest`, `results`, `certificate`. Runtime-visible operational members: `passed`, `to_dict`.

Contract (`D, C, H, R, X`). A case result stores one closed case name and kind, observed and expected canonical values, and its certificate. A report stores fixture path and digest, the ordered case results, and an aggregate certificate. Inputs must already satisfy the closed fixture evaluator contract. Serialization exposes JSON-compatible mappings. A failed case yields `passed == False`. Malformed fixture data is rejected before these records are returned.

Guarantees (`E, P, B, K`). The records preserve deterministic finite regression evidence. They prove only the enumerated committed cases and explicitly do not make the fixture exhaustive. No optional backend is required for the committed fixture. Storage is linear in the number and size of the case records.

Evidence and links (`V, L`). The reference fixture contains 15 cases and has digest `13bd8c499838593c9d9242ac10210f0695e16a690c9270d68f321c41d85835ea`. The aggregate certificate uses `KM-GOLDEN-011`. See Chapters 72 and 75 and `tests/test_block11_golden_profiling_beta.py`.

B.1 · `load_behavioral_golden_fixture`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.load_behavioral_golden_fixture`. Identity-equal audited re-exports `komorebi_math.load_behavioral_golden_fixture`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.golden.load_behavioral_golden_fixture`. Profile `B1-G2`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'tuple[Path, dict[str, Any], str]'
```

Definition. Load and validate the closed behavioral fixture document.

Contract (D, C, H, R, X). The loader accepts the default committed fixture or an explicit path, rejects duplicate JSON keys, validates the fixed schema and closed case document, and returns path, decoded mapping, and canonical digest. The runner dispatches only through the built-in case-kind registry and returns one aggregate report. Unknown kinds, malformed values, failed schema checks, unreadable files, or evaluator errors raise `ValidationError`. Mismatched expected values produce failed case and aggregate certificates.

Guarantees (E, P, B, K). Execution is deterministic for the committed exact and canonicalized numerical forms. It is a representative finite semantic regression suite rather than a proof of all package behavior. The default fixture exercises 15 cases. Time is the sum of those bounded computations and memory is linear in fixture and result size.

Evidence and links (V, L). The recorded reference audit executed all 15 committed cases and required an exact passing `KM-GOLDEN-011` certificate. The fixture spans packet snapshots, sparse and cached execution, migration and streaming, generating-function arithmetic, coordinates, and formal roundtrips. See Chapter 72.

B.1 · `run_behavioral_golden_fixture`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.run_behavioral_golden_fixture`. Identity-equal audited re-exports `komorebi_math.run_behavioral_golden_fixture`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.golden.run_behavioral_golden_fixture`. Profile `B1-G2`.

Manifest signature (s).

```
(path: 'str | Path | None' = None) -> 'BehavioralGoldenReport'
```

Definition. Execute every committed semantic fixture through its closed evaluator. The current closed evaluator covers 15 committed case kinds and does not execute import paths supplied by JSON.

Contract (D, C, H, R, X). The loader accepts the default committed fixture or an explicit path, rejects duplicate JSON keys, validates the fixed schema and closed case document, and returns path, decoded mapping, and canonical digest. The runner dispatches only through the built-in case-kind registry and returns one aggregate report. Unknown kinds, malformed values, failed schema checks, unreadable files, or evaluator errors raise `ValidationError`. Mismatched expected values produce failed case and aggregate certificates.

Guarantees (E, P, B, K). Execution is deterministic for the committed exact and canonicalized numerical forms. It is a representative finite semantic regression suite rather than a proof of all package behavior. The default fixture exercises 15 cases. Time is the sum of those bounded computations and memory is linear in fixture and result size.

Evidence and links (V, L). The recorded reference audit executed all 15 committed cases and required an exact passing `KM-GOLDEN-011` certificate. The fixture spans packet snapshots, sparse and cached execution, migration and streaming, generating-function arithmetic, coordinates, and formal roundtrips. See Chapter 72.

B.2 Nonlinear derivatives, jets, sparse storage, execution, and profiling

B.2 · DerivativeProvider

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.DerivativeProvider`. Identity-equal audited re-exports `komorebi_math.nonlinear.DerivativeProvider`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.derivatives.DerivativeProvider`. Profile `B2-D0`.

Manifest signature (s).

```
(*args, **kwargs)
```

Definition. Protocol implemented by finite dimensional derivative sources. It is a runtime-checkable structural protocol rather than an instantiable mathematical implementation. Runtime-visible operational members: `derivative`, `supports_order`, `value`.

Contract (D, C, H, R, X). This runtime protocol describes finite-dimensional derivative sources with `source_dimension`, `target_dimension`, `exactness`, and `name`, plus `value(point)`, `derivative(order, point, directions)`, and `supports_order(order)`. Implementations must accept an ordered direction tuple of the declared order and return a target-space value. A protocol declaration alone does not validate mathematics. Concrete providers define dimension, order, and exactness failures.

Guarantees (E, P, B, K). The protocol enables structural typing and backend-independent jet construction. It makes no implementation, complexity, persistence, or numerical-accuracy guarantee. Cost and dependencies are those of the concrete provider.

Evidence and links (V, L). Runtime protocol conformance is exercised through callable, finite-difference, polynomial, sparse, automatic-differentiation, and downstream packet-jet tests. See Chapter 37.

B.2 · CallableDerivativeProvider

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.CallableDerivativeProvider`. Identity-equal audited re-exports `komorebi_math.CallableDerivativeProvider`, `komorebi_math.nonlinear.CallableDerivativeProvider`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.derivatives.CallableDerivativeProvider`. Profile `B2-D1`.

Manifest signature (s).

```
(function: 'Callable[[Any], Any]', derivatives: 'Mapping[int, DirectionalDerivative]', source_dimension: 'int',
   ↪ target_dimension: 'int', exactness: 'Exactness' = <Exactness.NUMERICAL: 'numerical'>, name: 'str' =
   ↪ 'declared derivative provider') -> None
```

Definition. A map with explicitly supplied directional derivative callables. The `available_orders` property is the sorted declared derivative-order set. Stored fields: `function`, `derivatives`, `source_dimension`, `target_dimension`, `exactness`, `name`. Runtime-visible operational members: `available_orders`, `derivative`, `supports_order`, `validation_certificate`, `value`.

Contract (D, C, H, R, X). A function, explicit map from derivative order to directional-derivative callable, positive source and target dimensions, exactness label, and name define a declared derivative source. Each derivative callable receives `(point, directions)`. Unsupported orders, incorrect dimensions, malformed direction tuples, and failed optional validation probes are rejected or certified explicitly.

Guarantees (E, P, B, K). The provider preserves the declared exactness but does not infer correctness from user callables. `validation_certificate` performs only selected finite symmetry and optional Taylor probes. Runtime and memory depend on the supplied callables. No automatic fallback or codec is promised.

Evidence and links (V, L). Derivative-provider tests cover construction, order dispatch, dimension rejection, symmetry probes, and packet-jet use. Certificates from finite probes use `PSC-III-D02`. See Chapters 37 and 38.

B.2 · FiniteDifferenceDerivativeProvider

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.FiniteDifferenceDerivativeProvider`. Identity-equal audited re-exports `komorebi_math.FiniteDifferenceDerivativeProvider`, `komorebi_math.nonlinear.FiniteDifferenceDerivativeProvider`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.derivatives.FiniteDifferenceDerivativeProvider`. Profile `B2-D2`.

Manifest signature (s).

```
(function: 'Callable[[np.ndarray], Any]', source_dimension: 'int', target_dimension: 'int', step: 'float' =
    ↪ 0.0001, max_order: 'int' = 4, name: 'str' = 'central finite difference provider', exactness: 'Exactness' =
    ↪ <Exactness.NUMERICAL: 'numerical'>) -> None
```

Definition. Numerical directional derivatives by recursive central differences. The default step is `1e-4` and default maximum order is 4. Stored fields: `function`, `source_dimension`, `target_dimension`, `step`, `max_order`, `name`, `exactness`. Runtime-visible operational members: `derivative`, `supports_order`, `value`.

Contract (D, C, H, R, X). A NumPy-compatible function, positive dimensions, positive finite step, nonnegative maximum order, name, and numerical exactness define recursive central directional differences. Points and directions must have the declared source dimension, and the function output must match the target dimension. Unsupported order, invalid step, shape mismatch, or nonfinite setup raises validation or dimension errors.

Guarantees (E, P, B, K). Results are numerical approximations controlled by the supplied step. No exactness or universal truncation-error bound is claimed. The recursive rule uses approximately `2^r` function evaluations for derivative order `r`, before cost inside the user function. It uses NumPy and has no GPU fallback in this provider.

Evidence and links (V, L). Finite-difference tests compare low-order derivatives against known functions and exercise failures and packet projections. See Chapters 8, 37, 38, and 43.

B.2 · PolynomialDerivativeProvider

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PolynomialDerivativeProvider`. Identity-equal audited re-exports `komorebi_math.PolynomialDerivativeProvider`, `komorebi_math.nonlinear.PolynomialDerivativeProvider`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.derivatives.PolynomialDerivativeProvider`. Profile `B2-D3`.

Manifest signature (s).

```
(tensors: 'Mapping[int, Any]', *, source_dimension: 'int | None' = None, target_dimension: 'int | None' = None,
    ↪ exactness: 'Exactness' = <Exactness.NUMERICAL: 'numerical'>, tolerance: 'float' = 1e-10, name: 'str' =
    ↪ 'polynomial derivative provider') -> 'None'
```

Definition. A finite polynomial map represented by symmetric coefficient tensors. The `degree` property is the largest retained tensor order. Runtime-visible operational members: `degree`, `derivative`, `supports_order`, `symmetry_certificate`, `value`.

Contract (D, C, H, R, X). A finite map of symmetric coefficient tensors defines `F(x) = sum_r T_r[x,...,x]/r!`. `T_0` is a target vector and order-`r` tensors have one target axis followed by `r` source axes. Dimensions may be inferred or declared. Inconsistent tensor shapes, negative orders, failed symmetry, or invalid tolerance are rejected.

Guarantees (E, P, B, K). Exact input tensors may produce exact values and derivatives. Numerical tensors use tolerance-aware symmetry evidence. Evaluation contracts each retained tensor with the point or direction vectors. Dense storage grows as the sum of `target_dimension * source_dimension^r`. There is no hidden sparse or GPU fallback.

Evidence and links (V, L). Polynomial derivative tests verify value and directional derivatives, symmetry certificates under `PSC-III-D04`, and equivalence with sparse and packet-jet execution. See Chapters 37, 38, and 43.

B.2 · PacketJetAddress

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetAddress`. Identity-equal audited re-exports `komorebi_math.nonlinear.PacketJetAddress`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.jets.PacketJetAddress`. Profile `B2-J1`.

Manifest signature (s).

```
(output: 'str', inputs: 'tuple[str, ...]') -> None
```

Definition. The output and ordered input packet addresses of one jet block. The `order` property is the length of the ordered input packet tuple. Stored fields: `output`, `inputs`. Runtime-visible operational members: `order`, `to_dict`.

Contract (D, C, H, R, X). Address records identify one target packet and an ordered tuple of source packets. A packet jet combines a derivative provider, base point, source and target packet systems, one output index, and ordered input indices. Evaluation projects directions before calling the derivative and projects the result afterward. A family represents every address of one order and reconstructs the full derivative by summation. Invalid packet names or indices, dimensions, order, provider support, or backend compatibility raise explicit validation or dimension errors.

Guarantees (E, P, B, K). Exactness follows the provider and packet backends. Projection identities and family reconstruction are exact for exact systems and tolerance-certified otherwise. One jet evaluation performs one derivative call plus input and output projections. A full family has `target_packets * source_packets^order` addresses unless support pruning is applied.

Evidence and links (V, L). Jet block and family certificates use `PSC-III-D06` and `PSC-III-T07`. Tests verify projection, symmetry, reconstruction, serialization views, and exact/numerical behavior. See Chapters 38, 43, 64, and 67.

B.2 · PacketJet

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJet`. Identity-equal audited re-exports `komorebi_math.PacketJet`, `komorebi_math.nonlinear.PacketJet`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.jets.PacketJet`. Profile `B2-J1`.

Manifest signature (s).

```
(provider: 'DerivativeProvider', point: 'Any', source: 'PacketSystem', target: 'PacketSystem', output_index:
    ↪ 'int', input_indices: 'tuple[int, ...]') -> None
```

Definition. One projected multilinear derivative block. Operational members include `evaluate`, `norm_bound`, `symmetry_certificate`, and `to_dict`. Stored fields: `provider`, `point`, `source`, `target`, `output_index`, `input_indices`. Runtime-visible operational members: `address`, `exactness`, `order`, `evaluate`, `norm_bound`, `symmetry_certificate`, `to_dict`.

Contract (D, C, H, R, X). Address records identify one target packet and an ordered tuple of source packets. A packet jet combines a derivative provider, base point, source and target packet systems, one output index, and ordered input indices. Evaluation projects directions before calling the derivative and projects the result afterward. A family represents every address of one order and reconstructs the full derivative by summation. Invalid packet names or indices, dimensions, order, provider support, or backend compatibility raise explicit validation or dimension errors.

Guarantees (E, P, B, K). Exactness follows the provider and packet backends. Projection identities and family reconstruction are exact for exact systems and tolerance-certified otherwise. One jet evaluation performs one derivative call plus input and output projections. A full family has `target_packets * source_packets^order` addresses unless support pruning is applied.

Evidence and links (V, L). Jet block and family certificates use `PSC-III-D06` and `PSC-III-T07`. Tests verify projection, symmetry, reconstruction, serialization views, and exact/numerical behavior. See Chapters 38, 43, 64, and 67.

B.2 · PacketJetFamily

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetFamily`. Identity-equal audited re-exports `komorebi_math.PacketJetFamily`, `komorebi_math.nonlinear.PacketJetFamily`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.jets.PacketJetFamily`. Profile `B2-J1`.

Manifest signature (s).

```
(provider: 'DerivativeProvider', point: 'Any', source: 'PacketSystem', target: 'PacketSystem', order: 'int') ->
   ↪ 'None'
```

Definition. Every packet block of one derivative order at one base point. The family exposes deterministic address enumeration, per-address jet construction, evaluation, and reconstruction of the full derivative. Runtime-visible operational members: `addresses`, `jet`, `reconstruct`, `reconstruction_certificate`, `to_dict`.

Contract (D, C, H, R, X). Address records identify one target packet and an ordered tuple of source packets. A packet jet combines a derivative provider, base point, source and target packet systems, one output index, and ordered input indices. Evaluation projects directions before calling the derivative and projects the result afterward. A family represents every address of one order and reconstructs the full derivative by summation. Invalid packet names or indices, dimensions, order, provider support, or backend compatibility raise explicit validation or dimension errors.

Guarantees (E, P, B, K). Exactness follows the provider and packet backends. Projection identities and family reconstruction are exact for exact systems and tolerance-certified otherwise. One jet evaluation performs one derivative call plus input and output projections. A full family has `target_packets * source_packets^order` addresses unless support pruning is applied.

Evidence and links (V, L). Jet block and family certificates use `PSC-III-D06` and `PSC-III-T07`. Tests verify projection, symmetry, reconstruction, serialization views, and exact/numerical behavior. See Chapters 38, 43, 64, and 67.

B.2 · PacketJetSupport

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetSupport`. Identity-equal audited re-exports `komorebi_math.nonlinear.PacketJetSupport`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.jets.PacketJetSupport`. Profile `B2-J2`.

Manifest signature (s).

```
(order: 'int', nonzero: 'tuple[PacketJetAddress, ...]', zero: 'tuple[PacketJetAddress, ...]', untested:
   ↪ 'tuple[PacketJetAddress, ...]', evaluations: 'int', certificate: 'Certificate') -> None
```

Definition. Finite basis test for zero and nonzero packet derivative blocks. The `complete` property is true exactly when `untested` is empty. `contains()` classifies a specific address. Stored fields: `order`, `nonzero`, `zero`, `untested`, `evaluations`, `certificate`. Runtime-visible operational members: `complete`, `contains`.

Contract (D, C, H, R, X). The classifier exhaustively tests packet-range basis tuples for every family address up to `max_evaluations`, returning disjoint nonzero, zero, and untested address tuples plus a certificate. The family, tolerance, and budget must be valid. Insufficient budget is represented by explicit untested addresses rather than a false zero classification. Invalid tolerance, dimensions, or limits raise validation errors.

Guarantees (E, P, B, K). Multilinearity makes a complete exact-backend classification exact. Numerical backends use a declared tolerance and report bounded finite evidence. The worst-case number of basis evaluations is the sum of packet-range dimension products across addresses and is stopped by the explicit budget.

Evidence and links (V, L). Support tests cover complete, truncated, exact, and numerical classifications under theorem identifiers `PSC-III-C08` and `PSC-III-C09`, then verify that execution prunes only certified zero blocks. See Chapters 38 and 43.

B.2 · packet_jet_support

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.packet_jet_support`. Identity-equal audited re-exports `komorebi_math.packet_jet_support`, `komorebi_math.nonlinear.packet_jet_support`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.jets.packet_jet_support`. Profile `B2-J2`.

Manifest signature (s).

```
(family: 'PacketJetFamily', *, tolerance: 'float | None' = None, max_evaluations: 'int' = 100000) ->
    ↪ 'PacketJetSupport'
```

Definition. Classify packet jet blocks by exhaustive packet-range basis tests.

Contract (D, C, H, R, X). The classifier exhaustively tests packet-range basis tuples for every family address up to `max_evaluations`, returning disjoint nonzero, zero, and untested address tuples plus a certificate. The family, tolerance, and budget must be valid. Insufficient budget is represented by explicit untested addresses rather than a false zero classification. Invalid tolerance, dimensions, or limits raise validation errors.

Guarantees (E, P, B, K). Multilinearity makes a complete exact-backend classification exact. Numerical backends use a declared tolerance and report bounded finite evidence. The worst-case number of basis evaluations is the sum of packet-range dimension products across addresses and is stopped by the explicit budget.

Evidence and links (V, L). Support tests cover complete, truncated, exact, and numerical classifications under theorem identifiers `PSC-III-C08` and `PSC-III-C09`, then verify that execution prunes only certified zero blocks. See Chapters 38 and 43.

B.2 · SparseTensorEntry

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.SparseTensorEntry`. Identity-equal audited re-exports `komorebi_math.SparseTensorEntry`, `komorebi_math.nonlinear.SparseTensorEntry`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.sparse.SparseTensorEntry`. Profile `B2-S1`.

Manifest signature (s).

```
(output: 'int', inputs: 'tuple[int, ...]', value: 'Any') -> None
```

Definition. One coefficient of a symmetric tensor orbit. The coefficient applies to every distinct ordered permutation of its nondecreasing source-index tuple. Stored fields: `output`, `inputs`, `value`.

Contract (D, C, H, R, X). A sparse entry names one target coordinate and a nondecreasing source-index orbit. A sparse symmetric tensor validates finite dimensions, order, canonical orbit keys, and unique entries. Contraction expands orbit multiplicities without materializing the full tensor. The sparse polynomial provider collects such tensors by order under the same factorial-normalized polynomial convention as the dense provider. Invalid indices, duplicate or noncanonical entries, inconsistent dimensions, or malformed coefficients are rejected.

Guarantees (E, P, B, K). Exact coefficients preserve exact contractions. Numerical modes use the declared tolerance for storage certificates and dense comparisons. Sparse storage is proportional to retained source-index orbits, while dense expansion would require `target_dimension * source_dimension^order` elements. Conversion to dense is explicit and has no automatic sparse/GPU fallback.

Evidence and links (V, L). Sparse tensor and provider tests verify canonicalization, contractions, storage ratios, dense equivalence, and certificates `PSC-III-D04S` and `PSC-III-D04P`. The behavioral fixture includes a third-order sparse symmetric contraction. See Chapters 37 and 43.

B.2 · SparseSymmetricTensor

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.SparseSymmetricTensor`. Identity-equal audited re-exports `komorebi_math.SparseSymmetricTensor`, `komorebi_math.nonlinear.SparseSymmetricTensor`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.sparse.SparseSymmetricTensor`. Profile `B2-S1`.

Manifest signature (s).

```
(order: 'int', source_dimension: 'int', target_dimension: 'int', entries: 'tuple[SparseTensorEntry, ...]' = ()) ->
    ↪ None
```

Definition. One finite symmetric tensor stored by source-index orbits. Properties expose stored, expanded-nonzero, and dense entry counts and their storage ratio. Stored fields: `order`, `source_dimension`, `target_dimension`, `entries`. Runtime-visible operational members: `dense_entry_count`, `expanded_nonzero_count`, `storage_ratio`, `stored_entry_count`, `certificate`, `contract`, `to_dense`, `to_dict`.

Contract (D, C, H, R, X). A sparse entry names one target coordinate and a nondecreasing source-index orbit. A sparse symmetric tensor validates finite dimensions, order, canonical orbit keys, and unique entries. Contraction expands orbit multiplicities without materializing the full tensor. The sparse polynomial provider collects such tensors by order under the same factorial-normalized polynomial convention as the dense provider. Invalid indices, duplicate or noncanonical entries, inconsistent dimensions, or malformed coefficients are rejected.

Guarantees (E, P, B, K). Exact coefficients preserve exact contractions. Numerical modes use the declared tolerance for storage certificates and dense comparisons. Sparse storage is proportional to retained source-index orbits, while dense expansion would require `target_dimension * source_dimension^order` elements. Conversion to dense is explicit and has no automatic sparse/GPU fallback.

Evidence and links (V, L). Sparse tensor and provider tests verify canonicalization, contractions, storage ratios, dense equivalence, and certificates `PSC-III-D04S` and `PSC-III-D04P`. The behavioral fixture includes a third-order sparse symmetric contraction. See Chapters 37 and 43.

B.2 · SparsePolynomialDerivativeProvider

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.SparsePolynomialDerivativeProvider`. Identity-equal audited re-exports `komorebi_math.SparsePolynomialDerivativeProvider`, `komorebi_math.nonlinear.SparsePolynomialDerivativeProvider`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.sparse.SparsePolynomialDerivativeProvider`. Profile `B2-S1`.

Manifest signature (s).

```
(tensors: 'Mapping[int, SparseSymmetricTensor | Mapping[tuple[int, ...], Any] | Any]', *, source_dimension: 'int |
    ↪ None' = None, target_dimension: 'int | None' = None, exactness: 'Exactness' = <Exactness.NUMERICAL:
    ↪ 'numerical'>, tolerance: 'float' = 1e-10, name: 'str' = 'sparse polynomial derivative provider') -> 'None'
```

Definition. Polynomial derivatives evaluated from sparse symmetric tensor orbits. It can emit a dense provider explicitly. It never densifies as an undocumented fallback. Runtime-visible operational members: `degree`, `dense_entry_count`, `storage_ratio`, `stored_entry_count`, `derivative`, `storage_certificate`, `supports_order`, `to_dense_provider`, `to_dict`, `value`.

Contract (D, C, H, R, X). A sparse entry names one target coordinate and a nondecreasing source-index orbit. A sparse symmetric tensor validates finite dimensions, order, canonical orbit keys, and unique entries. Contraction expands orbit multiplicities without materializing the full tensor. The sparse polynomial provider collects such tensors by order under the same factorial-normalized polynomial convention as the dense provider. Invalid indices, duplicate or noncanonical entries, inconsistent dimensions, or malformed coefficients are rejected.

Guarantees (E, P, B, K). Exact coefficients preserve exact contractions. Numerical modes use the declared tolerance for storage certificates and dense comparisons. Sparse storage is proportional to retained source-index orbits, while dense expansion would require `target_dimension * source_dimension^order` elements. Conversion to dense is explicit and has no automatic sparse/GPU fallback.

Evidence and links (V, L). Sparse tensor and provider tests verify canonicalization, contractions, storage ratios, dense equivalence, and certificates `PSC-III-D04S` and `PSC-III-D04P`. The behavioral fixture includes a third-order sparse symmetric contraction. See Chapters 37 and 43.

B.2 · `PacketJetInputGroup`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetInputGroup`. Identity-equal audited re-exports `komorebi_math.nonlinear.PacketJetInputGroup`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.execution.PacketJetInputGroup`. Profile `B2-E1`.

Manifest signature (s).

```
(inputs: 'tuple[int, ...]', outputs: 'tuple[int, ...]') -> None
```

Definition. Active output packets sharing one ordered input-packet address. Stored fields: `inputs`, `outputs`.

Contract (D, C, H, R, X). Execution records describe groups sharing projected input addresses, a deterministic plan, individual projected evaluations, and the aggregate result including reconstructed and direct derivatives, operation counts, backend, host-transfer flag, and certificate. Records require coherent order, packet-name sets, unique address coverage, and nonnegative counts. Their constructors validate structural consistency. Execution failures arise in the functions that create them.

Guarantees (E, P, B, K). The records preserve deterministic planning and observed execution metadata. A valid batch certificate establishes equality or tolerance agreement for the supplied finite evaluation, not global function equivalence. Storage is linear in active addresses and groups plus the values retained in the result.

Evidence and links (V, L). Planning and execution tests check unique address coverage, deterministic grouping, count identities, reconstruction, direct comparison, and serialization. The execution certificate family uses `PSC-III-A10`. See Chapter 43.

B.2 · `PacketJetExecutionPlan`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetExecutionPlan`. Identity-equal audited re-exports `komorebi_math.PacketJetExecutionPlan`, `komorebi_math.nonlinear.PacketJetExecutionPlan`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.execution.PacketJetExecutionPlan`. Profile `B2-E1`.

Manifest signature (s).

```
(order: 'int', source_names: 'tuple[str, ...]', target_names: 'tuple[str, ...]', groups:
    ↪ 'tuple[PacketJetInputGroup, ...]', active_addresses: 'tuple[PacketJetAddress, ...]', pruned_addresses:
    ↪ 'tuple[PacketJetAddress, ...]', support_was_supplied: 'bool', support_complete: 'bool', certificate:
    ↪ 'Certificate') -> None
```

Definition. A deterministic grouping of packet-jet blocks by projected inputs. The plan stores active and pruned address tuples, input groups, source and target names, support-completeness flags, and a certificate. Stored fields: `order`, `source_names`, `target_names`, `groups`, `active_addresses`, `pruned_addresses`, `support_was_supplied`, `support_complete`, `certificate`. Runtime-visible operational members: `active_address_count`, `derivative_call_count`, `derivative_call_reduction`, `full_address_count`, `naive_derivative_call_count`, `pruned_address_count`, `matches`, `to_dict`.

Contract (D, C, H, R, X). Execution records describe groups sharing projected input addresses, a deterministic plan, individual projected evaluations, and the aggregate result including reconstructed and direct derivatives, operation counts, backend, host-transfer flag, and certificate. Records require coherent order, packet-name sets, unique address coverage, and nonnegative counts. Their constructors validate structural consistency. Execution failures arise in the functions that create them.

Guarantees (E, P, B, K). The records preserve deterministic planning and observed execution metadata. A valid batch certificate establishes equality or tolerance agreement for the supplied finite evaluation, not global function equivalence. Storage is linear in active addresses and groups plus the values retained in the result.

Evidence and links (V, L). Planning and execution tests check unique address coverage, deterministic grouping, count identities, reconstruction, direct comparison, and serialization. The execution certificate family uses `PSC-III-A10`. See Chapter 43.

B.2 · `PacketJetEvaluation`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetEvaluation`. Identity-equal audited re-exports `komorebi_math.nonlinear.PacketJetEvaluation`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.execution.PacketJetEvaluation`. Profile `B2-E1`.

Manifest signature (s).

```
(address: 'PacketJetAddress', value: 'Any') -> None
```

Definition. One evaluated packet-jet address and its projected target value. Stored fields: `address`, `value`.

Contract (D, C, H, R, X). Execution records describe groups sharing projected input addresses, a deterministic plan, individual projected evaluations, and the aggregate result including reconstructed and direct derivatives, operation counts, backend, host-transfer flag, and certificate. Records require coherent order, packet-name sets, unique address coverage, and nonnegative counts. Their constructors validate structural consistency. Execution failures arise in the functions that create them.

Guarantees (E, P, B, K). The records preserve deterministic planning and observed execution metadata. A valid batch certificate establishes equality or tolerance agreement for the supplied finite evaluation, not global function equivalence. Storage is linear in active addresses and groups plus the values retained in the result.

Evidence and links (V, L). Planning and execution tests check unique address coverage, deterministic grouping, count identities, reconstruction, direct comparison, and serialization. The execution certificate family uses `PSC-III-A10`. See Chapter 43.

B.2 · `PacketJetBatchResult`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetBatchResult`. Identity-equal audited re-exports `komorebi_math.PacketJetBatchResult`, `komorebi_math.nonlinear.PacketJetBatchResult`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.execution.PacketJetBatchResult`. Profile `B2-E1`.

Manifest signature (s).

```
(evaluations: 'tuple[PacketJetEvaluation, ...]', reconstructed: 'Any', direct: 'Any', derivative_calls: 'int',
    ↪ input_projections: 'int', output_projections: 'int', pruned_blocks: 'int', backend: 'str', returned_to_host:
    ↪ 'bool', certificate: 'Certificate') -> None
```

Definition. Result of one projection-cached packet-jet execution. `value()` returns the reconstructed derivative and `as_mapping()` indexes individual results by address. Stored fields: `evaluations`, `reconstructed`, `direct`, `derivative_calls`, `input_projections`, `output_projections`, `pruned_blocks`, `backend`, `returned_to_host`, `certificate`. Runtime-visible operational members: `as_mapping`, `to_dict`, `value`.

Contract (D, C, H, R, X). Execution records describe groups sharing projected input addresses, a deterministic plan, individual projected evaluations, and the aggregate result including reconstructed and direct derivatives, operation counts, backend, host-transfer flag, and certificate. Records require coherent order, packet-name sets, unique address coverage, and nonnegative counts. Their constructors validate structural consistency. Execution failures arise in the functions that create them.

Guarantees (E, P, B, K). The records preserve deterministic planning and observed execution metadata. A valid batch certificate establishes equality or tolerance agreement for the supplied finite evaluation, not global function equivalence. Storage is linear in active addresses and groups plus the values retained in the result.

Evidence and links (V, L). Planning and execution tests check unique address coverage, deterministic grouping, count identities, reconstruction, direct comparison, and serialization. The execution certificate family uses `PSC-III-A10`. See Chapter 43.

B.2 · compile_packet_jet_plan

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.compile_packet_jet_plan`. Identity-equal audited re-exports `komorebi_math.compile_packet_jet_plan`, `komorebi_math.nonlinear.compile_packet_jet_plan`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.execution.compile_packet_jet_plan`. Profile `B2-E2`.

Manifest signature (s).

```
(family: 'PacketJetFamily', support: 'PacketJetSupport | None' = None, *, max_addresses: 'int' = 1000000) ->
    ↪ 'PacketJetExecutionPlan'
```

Definition. Compile a projection-cached plan, pruning only certified zero blocks.

Contract (D, C, H, R, X). Compilation enumerates the finite family, applies an optional support record, prunes only certified zero addresses, and groups active blocks by ordered projected inputs. Execution validates plan/family identity and direction dimensions, caches each projected input group and derivative call, projects outputs, reconstructs the sum, and compares it with direct provider evaluation. The convenience function performs both steps. Invalid plans, incomplete or inconsistent support, excessive address counts, bad directions, backend mismatch, or failed tolerance checks raise validation or dimension errors or return an invalid certificate.

Guarantees (E, P, B, K). Ordering and counts are deterministic. Exact backends compare exact values. Numerical backends use the declared or backend tolerance. The plan caps enumeration with `max_addresses`. Planned derivative calls equal input groups rather than active output addresses, and memory is linear in plan, cached projections, and retained evaluations.

Evidence and links (V, L). Tests and the 15-case golden fixture verify projection caching, support pruning, direct reconstruction, exact count reductions, and the `PSC-III-A10` certificate. See Chapter 43 and the nonlinear execution example.

B.2 · execute_packet_jet_plan

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.execute_packet_jet_plan`. Identity-equal audited re-exports `komorebi_math.execute_packet_jet_plan`, `komorebi_math.nonlinear.execute_packet_jet_plan`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.execution.execute_packet_jet_plan`. Profile `B2-E2`.

Manifest signature (s).

```
(plan: 'PacketJetExecutionPlan', family: 'PacketJetFamily', directions: 'Sequence[Any]', *, tolerance: 'float |
    ↪ None' = None) -> 'PacketJetBatchResult'
```

Definition. Execute a packet-jet plan with cached input projections.

Contract (D, C, H, R, X). Compilation enumerates the finite family, applies an optional support record, prunes only certified zero addresses, and groups active blocks by ordered projected inputs. Execution validates plan/family identity and direction dimensions, caches each projected input group and derivative call, projects outputs, reconstructs the sum, and compares it with direct provider evaluation. The convenience function performs both steps. Invalid plans, incomplete or inconsistent support, excessive address counts, bad directions, backend mismatch, or failed tolerance checks raise validation or dimension errors or return an invalid certificate.

Guarantees (E, P, B, K). Ordering and counts are deterministic. Exact backends compare exact values. Numerical backends use the declared or backend tolerance. The plan caps enumeration with `max_addresses`. Planned derivative calls equal input groups rather than active output addresses, and memory is linear in plan, cached projections, and retained evaluations.

Evidence and links (V, L). Tests and the 15-case golden fixture verify projection caching, support pruning, direct reconstruction, exact count reductions, and the `PSC-III-A10` certificate. See Chapter 43 and the nonlinear execution example.

B.2 · execute_packet_jets

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.execute_packet_jets`. Identity-equal audited re-exports `komorebi_math.execute_packet_jets`, `komorebi_math.nonlinear.execute_packet_jets`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.execution.execute_packet_jets`. Profile `B2-E2`.

Manifest signature (s).

```
(family: 'PacketJetFamily', directions: 'Sequence[Any]', *, support: 'PacketJetSupport | None' = None, tolerance:
   ↪ 'float | None' = None, max_addresses: 'int' = 1000000) -> 'PacketJetBatchResult'
```

Definition. Compile and execute one projection-cached packet-jet family.

Contract (D, C, H, R, X). Compilation enumerates the finite family, applies an optional support record, prunes only certified zero addresses, and groups active blocks by ordered projected inputs. Execution validates plan/family identity and direction dimensions, caches each projected input group and derivative call, projects outputs, reconstructs the sum, and compares it with direct provider evaluation. The convenience function performs both steps. Invalid plans, incomplete or inconsistent support, excessive address counts, bad directions, backend mismatch, or failed tolerance checks raise validation or dimension errors or return an invalid certificate.

Guarantees (E, P, B, K). Ordering and counts are deterministic. Exact backends compare exact values. Numerical backends use the declared or backend tolerance. The plan caps enumeration with `max_addresses`. Planned derivative calls equal input groups rather than active output addresses, and memory is linear in plan, cached projections, and retained evaluations.

Evidence and links (V, L). Tests and the 15-case golden fixture verify projection caching, support pruning, direct reconstruction, exact count reductions, and the `PSC-III-A10` certificate. See Chapter 43 and the nonlinear execution example.

B.2 · PacketJetComplexityEstimate

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetComplexityEstimate`. Identity-equal audited re-exports `komorebi_math.PacketJetComplexityEstimate`, `komorebi_math.nonlinear.PacketJetComplexityEstimate`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.profiling.PacketJetComplexityEstimate`. Profile `B2-P1`.

Manifest signature (s).

```
(order: 'int', source_dimension: 'int', target_dimension: 'int', source_packets: 'int', target_packets: 'int',
   ↪ family_addresses: 'int', active_addresses: 'int', pruned_addresses: 'int', input_groups: 'int',
   ↪ naive_derivative_calls: 'int', planned_derivative_calls: 'int', projected_input_vectors: 'int',
   ↪ output_projections: 'int', dense_basis_evaluations: 'int', dense_tensor_elements: 'int', certificate:
   ↪ 'Certificate') -> None
```

Definition. Exact finite counts implied by packet and ambient dimensions. Its reduction property compares naive address-wise calls with planned grouped calls.

Contract (D, C, H, R, X). The estimator accepts a packet-jet family, optional support record, optional precompiled plan, and address budget. It derives exact integer counts for family and active addresses, groups, naive and planned derivative calls, projected vectors, output projections, dense basis evaluations, and dense tensor elements. Inconsistent support or plan identity and excessive address counts are rejected.

Guarantees (E, P, B, K). The counts are exact consequences of finite dimensions and the selected plan under `PSC-III-A61`. They are not elapsed-time, throughput, or memory-allocation measurements. Computation is dominated by finite address enumeration and grouping and uses no optional profiler backend.

Evidence and links (V, L). Unit tests compare every field with hand-counted small systems and check derivative-call reduction. See Chapter 43 and Appendix K.

B.2 · RuntimeProfileSample

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.RuntimeProfileSample`. Identity-equal audited re-exports `komorebi_math.RuntimeProfileSample`, `komorebi_math.nonlinear.RuntimeProfileSample`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.profiling.RuntimeProfileSample`. Profile `B2-P2`.

Manifest signature (s).

```
(duration_ns: 'int', traced_peak_bytes: 'int') -> None
```

Definition. One observed duration and Python allocation peak. Stored fields: `duration_ns`, `traced_peak_bytes`.

Contract (D, C, H, R, X). Runtime samples record duration in nanoseconds and Python traced peak bytes. Stage profiles aggregate named repeated samples after an explicit warmup. Packet-jet reports join exact complexity counts to selected local stages. Profiling functions require positive repetition counts and valid operations, families, directions, budgets, and optional stream settings. Exceptions raised by the profiled callable propagate rather than becoming benchmark data.

Guarantees (E, P, B, K). Measurements use `perf_counter_ns` and `tracemalloc`. They are environment-specific observations and are never interpreted as asymptotic evidence. Median, minimum, maximum, and peak summaries are deterministic functions of captured samples, but the measurements themselves are not reproducible constants. Profiling adds tracing overhead and does not measure all native or device allocation.

Evidence and links (V, L). Profiling tests validate record arithmetic, scope labels, stage inclusion, exact complexity joins under `PSC-III-A61`, and optional stream-write profiling. See Chapter 43 and Appendix K.

B.2 · RuntimeStageProfile

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.RuntimeStageProfile`. Identity-equal audited re-exports `komorebi_math.RuntimeStageProfile`, `komorebi_math.nonlinear.RuntimeStageProfile`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.profiling.RuntimeStageProfile`. Profile `B2-P2`.

Manifest signature (s).

```
(name: 'str', scope: 'str', warmup: 'int', samples: 'tuple[RuntimeProfileSample, ...]') -> None
```

Definition. Repeated observations for one precisely named runtime stage. Properties report repetition count and median/minimum/maximum duration plus median/maximum traced peak bytes. Stored fields: `name`, `scope`, `warmup`, `samples`. Runtime-visible operational members: `maximum_duration_ns`, `maximum_peak_bytes`, `median_duration_ns`, `median_peak_bytes`, `minimum_duration_ns`, `repetitions`, `to_dict`.

Contract (D, C, H, R, X). Runtime samples record duration in nanoseconds and Python traced peak bytes. Stage profiles aggregate named repeated samples after an explicit warmup. Packet-jet reports join exact complexity counts to selected local stages. Profiling functions require positive repetition counts and valid operations, families, directions, budgets, and optional stream settings. Exceptions raised by the profiled callable propagate rather than becoming benchmark data.

Guarantees (E, P, B, K). Measurements use `perf_counter_ns` and `tracemalloc`. They are environment-specific observations and are never interpreted as asymptotic evidence. Median, minimum, maximum, and peak summaries are deterministic functions of captured samples, but the measurements themselves are not reproducible constants. Profiling adds tracing overhead and does not measure all native or device allocation.

Evidence and links (V, L). Profiling tests validate record arithmetic, scope labels, stage inclusion, exact complexity joins under `PSC-III-A61`, and optional stream-write profiling. See Chapter 43 and Appendix K.

B.2 · PacketJetProfileReport

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetProfileReport`. Identity-equal audited re-exports `komorebi_math.PacketJetProfileReport`, `komorebi_math.nonlinear.PacketJetProfileReport`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.profiling.PacketJetProfileReport`. Profile `B2-P2`.

Manifest signature (s).

```
(estimate: 'PacketJetComplexityEstimate', stages: 'tuple[RuntimeStageProfile, ...]', environment: 'Mapping[str,
   ↪ Any]', certificate: 'Certificate') -> None
```

Definition. Exact counts paired with environment-specific runtime observations. The report joins exact finite complexity counts to named local runtime stages and an explicit profiling contract. Stored fields: `estimate`, `stages`, `environment`, `certificate`. Runtime-visible operational members: `to_dict`.

Contract (D, C, H, R, X). Runtime samples record duration in nanoseconds and Python traced peak bytes. Stage profiles aggregate named repeated samples after an explicit warmup. Packet-jet reports join exact complexity counts to selected local stages. Profiling functions require positive repetition counts and valid operations, families, directions, budgets, and optional stream settings. Exceptions raised by the profiled callable propagate rather than becoming benchmark data.

Guarantees (E, P, B, K). Measurements use `perf_counter_ns` and `tracemalloc`. They are environment-specific observations and are never interpreted as asymptotic evidence. Median, minimum, maximum, and peak summaries are deterministic functions of captured samples, but the measurements themselves are not reproducible constants. Profiling adds tracing overhead and does not measure all native or device allocation.

Evidence and links (V, L). Profiling tests validate record arithmetic, scope labels, stage inclusion, exact complexity joins under `PSC-III-A61`, and optional stream-write profiling. See Chapter 43 and Appendix K.

B.2 · estimate_packet_jet_complexity

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.estimate_packet_jet_complexity`. Identity-equal audited re-exports `komorebi_math.estimate_packet_jet_complexity`, `komorebi_math.nonlinear.estimate_packet_jet_complexity`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.profiling.estimate_packet_jet_complexity`. Profile `B2-P1`.

Manifest signature (s).

```
(family: 'PacketJetFamily', support: 'PacketJetSupport | None' = None, *, plan: 'PacketJetExecutionPlan | None' =
   ↪ None, max_addresses: 'int' = 1000000) -> 'PacketJetComplexityEstimate'
```

Definition. Return exact finite operation counts for a packet-jet family.

Contract (D, C, H, R, X). The estimator accepts a packet-jet family, optional support record, optional precompiled plan, and address budget. It derives exact integer counts for family and active addresses, groups, naive and planned derivative calls, projected vectors, output projections, dense basis evaluations, and dense tensor elements. Inconsistent support or plan identity and excessive address counts are rejected.

Guarantees (E, P, B, K). The counts are exact consequences of finite dimensions and the selected plan under `PSC-III-A61`. They are not elapsed-time, throughput, or memory-allocation measurements. Computation is dominated by finite address enumeration and grouping and uses no optional profiler backend.

Evidence and links (V, L). Unit tests compare every field with hand-counted small systems and check derivative-call reduction. See Chapter 43 and Appendix K.

B.2 · profile_operation

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.profile_operation`. Identity-equal audited re-exports `komorebi_math.profile_operation`, `komorebi_math.nonlinear.profile_operation`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.profiling.profile_operation`. Profile `B2-P2`.

Manifest signature (s).

```
(name: 'str', operation: 'Callable[[], T]', *, repetitions: 'int' = 5, warmup: 'int' = 1, scope: 'str' = 'Python
    ↪ call including allocations and synchronization performed by the callable') -> 'RuntimeStageProfile'
```

Definition. Observe one callable without interpreting timings as asymptotic evidence.

Contract (D, C, H, R, X). Runtime samples record duration in nanoseconds and Python traced peak bytes. Stage profiles aggregate named repeated samples after an explicit warmup. Packet-jet reports join exact complexity counts to selected local stages. Profiling functions require positive repetition counts and valid operations, families, directions, budgets, and optional stream settings. Exceptions raised by the profiled callable propagate rather than becoming benchmark data.

Guarantees (E, P, B, K). Measurements use `perf_counter_ns` and `tracemalloc`. They are environment-specific observations and are never interpreted as asymptotic evidence. Median, minimum, maximum, and peak summaries are deterministic functions of captured samples, but the measurements themselves are not reproducible constants. Profiling adds tracing overhead and does not measure all native or device allocation.

Evidence and links (V, L). Profiling tests validate record arithmetic, scope labels, stage inclusion, exact complexity joins under `PSC-III-A61`, and optional stream-write profiling. See Chapter 43 and Appendix K.

B.2 · profile_packet_jet_runtime

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.profile_packet_jet_runtime`. Identity-equal audited re-exports `komorebi_math.profile_packet_jet_runtime`, `komorebi_math.nonlinear.profile_packet_jet_runtime`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.profiling.profile_packet_jet_runtime`. Profile `B2-P2`.

Manifest signature (s).

```
(family: 'PacketJetFamily', directions: 'Sequence[Any]', *, support: 'PacketJetSupport | None' = None, jet:
    ↪ 'PacketJet | None' = None, repetitions: 'int' = 5, warmup: 'int' = 1, max_addresses: 'int' = 1000000,
    ↪ max_snapshot_evaluations: 'int' = 100000, include_stream_write: 'bool' = False, stream_chunk_size: 'int' =
    ↪ 1024) -> 'PacketJetProfileReport'
```

Definition. Profile selected packet-jet stages under one explicit local contract.

Contract (D, C, H, R, X). Runtime samples record duration in nanoseconds and Python traced peak bytes. Stage profiles aggregate named repeated samples after an explicit warmup. Packet-jet reports join exact complexity counts to selected local stages. Profiling functions require positive repetition counts and valid operations, families, directions, budgets, and optional stream settings. Exceptions raised by the profiled callable propagate rather than becoming benchmark data.

Guarantees (E, P, B, K). Measurements use `perf_counter_ns` and `tracemalloc`. They are environment-specific observations and are never interpreted as asymptotic evidence. Median, minimum, maximum, and peak summaries are deterministic functions of captured samples, but the measurements themselves are not reproducible constants. Profiling adds tracing overhead and does not measure all native or device allocation.

Evidence and links (V, L). Profiling tests validate record arithmetic, scope labels, stage inclusion, exact complexity joins under `PSC-III-A61`, and optional stream-write profiling. See Chapter 43 and Appendix K.

B.3 Resumable streaming and snapshots

B.3 · PACKET_JET_STREAM_SCHEMA

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PACKET_JET_STREAM_SCHEMA`. Identity-equal audited re-exports `komorebi_math.PACKET_JET_STREAM_SCHEMA`, `komorebi_math.nonlinear.PACKET_JET_STREAM_SCHEMA`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `B3-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `komorebi-math.packet-jet-stream`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the exact packet-jet stream or chunk schema name and integer schema version. There is no call-time failure. These constants are consumed by stream envelope validators and must not be substituted for payload validation.

Guarantees (E, P, B, K). Values are exact immutable identifiers, require no backend, and have constant lookup cost. Version 1 names the current directory-backed manifest/chunk contract. It does not imply authenticity or compatibility with unregistered future versions.

Evidence and links (V, L). Stream tests assert schema/version rejection, canonical encoding, and runtime identity. See Chapters 43 and 61.

B.3 · PACKET_JET_STREAM_SCHEMA_VERSION

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PACKET_JET_STREAM_SCHEMA_VERSION`. Identity-equal audited re-exports `komorebi_math.PACKET_JET_STREAM_SCHEMA_VERSION`, `komorebi_math.nonlinear.PACKET_JET_STREAM_SCHEMA_VERSION`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `B3-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `1`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the exact packet-jet stream or chunk schema name and integer schema version. There is no call-time failure. These constants are consumed by stream envelope validators and must not be substituted for payload validation.

Guarantees (E, P, B, K). Values are exact immutable identifiers, require no backend, and have constant lookup cost. Version 1 names the current directory-backed manifest/chunk contract. It does not imply authenticity or compatibility with unregistered future versions.

Evidence and links (V, L). Stream tests assert schema/version rejection, canonical encoding, and runtime identity. See Chapters 43 and 61.

B.3 · PACKET_JET_CHUNK_SCHEMA

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PACKET_JET_CHUNK_SCHEMA`. Identity-equal audited re-exports `komorebi_math.PACKET_JET_CHUNK_SCHEMA`, `komorebi_math.nonlinear.PACKET_JET_CHUNK_SCHEMA`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `B3-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `komorebi-math.packet-jet-stream.chunk`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the exact packet-jet stream or chunk schema name and integer schema version. There is no call-time failure. These constants are consumed by stream envelope validators and must not be substituted for payload validation.

Guarantees (E, P, B, K). Values are exact immutable identifiers, require no backend, and have constant lookup cost. Version 1 names the current directory-backed manifest/chunk contract. It does not imply authenticity or compatibility with unregistered future versions.

Evidence and links (V, L). Stream tests assert schema/version rejection, canonical encoding, and runtime identity. See Chapters 43 and 61.

B.3 · `PACKET_JET_CHUNK_SCHEMA_VERSION`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PACKET_JET_CHUNK_SCHEMA_VERSION`. Identity-equal audited re-exports `komorebi_math.PACKET_JET_CHUNK_SCHEMA_VERSION`, `komorebi_math.nonlinear.PACKET_JET_CHUNK_SCHEMA_VERSION`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `B3-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `1`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the exact packet-jet stream or chunk schema name and integer schema version. There is no call-time failure. These constants are consumed by stream envelope validators and must not be substituted for payload validation.

Guarantees (E, P, B, K). Values are exact immutable identifiers, require no backend, and have constant lookup cost. Version 1 names the current directory-backed manifest/chunk contract. It does not imply authenticity or compatibility with unregistered future versions.

Evidence and links (V, L). Stream tests assert schema/version rejection, canonical encoding, and runtime identity. See Chapters 43 and 61.

B.3 · `PacketJetCoefficient`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetCoefficient`. Identity-equal audited re-exports `komorebi_math.nonlinear.PacketJetCoefficient`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.snapshots.PacketJetCoefficient`. Profile `B3-S1`.

Manifest signature (s).

```
(indices: 'tuple[int, ...]', value: 'tuple[Any, ...]') -> None
```

Definition. One standard-basis coefficient of a persisted packet jet. Stored fields: `indices`, `value`.

Contract (D, C, H, R, X). A coefficient stores one ordered standard-basis multi-index and target tuple. A snapshot stores address, dimensions, provider name, exactness, point, sparse retained coefficients, and a capture certificate, and can evaluate directions or materialize a guarded dense tensor. Capture exhaustively evaluates the jet on standard-basis tuples after preflighting `max_evaluations`. Invalid indices, dimensions, certificate inconsistency, nonpositive limits, or excessive dense materialization raise validation or dimension errors.

Guarantees (E, P, B, K). Exact backends retain every nonzero coefficient. Numerical capture omits coefficients whose norm does not exceed the declared tolerance and records the largest omitted norm. Dense basis work is `source_dimension^order`. Retained sparse storage is linear in stored coefficients, while dense materialization is capped by `max_elements`.

Evidence and links (V, L). Snapshot tests and the golden fixture verify exact contraction, numerical omission evidence, portable migration, and theorem identifier PSC-III-D58. See Chapters 38, 43, and 61.

B.3 · PacketJetSnapshot

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.PacketJetSnapshot. Identity-equal audited re-exports komorebi_math.PacketJetSnapshot, komorebi_math.nonlinear.PacketJetSnapshot. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind class. Reflected implementation komorebi_math.nonlinear.snapshots.PacketJetSnapshot. Profile B3-S1.

Manifest signature (s).

```
(address: 'PacketJetAddress', source_dimension: 'int', target_dimension: 'int', provider_name: 'str', exactness:
    ↪ 'Exactness', point: 'tuple[Any, ...]', coefficients: 'tuple[PacketJetCoefficient, ...]',
    ↪ capture_certificate: 'Certificate') -> None
```

Definition. A provider-independent sparse coefficient record of one packet jet. Evaluation contracts stored standard-basis coefficients with supplied directions. to_dense() has an explicit element guard. Stored fields: address, source_dimension, target_dimension, provider_name, exactness, point, coefficients, capture_certificate. Runtime-visible operational members: dense_coefficient_count, nnz, order, coefficient, comparison_certificate, evaluate, to_dense, to_dict.

Contract (D, C, H, R, X). A coefficient stores one ordered standard-basis multi-index and target tuple. A snapshot stores address, dimensions, provider name, exactness, point, sparse retained coefficients, and a capture certificate, and can evaluate directions or materialize a guarded dense tensor. Capture exhaustively evaluates the jet on standard-basis tuples after preflighting max_evaluations. Invalid indices, dimensions, certificate inconsistency, nonpositive limits, or excessive dense materialization raise validation or dimension errors.

Guarantees (E, P, B, K). Exact backends retain every nonzero coefficient. Numerical capture omits coefficients whose norm does not exceed the declared tolerance and records the largest omitted norm. Dense basis work is source_dimension^order. Retained sparse storage is linear in stored coefficients, while dense materialization is capped by max_elements.

Evidence and links (V, L). Snapshot tests and the golden fixture verify exact contraction, numerical omission evidence, portable migration, and theorem identifier PSC-III-D58. See Chapters 38, 43, and 61.

B.3 · snapshot_packet_jet

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.snapshot_packet_jet. Identity-equal audited re-exports komorebi_math.snapshot_packet_jet, komorebi_math.nonlinear.snapshot_packet_jet. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind function. Reflected implementation komorebi_math.nonlinear.snapshots.snapshot_packet_jet. Profile B3-S1.

Manifest signature (s).

```
(jet: 'PacketJet', *, tolerance: 'float | None' = None, max_evaluations: 'int' = 100000) -> 'PacketJetSnapshot'
```

Definition. Capture one packet jet by exhaustive standard-basis evaluation.

Contract (D, C, H, R, X). A coefficient stores one ordered standard-basis multi-index and target tuple. A snapshot stores address, dimensions, provider name, exactness, point, sparse retained coefficients, and a capture certificate, and can evaluate directions or materialize a guarded dense tensor. Capture exhaustively evaluates the jet on standard-basis tuples after preflighting max_evaluations. Invalid indices, dimensions, certificate inconsistency, nonpositive limits, or excessive dense materialization raise validation or dimension errors.

Guarantees (E, P, B, K). Exact backends retain every nonzero coefficient. Numerical capture omits coefficients whose norm does not exceed the declared tolerance and records the largest omitted norm. Dense basis work is source_dimension^order. Retained sparse storage is linear in stored coefficients, while dense materialization is capped by max_elements.

Evidence and links (V, L). Snapshot tests and the golden fixture verify exact contraction, numerical omission evidence, portable migration, and theorem identifier PSC-III-D58. See Chapters 38, 43, and 61.

B.3 · PacketJetStreamChunkRecord

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetStreamChunkRecord`. Identity-equal audited re-exports `komorebi_math.PacketJetStreamChunkRecord`, `komorebi_math.nonlinear.PacketJetStreamChunkRecord`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.streaming.PacketJetStreamChunkRecord`. Profile `B3-R1`.

Manifest signature (s).

```
(index: 'int', filename: 'str', basis_start: 'int', basis_stop: 'int', coefficient_start: 'int', coefficient_stop:
    ↪  'int', payload_sha256: 'str', byte_count: 'int') -> None
```

Definition. One immutable chunk index entry in a packet-jet stream manifest. Stored fields: `index`, `filename`, `basis_start`, `basis_stop`, `coefficient_start`, `coefficient_stop`, `payload_sha256`, `byte_count`. Runtime-visible operational members: `basis_count`, `coefficient_count`, `to_dict`.

Contract (D, C, H, R, X). These immutable records describe one verified chunk, the complete or partial stream manifest, a bounded coefficient selection, write progress, or a chunk-wise evaluation with explicit coefficient coverage. Fields require contiguous nonnegative ranges, coherent counts and digests, valid schema metadata, strict ordering, and certificates matching completion state. Malformed ranges, duplicate or unordered coefficients, digest mismatch, or inconsistent progress is rejected.

Guarantees (E, P, B, K). Records make partial versus complete coverage explicit and preserve integrity metadata. A valid record does not authenticate the producer: an attacker able to replace payloads and digests can construct a different internally consistent stream. Storage is proportional to metadata plus the selected coefficients or evaluation value.

Evidence and links (V, L). Streaming tests validate constructor invariants, incomplete-state labeling, tamper detection, selection budgets, and `PSC-III-D60` coverage certificates. See Chapters 43 and 61.

B.3 · PacketJetStreamManifest

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PacketJetStreamManifest`. Identity-equal audited re-exports `komorebi_math.PacketJetStreamManifest`, `komorebi_math.nonlinear.PacketJetStreamManifest`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.nonlinear.streaming.PacketJetStreamManifest`. Profile `B3-R1`.

Manifest signature (s).

```
(state: 'StreamState', producer_version: 'str', address: 'PacketJetAddress', source_dimension: 'int',
    ↪  target_dimension: 'int', provider_name: 'str', exactness: 'Exactness', point: 'tuple[Any, ...]', tolerance:
    ↪  'float', dense_coefficient_count: 'int', capture_mode: 'CaptureMode', source_digest: 'str', metadata_sha256:
    ↪  'str', chunk_size: 'int', evaluations_completed: 'int', coefficients_completed: 'int',
    ↪  maximum_omitted_basis_norm: 'float', chunks: 'tuple[PacketJetStreamChunkRecord, ...]', capture_certificate:
    ↪  'Certificate | None', stream_sha256: 'str') -> None
```

Definition. Validated metadata and progress for one chunked packet-jet stream. The manifest binds source metadata, deterministic chunk records, progress, coefficient totals, completion state, and an integrity digest. Stored fields: `state`, `producer_version`, `address`, `source_dimension`, `target_dimension`, `provider_name`, `exactness`, `point`, `tolerance`, `dense_coefficient_count`, `capture_mode`, `source_digest`, `metadata_sha256`, `chunk_size`, `evaluations_completed`, `coefficients_completed`, `maximum_omitted_basis_norm`, `chunks`, `capture_certificate`, `stream_sha256`. Runtime-visible operational members: `complete`, `order`, `metadata_dict`, `to_payload`.

Contract (D, C, H, R, X). These immutable records describe one verified chunk, the complete or partial stream manifest, a bounded coefficient selection, write progress, or a chunk-wise evaluation with explicit coefficient coverage. Fields require contiguous nonnegative ranges, coherent counts and digests, valid schema metadata, strict ordering, and certificates matching completion state. Malformed ranges, duplicate or unordered coefficients, digest mismatch, or inconsistent progress is rejected.

Guarantees (E, P, B, K). Records make partial versus complete coverage explicit and preserve integrity metadata. A valid record does not authenticate the producer: an attacker able to replace payloads and digests can construct a

different internally consistent stream. Storage is proportional to metadata plus the selected coefficients or evaluation value.

Evidence and links (V, L). Streaming tests validate constructor invariants, incomplete-state labeling, tamper detection, selection budgets, and PSC-III-D60 coverage certificates. See Chapters 43 and 61.

B.3 · PacketJetStreamSelection

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.PacketJetStreamSelection. Identity-equal audited re-exports komorebi_math.PacketJetStreamSelection, komorebi_math.nonlinear.PacketJetStreamSelection. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind class. Reflected implementation komorebi_math.nonlinear.streaming.PacketJetStreamSelection. Profile B3-R1.

Manifest signature (s).

```
(coefficient_start: 'int', coefficient_stop: 'int', coefficients: 'tuple[PacketJetCoefficient, ...]',
   ↪ complete_snapshot: 'bool', certificate: 'Certificate') -> None
```

Definition. A bounded coefficient selection loaded from a packet-jet stream. The selection identifies a half-open coefficient range and whether it covers the complete snapshot. Stored fields: coefficient_start, coefficient_stop, coefficients, complete_snapshot, certificate.

Contract (D, C, H, R, X). These immutable records describe one verified chunk, the complete or partial stream manifest, a bounded coefficient selection, write progress, or a chunk-wise evaluation with explicit coefficient coverage. Fields require contiguous nonnegative ranges, coherent counts and digests, valid schema metadata, strict ordering, and certificates matching completion state. Malformed ranges, duplicate or unordered coefficients, digest mismatch, or inconsistent progress is rejected.

Guarantees (E, P, B, K). Records make partial versus complete coverage explicit and preserve integrity metadata. A valid record does not authenticate the producer: an attacker able to replace payloads and digests can construct a different internally consistent stream. Storage is proportional to metadata plus the selected coefficients or evaluation value.

Evidence and links (V, L). Streaming tests validate constructor invariants, incomplete-state labeling, tamper detection, selection budgets, and PSC-III-D60 coverage certificates. See Chapters 43 and 61.

B.3 · PacketJetStreamWriteResult

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.PacketJetStreamWriteResult. Identity-equal audited re-exports komorebi_math.PacketJetStreamWriteResult, komorebi_math.nonlinear.PacketJetStreamWriteResult. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind class. Reflected implementation komorebi_math.nonlinear.streaming.PacketJetStreamWriteResult. Profile B3-R1.

Manifest signature (s).

```
(destination: 'Path', active_path: 'Path', completed: 'bool', resumed: 'bool', chunks_written: 'int',
   ↪ evaluations_written: 'int', coefficients_written: 'int', manifest: 'PacketJetStreamManifest', certificate:
   ↪ 'Certificate') -> None
```

Definition. Progress returned by a direct or snapshot stream write. active_path identifies the final directory after completion or the .partial staging directory while interrupted. Stored fields: destination, active_path, completed, resumed, chunks_written, evaluations_written, coefficients_written, manifest, certificate.

Contract (D, C, H, R, X). These immutable records describe one verified chunk, the complete or partial stream manifest, a bounded coefficient selection, write progress, or a chunk-wise evaluation with explicit coefficient coverage. Fields require contiguous nonnegative ranges, coherent counts and digests, valid schema metadata, strict ordering, and certificates matching completion state. Malformed ranges, duplicate or unordered coefficients, digest mismatch, or inconsistent progress is rejected.

Guarantees (E, P, B, K). Records make partial versus complete coverage explicit and preserve integrity metadata. A valid record does not authenticate the producer: an attacker able to replace payloads and digests can construct a

different internally consistent stream. Storage is proportional to metadata plus the selected coefficients or evaluation value.

Evidence and links (V, L). Streaming tests validate constructor invariants, incomplete-state labeling, tamper detection, selection budgets, and PSC-III-D60 coverage certificates. See Chapters 43 and 61.

B.3 · StreamedPacketJetEvaluation

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.StreamedPacketJetEvaluation. Identity-equal audited re-exports komorebi_math.StreamedPacketJetEvaluation, komorebi_math.nonlinear.StreamedPacketJetEvaluation. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind class. Reflected implementation komorebi_math.nonlinear.streaming.StreamedPacketJetEvaluation. Profile B3-R1.

Manifest signature (s).

```
(value: 'np.ndarray', coefficient_start: 'int', coefficient_stop: 'int', total_coefficients: 'int',
    ↪ complete_snapshot: 'bool', certificate: 'Certificate') -> None
```

Definition. One chunk-wise packet-jet evaluation with an explicit coverage record. The half-open coefficient range and complete_snapshot flag prevent partial sums from being mistaken for full evaluation. Stored fields: value, coefficient_start, coefficient_stop, total_coefficients, complete_snapshot, certificate.

Contract (D, C, H, R, X). These immutable records describe one verified chunk, the complete or partial stream manifest, a bounded coefficient selection, write progress, or a chunk-wise evaluation with explicit coefficient coverage. Fields require contiguous nonnegative ranges, coherent counts and digests, valid schema metadata, strict ordering, and certificates matching completion state. Malformed ranges, duplicate or unordered coefficients, digest mismatch, or inconsistent progress is rejected.

Guarantees (E, P, B, K). Records make partial versus complete coverage explicit and preserve integrity metadata. A valid record does not authenticate the producer: an attacker able to replace payloads and digests can construct a different internally consistent stream. Storage is proportional to metadata plus the selected coefficients or evaluation value.

Evidence and links (V, L). Streaming tests validate constructor invariants, incomplete-state labeling, tamper detection, selection budgets, and PSC-III-D60 coverage certificates. See Chapters 43 and 61.

B.3 · PacketJetSnapshotStreamReader

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.PacketJetSnapshotStreamReader. Identity-equal audited re-exports komorebi_math.PacketJetSnapshotStreamReader, komorebi_math.nonlinear.PacketJetSnapshotStreamReader. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind class. Reflected implementation komorebi_math.nonlinear.streaming.PacketJetSnapshotStreamReader. Profile B3-R2.

Manifest signature (s).

```
(path: 'str | os.PathLike[str]', *, allow_incomplete: 'bool' = False, verify_chunks: 'bool' = False) -> 'None'
```

Definition. Bounded-memory reader for a complete or explicitly allowed partial stream. Reader operations include verified chunk iteration, bounded selection, chunk-wise evaluation, full verification, and guarded snapshot materialization. Runtime-visible operational members: complete, evaluate, iter_chunks, iter_coefficients, load_snapshot, select, verify.

Contract (D, C, H, R, X). The reader opens a validated directory-backed stream and exposes manifest metadata, chunk iteration, bounded selection, chunk-wise evaluation, verification, and guarded materialization. Complete streams are required by default. Incomplete streams require explicit opt-in. Chunk verification checks canonical envelopes, SHA-256 digests, contiguous ranges, strict lexicographic coefficient order, and manifest counts. Missing files, malformed JSON, digest tampering, unsupported schema, incomplete disallowed state, and budget overflow raise validation errors.

Guarantees (E, P, B, K). Iteration and evaluation can remain bounded by chunk size. Selection and full materialization obey explicit coefficient limits. A partial evaluation returns a certificate with unchecked coverage assumptions instead of masquerading as a complete jet. Integrity is SHA-256 based and is not producer authentication.

Evidence and links (V, L). Direct-resume, bounded-read, incomplete-policy, tamper, and full-materialization tests exercise theorem identifier PSC-III-D60. See Chapters 43 and 61.

B.3 · capture_packet_jet_stream

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.capture_packet_jet_stream. Identity-equal audited re-exports komorebi_math.capture_packet_jet_stream, komorebi_math.nonlinear.capture_packet_jet_stream. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind function. Reflected implementation komorebi_math.nonlinear.streaming.capture_packet_jet_stream. Profile B3-O1.

Manifest signature (s).

```
(jet: 'PacketJet', path: 'str | os.PathLike[str]', *, tolerance: 'float | None' = None, max_evaluations: 'int' =
    ↪ 10000000, chunk_size: 'int' = 1024, evaluation_budget: 'int | None' = None, resume: 'bool' = False,
    ↪ overwrite: 'bool' = False) -> 'PacketJetStreamWriteResult'
```

Definition. Capture a packet jet directly into bounded, resumable basis chunks.

Contract (D, C, H, R, X). Direct capture evaluates a packet jet in deterministic standard-basis order and writes verified chunks. Snapshot save emits an existing coefficient sequence. Both stage work in <destination>.partial, support explicit budgets and resumability, and promote only a complete verified staging directory. Paths, chunk sizes, evaluation or coefficient budgets, resume state, and overwrite policy must be valid. Conflicts, incompatible partial state, digest mismatch, malformed chunks, or exhausted budgets return partial progress where specified or raise validation errors.

Guarantees (E, P, B, K). Completed streams preserve exact or tolerance-qualified snapshot semantics and canonical integrity metadata. Resume continues only matching source metadata and contiguous verified progress. Memory is bounded by chunk size plus provider evaluation state. Total work follows dense basis evaluations for direct capture or retained coefficient count for snapshot save.

Evidence and links (V, L). The streaming beta verifier covers direct resume, snapshot streaming, budget interruption, deterministic continuation, tamper detection, and PSC-III-D60. See Chapter 43.

B.3 · save_packet_jet_snapshot_stream

Identity (q, a, t, k). Canonical beta route komorebi_math.beta.save_packet_jet_snapshot_stream. Identity-equal audited re-exports komorebi_math.save_packet_jet_snapshot_stream, komorebi_math.nonlinear.save_packet_jet_snapshot_stream. Tier [BETA] under 1.0-beta-additive-strict-signatures. Manifest kind function. Reflected implementation komorebi_math.nonlinear.streaming.save_packet_jet_snapshot_stream. Profile B3-O1.

Manifest signature (s).

```
(snapshot: 'PacketJetSnapshot', path: 'str | os.PathLike[str]', *, chunk_size: 'int' = 1024, coefficient_budget:
    ↪ 'int | None' = None, resume: 'bool' = False, overwrite: 'bool' = False) -> 'PacketJetStreamWriteResult'
```

Definition. Write an existing snapshot as independently verified coefficient chunks.

Contract (D, C, H, R, X). Direct capture evaluates a packet jet in deterministic standard-basis order and writes verified chunks. Snapshot save emits an existing coefficient sequence. Both stage work in <destination>.partial, support explicit budgets and resumability, and promote only a complete verified staging directory. Paths, chunk sizes, evaluation or coefficient budgets, resume state, and overwrite policy must be valid. Conflicts, incompatible partial state, digest mismatch, malformed chunks, or exhausted budgets return partial progress where specified or raise validation errors.

Guarantees (E, P, B, K). Completed streams preserve exact or tolerance-qualified snapshot semantics and canonical integrity metadata. Resume continues only matching source metadata and contiguous verified progress. Memory is bounded by chunk size plus provider evaluation state. Total work follows dense basis evaluations for direct capture or retained coefficient count for snapshot save.

Evidence and links (V, L). The streaming beta verifier covers direct resume, snapshot streaming, budget interruption, deterministic continuation, tamper detection, and PSC-III-D60. See Chapter 43.

B.3 · open_packet_jet_snapshot_stream

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.open_packet_jet_snapshot_stream`. Identity-equal audited re-exports `komorebi_math.open_packet_jet_snapshot_stream`, `komorebi_math.nonlinear.open_packet_jet_snapshot_stream`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.streaming.open_packet_jet_snapshot_stream`. Profile `B3-O2`.

Manifest signature (s).

```
(path: 'str | os.PathLike[str]', *, allow_incomplete: 'bool' = False, verify_chunks: 'bool' = False) ->
   ↪ 'PacketJetSnapshotStreamReader'
```

Definition. Open one packet-jet stream with explicit incomplete-stream policy.

Contract (D, C, H, R, X). Open validates stream metadata under an explicit incomplete and verification policy and returns a bounded reader. Load requires a complete stream, optionally verifies every chunk, enforces `max_coefficients`, and materializes a conventional snapshot. Invalid paths, missing or malformed files, unsupported schema, tampering, disallowed incompleteness, or coefficient-budget overflow raise validation errors.

Guarantees (E, P, B, K). Open can defer per-chunk verification when requested. Load defaults to verified chunks and never silently loads a partial stream. Reader iteration is chunk-bounded, while full loading uses memory linear in retained coefficients. There is no network or GPU backend.

Evidence and links (V, L). Tests cover complete and incomplete opening, eager and deferred verification, coefficient guards, exact reconstruction, and tamper rejection under `PSC-III-D60`. See Chapters 43 and 61.

B.3 · load_packet_jet_snapshot_stream

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.load_packet_jet_snapshot_stream`. Identity-equal audited re-exports `komorebi_math.load_packet_jet_snapshot_stream`, `komorebi_math.nonlinear.load_packet_jet_snapshot_stream`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.nonlinear.streaming.load_packet_jet_snapshot_stream`. Profile `B3-O2`.

Manifest signature (s).

```
(path: 'str | os.PathLike[str]', *, max_coefficients: 'int' = 1000000, verify_chunks: 'bool' = True) ->
   ↪ 'PacketJetSnapshot'
```

Definition. Load a complete stream into a conventional in-memory snapshot.

Contract (D, C, H, R, X). Open validates stream metadata under an explicit incomplete and verification policy and returns a bounded reader. Load requires a complete stream, optionally verifies every chunk, enforces `max_coefficients`, and materializes a conventional snapshot. Invalid paths, missing or malformed files, unsupported schema, tampering, disallowed incompleteness, or coefficient-budget overflow raise validation errors.

Guarantees (E, P, B, K). Open can defer per-chunk verification when requested. Load defaults to verified chunks and never silently loads a partial stream. Reader iteration is chunk-bounded, while full loading uses memory linear in retained coefficients. There is no network or GPU backend.

Evidence and links (V, L). Tests cover complete and incomplete opening, eager and deferred verification, coefficient guards, exact reconstruction, and tamper rejection under `PSC-III-D60`. See Chapters 43 and 61.

B.4 Portable beta records and migrations

B.4 · PORTABLE_SCHEMA

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PORTABLE_SCHEMA`. Identity-equal audited re-exports `komorebi_math.export.PORTABLE_SCHEMA`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.str`. Profile `B4-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `komorebi-math.portable`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the exact portable-envelope schema name or integer version. Attribute access cannot validate a payload and has no call-time exception path.

Guarantees (E, P, B, K). The values are exact immutable identifiers with constant lookup cost and no backend dependency. Schema version 1 defines the outer digest-checked JSON envelope. Individual codecs retain their own versions.

Evidence and links (V, L). Persistence tests assert the envelope identifiers, duplicate-key and nonfinite rejection, and runtime identity. See Chapter 61.

B.4 · PORTABLE_SCHEMA_VERSION

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PORTABLE_SCHEMA_VERSION`. Identity-equal audited re-exports `komorebi_math.export.PORTABLE_SCHEMA_VERSION`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `data`. Reflected implementation `builtins.int`. Profile `B4-I1`.

Manifest signature (s).

```
null
```

Definition. The immutable runtime value is `1`.

Contract (D, C, H, R, X). The domain is import-time binding and the codomain is the exact portable-envelope schema name or integer version. Attribute access cannot validate a payload and has no call-time exception path.

Guarantees (E, P, B, K). The values are exact immutable identifiers with constant lookup cost and no backend dependency. Schema version 1 defines the outer digest-checked JSON envelope. Individual codecs retain their own versions.

Evidence and links (V, L). Persistence tests assert the envelope identifiers, duplicate-key and nonfinite rejection, and runtime identity. See Chapter 61.

B.4 · PortableCodec

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.PortableCodec`. Identity-equal audited re-exports `komorebi_math.PortableCodec`, `komorebi_math.export.PortableCodec`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.export.persistence.PortableCodec`. Profile `B4-R1`.

Manifest signature (s).

```
(tag: 'str', version: 'int', type_: 'type[Any]', encoder: 'Encoder', decoder: 'Decoder') -> None
```

Definition. One explicit type codec in the portable persistence registry. The codec version belongs to the stable tag and is independent of the outer portable-envelope schema version. Stored fields: `tag`, `version`, `type_`, `encoder`, `decoder`.

Contract (D, C, H, R, X). Codec records bind a stable tag and positive version to one Python type and explicit encoder/decoder. Migration records bind one adjacent `n -> n+1` safe-data transformation. Registration validates tags, versions, type conflicts, adjacency, and replacement policy. Registry queries return deterministic tag/version order.

Duplicate registrations, nonadjacent migrations, missing migration steps, invalid tags, or incompatible versions raise `ValidationError`.

Guarantees (`E`, `P`, `B`, `K`). The registry is explicit and never imports a class named by persisted data. Encoders and decoders determine mathematical fidelity. The registry provides deterministic dispatch and migration sequencing. The reference package registers 51 codecs and one adjacent packet-jet-snapshot migration. Lookup is dictionary-based. Listing sorts the finite registry.

Evidence and links (`V`, `L`). Persistence, migration, and release-contract tests verify all registered tags, versions, type names, adjacent paths, and roundtrips. See Chapters 61 and 72 and Appendix G.

B.4 · `PortableMigration`

Identity (`q`, `a`, `t`, `k`). Canonical beta route `komorebi_math.beta.PortableMigration`. Identity-equal audited re-exports `komorebi_math.PortableMigration`, `komorebi_math.export.PortableMigration`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `class`. Reflected implementation `komorebi_math.export.persistence.PortableMigration`. Profile `B4-R1`.

Manifest signature (`s`).

```
(tag: 'str', from_version: 'int', to_version: 'int', migrator: 'Migrator') -> None
```

Definition. One explicit, adjacent codec-data migration. Only adjacent migrations are valid, so multi-version upgrades are an auditable sequence of registered steps. Stored fields: `tag`, `from_version`, `to_version`, `migrator`.

Contract (`D`, `C`, `H`, `R`, `X`). Codec records bind a stable tag and positive version to one Python type and explicit encoder/decoder. Migration records bind one adjacent `n -> n+1` safe-data transformation. Registration validates tags, versions, type conflicts, adjacency, and replacement policy. Registry queries return deterministic tag/version order. Duplicate registrations, nonadjacent migrations, missing migration steps, invalid tags, or incompatible versions raise `ValidationError`.

Guarantees (`E`, `P`, `B`, `K`). The registry is explicit and never imports a class named by persisted data. Encoders and decoders determine mathematical fidelity. The registry provides deterministic dispatch and migration sequencing. The reference package registers 51 codecs and one adjacent packet-jet-snapshot migration. Lookup is dictionary-based. Listing sorts the finite registry.

Evidence and links (`V`, `L`). Persistence, migration, and release-contract tests verify all registered tags, versions, type names, adjacent paths, and roundtrips. See Chapters 61 and 72 and Appendix G.

B.4 · `register_portable_codec`

Identity (`q`, `a`, `t`, `k`). Canonical beta route `komorebi_math.beta.register_portable_codec`. Identity-equal audited re-exports `komorebi_math.register_portable_codec`, `komorebi_math.export.register_portable_codec`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.register_portable_codec`. Profile `B4-R1`.

Manifest signature (`s`).

```
(type_: 'type[T]', *, tag: 'str', version: 'int', encoder: 'Callable[[T], Any]', decoder: 'Callable[[Any], T]',
    ↪ replace: 'bool' = False) -> 'None'
```

Definition. Register one stable round-trip codec.

Contract (`D`, `C`, `H`, `R`, `X`). Codec records bind a stable tag and positive version to one Python type and explicit encoder/decoder. Migration records bind one adjacent `n -> n+1` safe-data transformation. Registration validates tags, versions, type conflicts, adjacency, and replacement policy. Registry queries return deterministic tag/version order. Duplicate registrations, nonadjacent migrations, missing migration steps, invalid tags, or incompatible versions raise `ValidationError`.

Guarantees (`E`, `P`, `B`, `K`). The registry is explicit and never imports a class named by persisted data. Encoders and decoders determine mathematical fidelity. The registry provides deterministic dispatch and migration sequencing.

The reference package registers 51 codecs and one adjacent packet-jet-snapshot migration. Lookup is dictionary-based. Listing sorts the finite registry.

Evidence and links (V, L). Persistence, migration, and release-contract tests verify all registered tags, versions, type names, adjacent paths, and roundtrips. See Chapters 61 and 72 and Appendix G.

B.4 · register_portable_migration

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.register_portable_migration`. Identity-equal audited re-exports `komorebi_math.register_portable_migration`, `komorebi_math.export.register_portable_migration`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.register_portable_migration`. Profile `B4-R1`.

Manifest signature (s).

```
(*, tag: 'str', from_version: 'int', to_version: 'int', migrator: 'Migrator', replace: 'bool' = False) -> 'None'
```

Definition. Register one deterministic adjacent migration for codec data.

Contract (D, C, H, R, X). Codec records bind a stable tag and positive version to one Python type and explicit encoder/decoder. Migration records bind one adjacent `n -> n+1` safe-data transformation. Registration validates tags, versions, type conflicts, adjacency, and replacement policy. Registry queries return deterministic tag/version order. Duplicate registrations, nonadjacent migrations, missing migration steps, invalid tags, or incompatible versions raise `ValidationError`.

Guarantees (E, P, B, K). The registry is explicit and never imports a class named by persisted data. Encoders and decoders determine mathematical fidelity. The registry provides deterministic dispatch and migration sequencing. The reference package registers 51 codecs and one adjacent packet-jet-snapshot migration. Lookup is dictionary-based. Listing sorts the finite registry.

Evidence and links (V, L). Persistence, migration, and release-contract tests verify all registered tags, versions, type names, adjacent paths, and roundtrips. See Chapters 61 and 72 and Appendix G.

B.4 · portable_codecs

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.portable_codecs`. Identity-equal audited re-exports `komorebi_math.portable_codecs`, `komorebi_math.export.portable_codecs`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.portable_codecs`. Profile `B4-R1`.

Manifest signature (s).

```
() -> 'tuple[PortableCodec, ...]'
```

Definition. Return the active codecs ordered by stable tag.

Contract (D, C, H, R, X). Codec records bind a stable tag and positive version to one Python type and explicit encoder/decoder. Migration records bind one adjacent `n -> n+1` safe-data transformation. Registration validates tags, versions, type conflicts, adjacency, and replacement policy. Registry queries return deterministic tag/version order. Duplicate registrations, nonadjacent migrations, missing migration steps, invalid tags, or incompatible versions raise `ValidationError`.

Guarantees (E, P, B, K). The registry is explicit and never imports a class named by persisted data. Encoders and decoders determine mathematical fidelity. The registry provides deterministic dispatch and migration sequencing. The reference package registers 51 codecs and one adjacent packet-jet-snapshot migration. Lookup is dictionary-based. Listing sorts the finite registry.

Evidence and links (V, L). Persistence, migration, and release-contract tests verify all registered tags, versions, type names, adjacent paths, and roundtrips. See Chapters 61 and 72 and Appendix G.

B.4 · portable_migrations

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.portable_migrations`. Identity-equal audited re-exports `komorebi_math.portable_migrations`, `komorebi_math.export.portable_migrations`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.portable_migrations`. Profile `B4-R1`.

Manifest signature (s).

```
() -> 'tuple[PortableMigration, ...]'
```

Definition. Return registered codec migrations in deterministic order.

Contract (D, C, H, R, X). Codec records bind a stable tag and positive version to one Python type and explicit encoder/decoder. Migration records bind one adjacent `n -> n+1` safe-data transformation. Registration validates tags, versions, type conflicts, adjacency, and replacement policy. Registry queries return deterministic tag/version order. Duplicate registrations, nonadjacent migrations, missing migration steps, invalid tags, or incompatible versions raise `ValidationError`.

Guarantees (E, P, B, K). The registry is explicit and never imports a class named by persisted data. Encoders and decoders determine mathematical fidelity. The registry provides deterministic dispatch and migration sequencing. The reference package registers 51 codecs and one adjacent packet-jet-snapshot migration. Lookup is dictionary-based. Listing sorts the finite registry.

Evidence and links (V, L). Persistence, migration, and release-contract tests verify all registered tags, versions, type names, adjacent paths, and roundtrips. See Chapters 61 and 72 and Appendix G.

B.4 · to_portable_data

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.to_portable_data`. Identity-equal audited re-exports `komorebi_math.export.to_portable_data`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.to_portable_data`. Profile `B4-C1`.

Manifest signature (s).

```
(value: 'Any', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Encode one value into the versioned portable payload tree.

Contract (D, C, H, R, X). Encoding maps supported primitive containers and registered types to a versioned safe payload tree. Decoding validates that tree and applies every registered adjacent migration to the active codec version. Digest computes canonical SHA-256 over encoded payload. Text functions wrap or validate the complete schema/version/payload/digest JSON envelope. Unsupported types, excessive depth, duplicate keys, nonfinite numbers, malformed envelopes, digest mismatch, unknown tags, future versions, or missing migrations raise `ValidationError`.

Guarantees (E, P, B, K). Canonical JSON uses sorted keys, compact separators for digests, UTF-8, and no NaN or infinity. SHA-256 supplies corruption detection, not authentication. Roundtrip fidelity is the codec contract. Work and memory are linear in encoded payload size subject to default depth guard 128. No arbitrary import, pickle, network, or backend fallback occurs.

Evidence and links (V, L). Codec tests cover 51 built-ins, nested containers, deterministic digests, depth limits, malformed and adversarial JSON, v1-to-v2 packet-jet snapshot migration, and exact roundtrips. See Chapters 61 and 72.

B.4 · from_portable_data

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.from_portable_data`. Identity-equal audited re-exports `komorebi_math.export.from_portable_data`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.from_portable_data`. Profile `B4-C1`.

Manifest signature (`s`).

```
(value: 'Any', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Decode one previously encoded portable payload tree.

Contract (`D, C, H, R, X`). Encoding maps supported primitive containers and registered types to a versioned safe payload tree. Decoding validates that tree and applies every registered adjacent migration to the active codec version. Digest computes canonical SHA-256 over encoded payload. Text functions wrap or validate the complete schema/version/payload/digest JSON envelope. Unsupported types, excessive depth, duplicate keys, nonfinite numbers, malformed envelopes, digest mismatch, unknown tags, future versions, or missing migrations raise `ValidationError`.

Guarantees (`E, P, B, K`). Canonical JSON uses sorted keys, compact separators for digests, UTF-8, and no NaN or infinity. SHA-256 supplies corruption detection, not authentication. Roundtrip fidelity is the codec contract. Work and memory are linear in encoded payload size subject to default depth guard 128. No arbitrary import, pickle, network, or backend fallback occurs.

Evidence and links (`V, L`). Codec tests cover 51 built-ins, nested containers, deterministic digests, depth limits, malformed and adversarial JSON, v1-to-v2 packet-jet snapshot migration, and exact roundtrips. See Chapters 61 and 72.

B.4 · `portable_digest`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.portable_digest`. Identity-equal audited re-exports `komorebi_math.portable_digest`, `komorebi_math.export.portable_digest`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.portable_digest`. Profile `B4-C1`.

Manifest signature (`s`).

```
(value: 'Any', *, max_depth: 'int' = 128) -> 'str'
```

Definition. Return the canonical SHA256 digest of one encoded payload. The digest is computed over the encoded payload tree rather than presentation indentation.

Contract (`D, C, H, R, X`). Encoding maps supported primitive containers and registered types to a versioned safe payload tree. Decoding validates that tree and applies every registered adjacent migration to the active codec version. Digest computes canonical SHA-256 over encoded payload. Text functions wrap or validate the complete schema/version/payload/digest JSON envelope. Unsupported types, excessive depth, duplicate keys, nonfinite numbers, malformed envelopes, digest mismatch, unknown tags, future versions, or missing migrations raise `ValidationError`.

Guarantees (`E, P, B, K`). Canonical JSON uses sorted keys, compact separators for digests, UTF-8, and no NaN or infinity. SHA-256 supplies corruption detection, not authentication. Roundtrip fidelity is the codec contract. Work and memory are linear in encoded payload size subject to default depth guard 128. No arbitrary import, pickle, network, or backend fallback occurs.

Evidence and links (`V, L`). Codec tests cover 51 built-ins, nested containers, deterministic digests, depth limits, malformed and adversarial JSON, v1-to-v2 packet-jet snapshot migration, and exact roundtrips. See Chapters 61 and 72.

B.4 · `dumps_portable`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.dumps_portable`. Identity-equal audited re-exports `komorebi_math.dumps_portable`, `komorebi_math.export.dumps_portable`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.dumps_portable`. Profile `B4-C1`.

Manifest signature (s).

```
(value: 'Any', *, indent: 'int | None' = 2, max_depth: 'int' = 128) -> 'str'
```

Definition. Serialize one value into a complete digest-checked JSON envelope.

Contract (D, C, H, R, X). Encoding maps supported primitive containers and registered types to a versioned safe payload tree. Decoding validates that tree and applies every registered adjacent migration to the active codec version. Digest computes canonical SHA-256 over encoded payload. Text functions wrap or validate the complete schema/version/payload/digest JSON envelope. Unsupported types, excessive depth, duplicate keys, nonfinite numbers, malformed envelopes, digest mismatch, unknown tags, future versions, or missing migrations raise `ValidationError`.

Guarantees (E, P, B, K). Canonical JSON uses sorted keys, compact separators for digests, UTF-8, and no NaN or infinity. SHA-256 supplies corruption detection, not authentication. Roundtrip fidelity is the codec contract. Work and memory are linear in encoded payload size subject to default depth guard 128. No arbitrary import, pickle, network, or backend fallback occurs.

Evidence and links (V, L). Codec tests cover 51 built-ins, nested containers, deterministic digests, depth limits, malformed and adversarial JSON, v1-to-v2 packet-jet snapshot migration, and exact roundtrips. See Chapters 61 and 72.

B.4 · `loads_portable`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.loads_portable`. Identity-equal audited re-exports `komorebi_math.loads_portable, komorebi_math.export.loads_portable`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.loads_portable`. Profile `B4-C1`.

Manifest signature (s).

```
(text: 'str | bytes', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Validate and deserialize one complete portable JSON envelope.

Contract (D, C, H, R, X). Encoding maps supported primitive containers and registered types to a versioned safe payload tree. Decoding validates that tree and applies every registered adjacent migration to the active codec version. Digest computes canonical SHA-256 over encoded payload. Text functions wrap or validate the complete schema/version/payload/digest JSON envelope. Unsupported types, excessive depth, duplicate keys, nonfinite numbers, malformed envelopes, digest mismatch, unknown tags, future versions, or missing migrations raise `ValidationError`.

Guarantees (E, P, B, K). Canonical JSON uses sorted keys, compact separators for digests, UTF-8, and no NaN or infinity. SHA-256 supplies corruption detection, not authentication. Roundtrip fidelity is the codec contract. Work and memory are linear in encoded payload size subject to default depth guard 128. No arbitrary import, pickle, network, or backend fallback occurs.

Evidence and links (V, L). Codec tests cover 51 built-ins, nested containers, deterministic digests, depth limits, malformed and adversarial JSON, v1-to-v2 packet-jet snapshot migration, and exact roundtrips. See Chapters 61 and 72.

B.4 · `save_portable`

Identity (q, a, t, k). Canonical beta route `komorebi_math.beta.save_portable`. Identity-equal audited re-exports `komorebi_math.save_portable, komorebi_math.export.save_portable`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.save_portable`. Profile `B4-F1`.

Manifest signature (`s`).

```
(value: 'Any', path: 'str | os.PathLike[str]', *, overwrite: 'bool' = False, indent: 'int | None' = 2, max_depth:
   ↪  'int' = 128) -> 'Path'
```

Definition. Atomically write a portable envelope to disk. The default is refusal to overwrite and two-space JSON indentation.

Contract (`D, C, H, R, X`). Save encodes one supported value, creates a complete digest-checked envelope, writes a sibling temporary file, and atomically replaces the destination. Overwrite is refused unless explicitly enabled. Load reads UTF-8 text and delegates to strict envelope validation and decoding. Invalid paths, existing destinations, unsupported values, depth violations, I/O errors, malformed JSON, digest mismatch, unknown codecs, or migration gaps raise explicit exceptions.

Guarantees (`E, P, B, K`). A successful save is atomic at the filesystem replacement boundary and deterministic for the same encoded value and indentation policy. It provides integrity but not authenticity or crash-proof guarantees beyond the host filesystem. Runtime and memory are linear in serialized payload size. No remote storage or GPU backend is used.

Evidence and links (`V, L`). Filesystem persistence tests cover overwrite refusal, atomic replacement, exact roundtrip, tamper and truncation rejection, and migration on load. See Chapter 61 and Appendix G.

B.4 · `load_portable`

Identity (`q, a, t, k`). Canonical beta route `komorebi_math.beta.load_portable`. Identity-equal audited re-exports `komorebi_math.load_portable`, `komorebi_math.export.load_portable`. Tier `[BETA]` under `1.0-beta-additive-strict-signatures`. Manifest kind `function`. Reflected implementation `komorebi_math.export.persistence.load_portable`. Profile `B4-F1`.

Manifest signature (`s`).

```
(path: 'str | os.PathLike[str]', *, max_depth: 'int' = 128) -> 'Any'
```

Definition. Read and validate a portable envelope from disk.

Contract (`D, C, H, R, X`). Save encodes one supported value, creates a complete digest-checked envelope, writes a sibling temporary file, and atomically replaces the destination. Overwrite is refused unless explicitly enabled. Load reads UTF-8 text and delegates to strict envelope validation and decoding. Invalid paths, existing destinations, unsupported values, depth violations, I/O errors, malformed JSON, digest mismatch, unknown codecs, or migration gaps raise explicit exceptions.

Guarantees (`E, P, B, K`). A successful save is atomic at the filesystem replacement boundary and deterministic for the same encoded value and indentation policy. It provides integrity but not authenticity or crash-proof guarantees beyond the host filesystem. Runtime and memory are linear in serialized payload size. No remote storage or GPU backend is used.

Evidence and links (`V, L`). Filesystem persistence tests cover overwrite refusal, atomic replacement, exact roundtrip, tamper and truncation rejection, and migration on load. See Chapter 61 and Appendix G.

> **Beta-reference coverage.** The recorded validation found 83/83 unique export cards and 83/83 unique canonical anchors. It matched all 67 non-null manifest signatures and all 16 literal `null` signatures and covered all 208 audited beta/root/domain qualified identities. The strict `KM-API-010` compatibility check reported zero added, removed, kind-changed, or signature-changed entries, and the 15-case `KM-GOLDEN-011` fixture passed. This establishes the curated beta exported-symbol reference only. Appendix C records the research surface, and the following appendices provide its operational crosswalks.

Appendix C. Research API: 1,312-entry reference

Finding an object in the research reference. This appendix is designed for lookup as well as sustained reading. If you know the exported name, go to the alphabetical index in Section C.8 and follow the route for the namespace used by your program. If you know its implementation module, use the owner index in C.7. If you know only the mathematical task, use the namespace map below and the corresponding explanatory chapters.

Task or domain	Reference destination	Explanatory chapters
Certificates, configuration, compatibility, and provenance	Root contracts in C.1A	5 through 8 and 62
Typed expressions, evaluation, and planning	Root expression cards in C.1B	50 through 52
Bases, changes of coordinates, interpolation, and frames	Coordinate cards in C.2	15 through 20
Formal series, normalization, masks, and arithmetic generating functions	Generating cards in C.3	21 through 25
Windows, filters, spectral transforms, resampling, and wavelets	Signal cards in C.4	31 through 36A
Derivatives, packet jets, correction, lifting, and streaming	Nonlinear cards in C.5	37 through 44
Rendering, writing files, and portable objects	Export cards in C.6	59 through 62
Other root-level mathematical families	Root cards in C.1 and the owner index in C.7	Follow the individual card's chapter links

The root namespace and a domain namespace can expose the same runtime object. Their separate cards preserve the import routes that users encounter. Section C.10 collects the alias and tier relationships, so a second matching name does not need to be interpreted as a second algorithm. Conversely, similar names or signatures do not establish equivalence. Read each card's definition, domain, and guarantees before substituting one object for another.

Use the card as a contract. The reading key in Appendix A explains the fields shared by all API cards. Begin with the definition and import route, then read the signature together with the input shapes, hypotheses, and return contract. Follow the evidence links for an example before adapting the operation to larger or different data. Research is a compatibility tier, not a single mathematical truth status: an exact finite algorithm, a tolerance-qualified numerical computation, and a conditional construction can all appear here. The individual guarantees state which one you are using.

When comparing two possible operations, keep five questions beside the cards:

1. Do they accept the same scalar domain and dimensions?
2. Do their labels, basis order, coordinate conventions, and units agree?
3. Do they return the same kind of value or certificate-bearing record?
4. Do they require different backends, hypotheses, or resource budgets?
5. Do their guarantees cover the result you intend to use?

Answering these questions is more reliable than selecting a function because its name sounds closest to the task. Chapter 8 explains scalar and backend choices; the domain chapters supply the ordering conventions and examples.

Reading the indices. Section C.7 groups routes by the module that owns the implementation. Section C.8 groups them by exported name. Section C.9 groups exact reflected signatures, including names for which the manifest

records `null`. Section C.10 groups declared aliases across stability tiers. Each index answers a different lookup question; none replaces the card's operational contract. In particular, a shared signature is a shared calling form, not proof of identical mathematical behavior.

Working from a failure. Keep the exact exported route, the input dimensions and scalar domain, the backend, and the diagnostic together. Compare them with the card's preconditions and failure paragraph. Appendix I provides recovery guidance, Appendix J lists dependency and platform boundaries, and Appendix K explains resource budgets. If the result is conditional, retain the unchecked assumptions when reporting it. If the result is numerical, retain the tolerance and residual information. This makes the result useful to the next reader as well as to the program that produced it.

The signatures and execution observations below belong to the reference baseline stated in the preface. Literal version strings, source identifiers, and recorded outputs are retained for reproducibility. Use the current-source crosswalk when you need to distinguish that record from later source tests.

Appendix C assigns one card to each namespace/name pair in the broad public manifest. The root namespace contributes 516 of the 1,312 entries. Cards are grouped by namespace and contract family rather than by a purely alphabetic order. The records were built from the committed `1.0.0b4` manifest, matched to runtime reflection, and checked against their implementation and focused tests. The evidence applies to the reference baseline and retains the scope stated on each card.

C.1 Root namespace: 516 entries

C.1A Foundational contracts, compatibility, configuration, provenance, and schemas: 46 entries

This foundational root section covers the package metadata and type aliases that govern portable formats, certificate records, context-local settings, deterministic API manifests, deprecation behavior, provenance lookup, and the closed behavioral-golden fixture. Several names are also exposed through curated beta or stable facades. Their stronger facade contracts are stated on each card and do not change the additive policy of the root route.

C.1A · `API_STABILITY_LEVEL`

Identity (`q, a, t, k`). Public research-manifest route `komorebi_math.API_STABILITY_LEVEL`. Reflected implementation `builtins.str`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (`s`).

```
null
```

Definition. The string `pre-beta-additive`, which names the compatibility policy for the broad public manifest.

Contract (`D, C, H, R, X`). Import returns a policy label string. Compatibility functions copy the label into manifests and reports, but the string does not itself run a check or establish semantic equivalence. There is no call-time exception.

Guarantees (`E, P, B, K`). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (`V, L`). The committed manifest, runtime reflection audit, and the manifest source audit and compatibility tests cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · ApiCompatibilityReport

Identity (q, a, t, k). Public research-manifest route `komorebi_math.ApiCompatibilityReport`. Reflected implementation `komorebi_math.compatibility.ApiCompatibilityReport`. The same object is available through the curated beta route `komorebi_math.beta.ApiCompatibilityReport` and the curated stable routes `komorebi_math.stable.ApiCompatibilityReport`, `komorebi_math.v1.ApiCompatibilityReport`, and `komorebi_math.api.v1.ApiCompatibilityReport`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-API-REPORT`.

Manifest signature (s).

```
(reference_digest: 'str', current_digest: 'str', added: 'tuple[tuple[str, str], ...]', removed: 'tuple[tuple[str,
    ↪ str], ...]', kind_changed: 'tuple[tuple[str, str, str, str], ...]', signature_changed: 'tuple[tuple[str,
    ↪ str, str | None, str | None], ...]', strict_signatures: 'bool', certificate: 'Certificate') -> None
```

Definition. An immutable structural diff between a reference API manifest and an observed manifest, together with the compatibility certificate.

Contract (D, C, H, R, X). The constructor stores both digests and the four structural difference sets. `compatible` delegates to the embedded certificate. `to_dict()` returns the report and serialized certificate. The record does not rerun reflection and does not establish behavioral or mathematical equivalence.

Guarantees (E, P, B, K). The records are exact structural metadata, not semantic certificates. Storage is linear in the number and length of recorded symbols. Manifest sorting and canonical digest construction are `O(n log n)` in symbol count plus serialized size. Map construction is linear. The implementation uses the standard library and imports no optional numerical backend.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block10_compatibility.py`, `test_block11_golden_profiling_beta.py`, and the CLI compatibility tests cover this route. See Chapters 7, 72, and 73.

C.1A · BEHAVIORAL_GOLDEN_SCHEMA

Identity (q, a, t, k). Public research-manifest route `komorebi_math.BEHAVIORAL_GOLDEN_SCHEMA`. Reflected implementation `builtins.str`. The same object is available through the curated beta route `komorebi_math.beta.BEHAVIORAL_GOLDEN_SCHEMA`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (s).

```
null
```

Definition. The schema identifier `komorebi-math.behavioral-golden` used by the closed semantic fixture document.

Contract (D, C, H, R, X). Import has no arguments and returns the recorded immutable schema string or integer. The constant does not parse or validate a fixture by itself. Validation occurs in `load_behavioral_golden_fixture`. There is no call-time exception.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block11_golden_profiling_beta.py` cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · BEHAVIORAL_GOLDEN_SCHEMA_VERSION

Identity (q, a, t, k). Public research-manifest route `komorebi_math.BEHAVIORAL_GOLDEN_SCHEMA_VERSION`. Reflected implementation `builtins.int`. The same object is available through the curated beta route `komorebi_math.beta.BEHAVIORAL_GOLDEN_SCHEMA_VERSION`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (s).

```
null
```

Definition. The integer `1`, the only behavioral-golden schema version accepted by this release.

Contract (D, C, H, R, X). Import has no arguments and returns the recorded immutable schema string or integer. The constant does not parse or validate a fixture by itself. Validation occurs in `load_behavioral_golden_fixture`. There is no call-time exception.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block11_golden_profiling_beta.py` cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · BETA_API_STABILITY_LEVEL

Identity (q, a, t, k). Public research-manifest route `komorebi_math.BETA_API_STABILITY_LEVEL`. Reflected implementation `builtins.str`. The same object is available through the curated beta route `komorebi_math.beta.BETA_API_STABILITY_LEVEL`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (s).

```
null
```

Definition. The string `1.0-beta-additive-strict-signatures`, which names the curated beta compatibility policy.

Contract (D, C, H, R, X). Import returns a policy label string. Compatibility functions copy the label into manifests and reports, but the string does not itself run a check or establish semantic equivalence. There is no call-time exception.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and the manifest source audit and compatibility tests cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · BETA_PUBLIC_NAMESPACES

Identity (q, a, t, k). Public research-manifest route `komorebi_math.BETA_PUBLIC_NAMESPACES`. Reflected implementation `builtins.tuple`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (s).

```
null
```

Definition. The one-element tuple `('komorebi_math.beta',)` inspected when the curated beta manifest is created or checked.

Contract (D, C, H, R, X). Import returns a tuple of namespace strings. Compatibility helpers consume it as the complete curated beta namespace set. The tuple is data, not an import operation, and raises no call-time exception.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and the manifest source audit and compatibility tests cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · BehavioralGoldenCaseResult

Identity (q, a, t, k). Public research-manifest route `komorebi_math.BehavioralGoldenCaseResult`. Reflected implementation `komorebi_math.golden.BehavioralGoldenCaseResult`. The same object is available through the curated beta route `komorebi_math.beta.BehavioralGoldenCaseResult`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-GOLDEN-CASE`.

Manifest signature (s).

```
(name: 'str', kind: 'str', observed: 'Any', expected: 'Any', certificate: 'Certificate') -> None
```

Definition. An immutable record containing one golden case's name, kind, observed value, expected value, and certificate.

Contract (D, C, H, R, X). The constructor stores observed and expected values plus a certificate. `passed` delegates to the certificate, and `to_dict()` serializes the result and certificate. Equality policy was decided by the runner that created the record. Constructing the record does not recompute it.

Guarantees (E, P, B, K). The record preserves exactness and pass status supplied by its certificate. Storage and serialization are linear in contained values and case count. No runner executes during record construction, and no backend fallback occurs.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block11_golden_profiling_beta.py` cover this route. See Chapters 7 and 72.

C.1A · BehavioralGoldenReport

Identity (q, a, t, k). Public research-manifest route `komorebi_math.BehavioralGoldenReport`. Reflected implementation `komorebi_math.golden.BehavioralGoldenReport`. The same object is available through the curated beta route `komorebi_math.beta.BehavioralGoldenReport`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-GOLDEN-REPORT`.

Manifest signature (s).

```
(fixture_path: 'Path', fixture_digest: 'str', results: 'tuple[BehavioralGoldenCaseResult, ...]', certificate:
    ↪ 'Certificate') -> None
```

Definition. An immutable aggregate of the fixture path, canonical fixture digest, case results, and overall certificate.

Contract (D, C, H, R, X). The constructor stores the fixture path, 64-character digest text, ordered case results, and aggregate certificate. `passed` delegates to that certificate, and `to_dict()` converts the path to text and serializes every case. Construction alone does not rerun the fixture.

Guarantees (E, P, B, K). The record preserves exactness and pass status supplied by its certificate. Storage and serialization are linear in contained values and case count. No runner executes during record construction, and no backend fallback occurs.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block11_golden_profiling_beta.py` cover this route. See Chapters 7 and 72.

C.1A · Certificate

Identity (q, a, t, k). Public research-manifest route `komorebi_math.Certificate`. Reflected implementation `komorebi_math.certificates.Certificate`. The same object is available through the curated beta route `komorebi_math.beta.Certificate` and the curated stable routes `komorebi_math.stable.Certificate`, `komorebi_math.v1.Certificate`, and `komorebi_math.api.v1.Certificate`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-CERT`.

Manifest signature (s).

```
(valid: 'bool', exactness: 'Exactness', residuals: 'dict[str, float]' = <factory>, tolerance: 'float | None' =
    ↪ None, assumptions_checked: 'tuple[str, ...]' = (), assumptions_unchecked: 'tuple[str, ...]' = (),
    ↪ diagnostics: 'dict[str, Any]' = <factory>, theorem_id: 'str | None' = None, message: 'str' = '') -> None
```

Definition. An immutable machine-readable validation record carrying validity, evidence class, residuals, tolerances, assumptions, diagnostics, an optional theorem identifier, and a message.

Contract (D, C, H, R, X). The constructor records the supplied fields without running a theorem or backend. `require()` returns the certificate when `valid` is true and otherwise raises `ValidationError` using `message` or a default failure message. `to_dict()` converts `exactness` to its string value. `to_json()` emits sorted JSON and stringifies otherwise unsupported diagnostic values.

Guarantees (E, P, B, K). These records are backend-neutral and allocate storage proportional to the supplied residual, assumption, and diagnostic payloads. They preserve the declared evidence class but do not strengthen it. Serialization work is linear in the serialized record size. No numerical computation occurs unless caller-supplied diagnostic conversion performs it.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_certificates_registry.py` and `test_export_serialization.py` cover this route. See Chapters 1, 5, 6, and 72.

C.1A · `ClaimStatus`

Identity (q, a, t, k). Public research-manifest route `komorebi_math.ClaimStatus`. Reflected implementation `komorebi_math.provenance.ClaimStatus`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-PROV-ENUM`.

Manifest signature (s).

```
(*values)
```

Definition. A string-valued provenance enumeration distinguishing definition, proved, classical, conditional, finite-certificate, heuristic, conjectural, and planned claims.

Contract (D, C, H, R, X). Construction follows `StrEnum` semantics. The eight string values classify the status of a documented claim and do not themselves verify it. Invalid values raise the standard enum `ValueError`.

Guarantees (E, P, B, K). Provenance metadata is descriptive and does not prove the cited claim. Record lookup is constant-time for registered names and otherwise includes module import plus attribute traversal proportional to path length. The registry is process-local, backend-neutral, and unauthenticated.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_certificates_registry.py` and provenance-bearing domain tests cover this route. See Chapters 5 and 72.

C.1A · `ComputationResult`

Identity (q, a, t, k). Public research-manifest route `komorebi_math.ComputationResult`. Reflected implementation `komorebi_math.certificates.ComputationResult`. The same object is available through the curated beta route `komorebi_math.beta.ComputationResult` and the curated stable routes `komorebi_math.stable.ComputationResult`, `komorebi_math.v1.ComputationResult`, and `komorebi_math.api.v1.ComputationResult`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-CERT-RESULT`.

Manifest signature (s).

```
(value: 'T', certificate: 'Certificate') -> None
```

Definition. An immutable generic pair of a computed value and the `Certificate` that qualifies it.

Contract (D, C, H, R, X). The constructor stores an arbitrary value and its certificate. `valid` delegates to `certificate.valid`, `exact` is true only for `Exactness.EXACT`, and `require()` first requires the certificate and then returns the value. Any `ValidationError` from the certificate is propagated.

Guarantees (E, P, B, K). These records are backend-neutral and allocate storage proportional to the supplied residual, assumption, and diagnostic payloads. They preserve the declared evidence class but do not strengthen it. Serialization work is linear in the serialized record size. No numerical computation occurs unless caller-supplied diagnostic conversion performs it.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_certificates_registry.py` and `test_export_serialization.py` cover this route. See Chapters 5 and 61.

C.1A · `ConditionalResult`

Identity (q, a, t, k). Public research-manifest route `komorebi_math.ConditionalResult`. Reflected implementation `komorebi_math.certificates.ConditionalResult`. The same object is available through the curated beta route `komorebi_math.beta.ConditionalResult` and the curated stable routes `komorebi_math.stable.ConditionalResult`, `komorebi_math.v1.ConditionalResult`, and `komorebi_math.api.v1.ConditionalResult`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-CERT-COND`.

Manifest signature (s).

```
(value: 'T', certificate: 'Certificate') -> None
```

Definition. An immutable generic pair whose certificate must have `Exactness.CONDITIONAL`.

Contract (D, C, H, R, X). The constructor accepts an arbitrary value and a certificate, then rejects the pair with `ValueError` unless `certificate.exactness` is `Exactness.CONDITIONAL`. It does not independently verify the listed assumptions or the mathematical conclusion.

Guarantees (E, P, B, K). These records are backend-neutral and allocate storage proportional to the supplied residual, assumption, and diagnostic payloads. They preserve the declared evidence class but do not strengthen it. Serialization work is linear in the serialized record size. No numerical computation occurs unless caller-supplied diagnostic conversion performs it.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_certificates_registry.py` and `test_export_serialization.py` cover this route. See Chapters 5 and 6.

C.1A · `CoordinateSpace`

Identity (q, a, t, k). Public research-manifest route `komorebi_math.CoordinateSpace`. Reflected implementation `types.UnionType`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-TYPE`.

Manifest signature (s).

```
null
```

Definition. A PEP 604 union alias for `RationalSpace | PolynomialCoordinateSpace`.

Contract (D, C, H, R, X). Import returns a runtime PEP 604 union object used by annotations and type checks. It is not a factory and has no project-defined constructor contract. Values must be instances of one of the listed exact expression-space classes. Unsupported values are rejected by the consuming expression APIs, not by importing the alias.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block20_expression_calculus.py` cover this route. See Chapters 50 and 52.

C.1A · EXPRESSION_NODE_VERSION

Identity (q, a, t, k). Public research-manifest route `komorebi_math.EXPRESSION_NODE_VERSION`. Reflected implementation `builtins.int`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (s).

```
null
```

Definition. The integer `1`, attached to each supported serialized expression-node record.

Contract (D, C, H, R, X). Import has no arguments and returns the recorded immutable schema string or integer. The binding is metadata for strict expression serialization and does not encode, decode, or validate an expression by itself. There is no call-time exception.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block20_expression_calculus.py` cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · EXPRESSION_SCHEMA

Identity (q, a, t, k). Public research-manifest route `komorebi_math.EXPRESSION_SCHEMA`. Reflected implementation `builtins.str`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (s).

```
null
```

Definition. The envelope schema identifier `komorebi_math.expression.v1` for strict portable typed expressions.

Contract (D, C, H, R, X). Import has no arguments and returns the recorded immutable schema string or integer. The binding is metadata for strict expression serialization and does not encode, decode, or validate an expression by itself. There is no call-time exception.

Guarantees (E, P, B, K). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_block20_expression_calculus.py` cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · EXPRESSION_SCHEMA_VERSION

Identity (q, a, t, k). Public research-manifest route `komorebi_math.EXPRESSION_SCHEMA_VERSION`. Reflected implementation `builtins.int`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (`s`).

```
null
```

Definition. The integer `1`, the accepted version of the outer expression envelope.

Contract (`D, C, H, R, X`). Import has no arguments and returns the recorded immutable schema string or integer. The binding is metadata for strict expression serialization and does not encode, decode, or validate an expression by itself. There is no call-time exception.

Guarantees (`E, P, B, K`). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (`V, L`). The committed manifest, runtime reflection audit, and `test_block20_expression_calculus.py` cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · `EXPRESSION_TYPE_VERSION`

Identity (`q, a, t, k`). Public research-manifest route `komorebi_math.EXPRESSION_TYPE_VERSION`. Reflected implementation `builtins.int`. No stronger curated facade exports this name in the reference manifest. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `data`. Profile `C1-META`.

Manifest signature (`s`).

```
null
```

Definition. The integer `1`, attached to supported serialized expression-type records.

Contract (`D, C, H, R, X`). Import has no arguments and returns the recorded immutable schema string or integer. The binding is metadata for strict expression serialization and does not encode, decode, or validate an expression by itself. There is no call-time exception.

Guarantees (`E, P, B, K`). The binding is deterministic package metadata and makes no independent mathematical claim. Import and lookup are constant-time in ordinary Python terms and use no numerical backend, accelerator, network, or filesystem operation. Any later file access or validation belongs to the consuming API.

Evidence and links (`V, L`). The committed manifest, runtime reflection audit, and `test_block20_expression_calculus.py` cover this route. See Chapters 4, 7, 43, 52, and 72 as applicable.

C.1A · `Exactness`

Identity (`q, a, t, k`). Public research-manifest route `komorebi_math.Exactness`. Reflected implementation `komorebi_math.certificates.Exactness`. The same object is available through the curated beta route `komorebi_math.beta.Exactness` and the curated stable routes `komorebi_math.stable.Exactness`, `komorebi_math.v1.Exactness`, and `komorebi_math.api.v1.Exactness`. The root route is governed by `[RESEARCH]` policy `pre-beta-additive`. Stronger facade contracts apply only on the listed facade routes. Manifest kind `class`. Profile `C1-CERT-ENUM`.

Manifest signature (`s`).

```
(*values)
```

Definition. A string-valued enumeration with the members `EXACT`, `NUMERICAL`, `CONDITIONAL`, `HEURISTIC`, and `PLANNED`.

Contract (`D, C, H, R, X`). Construction follows `StrEnum` semantics. The accepted values are `exact`, `numerical`, `conditional`, `heuristic`, and `planned`. Consumers compare enum members to prevent accidental evidence promotion. Invalid values raise the standard enum `ValueError`.

Guarantees (`E, P, B, K`). These records are backend-neutral and allocate storage proportional to the supplied residual, assumption, and diagnostic payloads. They preserve the declared evidence class but do not strengthen it. Serialization work is linear in the serialized record size. No numerical computation occurs unless caller-supplied diagnostic conversion performs it.

Evidence and links (V, L). The committed manifest, runtime reflection audit, and `test_certificates_registry.py` and `test_export_serialization.py` cover this route. See Chapters 1, 5, and 6.
